Pediatric Surgery
Diagnosis and Management

System requirement:
- Windows XP or above
- Power DVD player (Software)
- Windows Media Player version 10.0 or above
- Quick time player version 6.5 or above

Accompanying DVD ROM is playable only in Computer and not in DVD player.
Kindly wait for few seconds for DVD to autorun. If it does not autorun then please follow the steps:
- Click on my computer
- Click the drive labelled JAYPEE and after opening the drive, kindly double click the file Jaypee
DVD CONTENTS

DVD – 1

• Gastric Transposition   DK Gupta
• Colonic Interposition   A Hamza, DK Gupta
• Thal Fundoplication     KW Ashcraft
• Kasai’s Portoenterostomy R Ohi, M Nio

DVD – 2

• PSARP in a Male          A Pena
• PSARP in a Female        A Pena
• Common Cloaca            A Pena

Foreword

This book marks an important milestone in the growth of pediatric surgery in India. Its significance is indicated by the fact that it has been officially sponsored by IAPS, the Indian Association of Pediatric Surgeons.

The IAPS has grown, from a modest beginning in 1965, into a vibrant organization with more than 900 members. Thirty to thirty-five new members join each year after completing their training in 23 centers in the country. It is, therefore, time for it to have its own standard compendium of information relevant to the needs of its members. Trainees too need an authoritative textbook written by experts who are familiar with the needs of a developing country like India. Unfortunately, books written and published in the West are too exhaustive, often prohibitively expensive and largely unrealistic for our needs. I have no doubt that pediatric surgical trainees in neighboring countries of Asia will also appreciate the significance of this book.

There are more than 400 million children below the age of 12 years in India and the volume of surgical work is simply astounding. The kind of experience that a pediatric surgeon gets in India is the envy of many a surgeon in the developed world. Yet it is not very often that Indian authors find a place in the list of contributors to books published in the West and one gets the impression that children’s surgery hardly exists in this vast subcontinent. Our authors need to be recognized for their rich and authentic experience. At the same time, our trainees need to be acquainted with the wide range of expertise from abroad. They need to have a broad vision, yet focused to the needs of a country like India. This is another valid reason for bringing out this book.

It is commendable that Professor Devendra K Gupta, Chief of pediatric surgery at the All India Institute of Medical Sciences has been chosen as the Editor. Professor Gupta is a highly regarded leader in pediatric surgery, recognized nationally and internationally for his writings. He has a wide base of valuable experience, which is admirably reflected in his editorship of this book. He has, very wisely, taken a younger colleague Dr Shilpa Sharma as Associate Editor to bring in, open-minded dynamism of the youth in the editing process. Significantly, he has also succeeded in getting the able guidance of Prof Richard Azizkhan, of Cincinnati, USA, as Guest Editor.

Professor Gupta has chosen contributors who are either working in India or who have been associated with Indian departments of pediatric surgery for some time. In fact, nearly one third of the contributors are working in countries abroad. It is noteworthy that authors have been selected not so much for their prominence in the profession as for proficiency in their fields of interest. In the fast changing world of medicine, dynamic young surgeons have acquired new expertise and amassed enormous experience that would be unimaginable in the West. I heartily welcome this move to include younger authors. They may not be well known today, but they certainly need to be taken note of, for they will be the leaders of tomorrow.

It usually takes several years to produce a multi-authored book – it is hard work collecting manuscripts and making the matter suitable for publication. Often, the information is outdated, if not obsolete, by the time the book is published. I would like to compliment the editors for bringing out this book as quickly as they have. The information provided is current, and presented with clarity of expression. Surgical techniques are described in a way that facilitates understanding. Wherever necessary, the subject has been discussed by more than one author so that varying points of view are accommodated.

I feel assured that this book will become an invaluable aid to pediatric surgeons not only in India but also in other parts of the world. With this book the editors have given an international identity to Indian pediatric surgery. This in itself is a commendable achievement.

Purushottam Upadhyaya MS, FRCS, FAMS
Emeritus Professor and Advisor
Himalayan Institute of Medical Sciences
Dehra Dun, India
Professor Devendra Gupta deserves to be congratulated for his enormous effort in producing this valuable textbook in pediatric surgery. This book which comprises 130 chapters and 132 contributors from all five continents of the world provides an authoritative, comprehensive and complete account of various surgical conditions in children. This detailed reference text is suitable for both specialist pediatric surgeons as well as trainees in pediatric surgery as it covers both common and uncommon paediatric surgical conditions. The book has the added attraction because it covers recent developments in the care of children with congenital malformations and acquired surgical conditions. There are full chapters devoted to ethics in pediatric surgery, robotics, stem cell therapy, tissue engineering, laser applications in pediatric surgery, nanotechnology and computers.

Professor Gupta was successful in persuading well known pediatric surgeons to provide an authoritative and complete account of their respective topics. Pediatric surgical community should find this book a useful reference in the management of childhood surgical disorders.

We applaud the efforts of Professor Gupta and contributors for this comprehensive textbook in pediatric surgery.

Prem Puri MS, FRCS, FRCS (Ed), FACS
President, World Federation of Associations of Pediatric Surgeons
Preface

“IT IS NOT ENOUGH TO BEGIN. CONTINUANCE IS NECESSARY.
THE REASON OF FAILURE IN MOST CASES IS LACK OF PERSEVERANCE.”

Though there are number of high quality books available in pediatric surgery, yet most of them are not accessible to the majority of pediatric surgeons in the world due to their high cost. The proposal from the Indian Association of Pediatric Surgeons (IAPS) to publish a multi-authored pediatric surgery book that was complete in all respects and still affordable, was quite a challenge. The Editor accepted this responsibility to bring out a book that would be of international quality, high in scientific value and still low in cost. To accomplish this task, the help and support received from Dr Shilpa Sharma as the Associate Editor and Prof Richard Azizkhan as the Guest Editor were simply outstanding and are greatly acknowledged.

The initial concept for the book was to include many pediatric surgical sub-specialties, e.g. General Pediatric Surgery, Neonatal Surgery, Pediatric Oncology, Pediatric Urology, Cardiothoracic Surgery and others, all in a single book. However, since the contents became too voluminous, this book was restricted to “Pediatric Surgery—Diagnosis and Management”, primarily to cover general pediatric surgery; yet still these required two volumes to keep the book handy.

The scope of the book remains very broad and covers the spectrum of General Pediatric Surgery. It includes some relevant basic science, embryology and pathophysiology, diagnosis and management, as well as complications and includes long-term results. The descriptions and pictures of operative procedures have also been added wherever indicated. Many subjects have been covered by more than one expert still without duplicating the text.

The book with about 1200 figures (Clinical photographs, flow charts, X-rays and the ones drawn by the artist) makes it unique. The book also includes chapters on Nanotechnology, Minimal invasive procedures, Endoscopic procedures, Lasers, Robotic surgery, Stem cell regeneration, Tissue engineering, Computers and Molecular genetics to offer state-of-the-art information to the pediatric surgical community. The book also extends to adolescent surgery as it includes the chapters on Empyema, Intestinal obstruction, Bariatric surgery, Tuberculosis, Hydatid disease and Bezoars.

The authors in this book have been outstanding. Their contributions have been excellent. I was rather bestowed with faith to edit their work (Chapters, photographs, charts, tables, references, etc.), so as to maintain uniformity and regular flow of thoughts.

A foreword for this book has been written by Prof P Upadhyaya who had not only been my teacher and the Founder Professor and the Chief of the Department of Pediatric Surgery at the All India Institute of Medical Sciences, New Delhi, but also a perfectionist, and an academician with utmost human values. Prof Prem Puri, President of WOFAPS who is known internationally for his deep interest in research and surgical care has not only applauded our efforts but written a Foreword as well.

The support received from the colleagues and the staff from the department at All India Institute of Medical Sciences, New Delhi (AIIMS), especially from Mr Ved Grover, is greatly appreciated. I also thank my wife, Dr Rani and the daughters Dr Malvika and Deepika, for being the force behind to complete this book.

The book has been published by M/s Jaypee Brothers, the reputed exclusive Medical Publishers from New Delhi. Shri JP Vij, Chairman and Managing Director; Mr Tarun Duneja, the Director (Publishing), had shown special interest while publishing this book.

It is hoped that the book would serve its purpose if it reaches the pediatric surgical community in the developed and the developing world alike, for its scientific contents, quality of production, affordability and balanced approach.

When you light a lantern for another, it brightens up your path as well —Nichiren Daishonin.

Devendra K Gupta
On behalf of the Indian Association of Pediatric Surgeons (IAPS), I take great honour and privilege to write a brief message for the long awaited book “Pediatric Surgery—Diagnosis and Management”, edited by Prof DK Gupta. The book published by Jaypee Brothers, New Delhi has been creditably supported by the rich experience of Prof Richard Azizkhan from Cincinnati Children Hospital, USA and Dr Shilpa Sharma from New Delhi.

It was the year 2000 that after the success of “Textbook of Neonatal surgery” published by Dr DK Gupta, the IAPS wanted more such books in the specialty and thus requested Dr Gupta to bring out the much needed book in Pediatric Surgery that would be complete, informative, affordable and at the same time matched with the best international standards in its presentation and scientific contents. It is commendable that the editors have accomplished this daunting task so well that would be beneficial for the pediatric surgical community.

This book, Pediatric Surgery—Diagnosis and Management, is first of its kind from the developing part of the world. It is well divided in sections, and covers the complete spectrum of diseases including recent advances. Despite being a multi-authored book, it has been dominated by the Indian contributors, reflecting the maturity of pediatric surgery specialty in India. Many chapters have been covered by more than one expert known for their professional standing in the field, so as to incorporate the differing views of various experts. Chapters have been supplemented generously with operative techniques, line diagrams, charts and clinical photographs to make the book educative and informative.

I am sure this book would be an asset and reach a large number of pediatric surgeons. It should serve as a reference book in general pediatric surgery not only to the postgraduates and the pediatric surgeons but also the institutional libraries across the world.

Anirudh Shah
President, Indian Association of Pediatric Surgeons
Ahmedabad
Acknowledgements

The Editors would like to thank the Indian Association of Pediatric Surgeons (IAPS), for giving us the singular honour and the major responsibility to write this book for the benefit of the pediatric surgical fraternity especially from the developing world.

The editors admire the support that has been received from the authors from around the world. The willingness, with which all of them gave us their valuable time, leaves us personally indebted.

The Editors acknowledge the blanket permission granted by MBD publishers to reproduce the published material free of charge (text, photographs, diagrams, charts, tables, etc.) from the Textbook of Neonatal Surgery, edited by DK Gupta, New Delhi 2000, in various chapters of this book. Though, every effort has been taken by the contributors to acknowledge the published text, color photographs, charts and diagrams reproduced/quoted from the books and the journals, an inadvertent error, if any, in any chapter of this book, would only be due to an oversight.

We also appreciate the support and the encouragement received from the World Federation of Association of Pediatric Surgeons (WOFAPS), Asian Association of Pediatric Surgeons (AAPS), the Federation of Association of Pediatric Surgeons from SAARC Nations (FAPSS) and the International Foundation for Pediatric Surgery and Research for producing the book aimed at improving the surgical care of children around the globe.

Finally, our appreciation to Shri JP Vij, Chairman and Managing Director of Jaypee Brothers, Mr Tarun Duneja, and members of the publishing team, including the artists, for their hard work and special interest taken to produce a book of this quality.
To
The students of Pediatric Surgery,
“at all levels”,
in their quest for knowledge

The mere formulation of a problem is far more essential than its solution, which may be merely a matter of mathematical or experimental skills. To raise new questions, new possibilities, to regard old problems from a new angle requires creative imagination and marks real advances in science. —Albert Einstein

Recently, when pediatrics was separated from the general medicine, a strong need was also felt, though much later, that children need the services of a specialized surgeon to deal with their surgical problems. The reasons being the different anatomical and physiological parameters, smaller size of the organs needing intricate surgical skills, special dosage schedules, difficult venous access, and especially the spectrum of surgical diseases much different from those seen in adults.

The World Federation of Associations of Pediatric Surgeons had signed a document during the council meeting of the World Federation of Association of Pediatric Surgeons (WOFAPS) held in Kyoto, 2002, to protect the rights of the surgical child. It is popularly known as "Kyoto Declaration", reproduced as below:

- Children are not just small adults and have medical and surgical problems and needs that are often quite different from those encountered by adult physicians. Infants and children deserve the very best medical care available. Every infant and child who suffers from an illness or disease has the right to be treated in an environment devoted to their care by a pediatric medical or surgical specialist.
- Pediatric Surgeons are specially trained physicians with extensive experience and expertise in treating infants and children of all ages (from birth to adolescence) with surgical disorders. Because of their unique training, pediatric surgical specialists provide a wide range treatment options and the highest quality care to children.
- Pediatric Surgeons diagnose, treat, and manage children’s surgical needs including: surgical repair of birth defects, serious injuries in children, childhood solid tumors, conditions requiring endoscopy and minimally invasive procedures, and all other surgical procedures in children.
- In order to provide the best surgical care for infants and children, complex pediatric surgical procedures should be carried out in specialized pediatric centers with appropriately equipped intensive care facilities staffed 24 hours per day seven days per week. In addition to the trained pediatric surgeons, these facilities should be staffed with other pediatric specialists including radiologists, anesthesiologists and pathologists. These specialized centers should provide postgraduate education and research.

There are many children’s hospitals and pediatric centres in the developed world that are celebrating their 200 years of establishments. However, developing world is yet to have adequate facilities to treat large volume of work related to congenital malformations, trauma, tumors, transplants, infections and many other pediatric surgical problems.1-5

WHO SHOULD DO PEDIATRIC SURGERY?

Only the Pediatric Surgeons who are qualified by virtue of their training in the field, should tackle the surgical cases in newborns, infants and children up to
adolescents. There are however, many variations depending on local circumstances, practices and compulsions. Many institutions with a heavy workload, would accept children only up to 12-year of age. However, all newborns with emergencies (Acute Intestinal obstructions, respiratory distress) would normally be referred to the qualified pediatric surgeons who are all trained in the sub-specialty of newborn surgery.6 In absence of availability of the trained pediatric surgeons in all the centers, at all times, in all sub-specialties, the common pediatric surgical problems have been treated by general surgeons. This is true even in developed world. In the best interest of the patient, the treating general surgeon dealing with such routine cases should not only be familiar with the latest approach but also should have enough experience dealing with their special requirements.

WHAT IS THE SCOPE OF PEDIATRIC SURGERY?

Parents are becoming now more aware about the scope and the postsurgical results. Pediatric surgery is a wide field and deals with most body parts and organs in newborns, infants and children. These include various sub-branches like; neurosurgery (spina bifida, hydrocephalus, craniosynostosis), head and neck lesions, thoracic surgery (various congenital lung anomalies, empyemas, hydatid cysts, eventration of diaphragm, congenital diaphragmatic hernia, tracheoesophageal fistula, esophageal replacements using gastric tube, colon transposition, stomach pullup, and rarely the tumors), abdominal surgery related to the disease of the liver, biliary tract, spleen, large and small bowel, anorectal malformations, Hirschsprung’s disease, abdominal wall defects, undescended testis, hernia, torsion of testis, and others), plastic surgery (dealing with defects like cleft lip and palate, hypospadias, syndactyly, reconstruction of various flaps), urologic surgery (pyeloplasty, ureteric reimplantation, reconstruction of epispadias and extrophy complex, vesico-intestinal fissure, partial and complete nephrectomies, urinary bladder augmentation, colon conduits and many more). Even in centers with well developed sub-specialties, a general Pediatric Surgeon is allowed to operate on patients with neonatal emergencies, trauma and routine surgical procedures to remain in stream.

Thus, the spectrum of the pediatric surgery is very wide and covers whole body except the open heart surgery, brain tumors, orthopedic anomalies, ophthalmology and ear, nose and throat. Presently, there are only few centers, mostly in developed nations, where the pediatric surgical specialists devote most of their time to a particular sub-specialty and they are satisfied with the volume as well the returns. Others would like to continue as general pediatric surgeons to cater to large spectrum of diseases. In the interest of patient care it is important now to define and develop the sub-specialties as the distinct disciplines, e.g. urology, neurosurgery, hepatobiliary, oncology, thoracic surgery, and may be in the neonatal surgery also.7 This may be feasible only in fully funded centers and the teaching institutes of national importance.

WHERE SHOULD PEDIATRIC SURGEONS FUNCTION?

Congenital anomalies differ from region to region and so the spectrum of anomalies seen in a developed country differ from those in a developing countries. Ideally each newborn should have the facility of being seen by a pediatric surgeon without having to travel long distances. In many countries, it is not the distance but the mode of transport what is most important. To travel even small distances (from hills, remote areas which are not well connected with roads, air and rail network), parents might take many hours or even days to bring the baby to the nearest center for medical care.

Generally, a group of 3 Pediatric Surgeons is required for a center catering to the general population of one million. Similarly, there should be a neonatal surgical ICU for the same sized population. Though, the future need would be to have Pediatric Surgeons even at the district level to manage general pediatric surgical problems, presently, all medical colleges, referral centers and institutes of national importance should have a teaching department of pediatric surgery with at least 3-5 teachers and supporting staff (resident, nursing and technical staff).

In urban areas, with the good antenatal ultrasonography, a large percentage of anomalies, can be diagnosed well in time and thus can be referred to a tertiary center as the case may be. The types of patients managed in a rural center are different from
those seen in an urban center. The facilities in a government center would also differ from those in a private set up and similarly the type of surgeries would also be quite different in different places.

**TRAINING IN PEDIATRIC SURGERY**

The pediatric surgical specialty is different from others, requiring involvement, commitment and dedication. Presently, it is neither paying nor glamorous. Only those with a zeal and interest to serve the delicate babies should opt for it. The pattern of training differs in different parts of the world. The learning becomes meaningful with the depth of involvement, large volume of workload faced and the surgical experience gained in managing various types of anomalies during the limited period of surgical training.

In most setups the surgeons first trains himself/herself in general surgery to acquire the basic principles and the skill of general surgery. One should then get training in pediatric surgery to acquire experience and finer skills. The period of training also varies from place to place. In India, it is minimal period of 12 years including the medical graduation, to become a qualified pediatric surgeon. However, this does not include the period required for the fellowships (urology, neonatal surgery, oncology, laparoscopy, etc.). As there may be more than one technique for diseases like Hirschsprung's disease, hypospadias, pyeloplasty, esophageal replacement and bladder augmentation. It is ideal that a pediatric surgeon is posted to work under the supervision of at least 3-4 pediatric surgeons to get exposed and experience the different techniques. Then he can adopt the one he feels most comfortable. Training courses should also be imparted to teachers to keep them updated on the subject.

**AGE GROUP FOR A PEDIATRIC SURGICAL PATIENT**

This varies from 12-18 in different parts of the world. Most developed countries however limit the upper age to 18 while developing countries keep it as 12. This depends on the doctor to patient ratio. Countries with limited workload, allow children up to 18 years to be included in the pediatric surgical group, while others with major workload, would like to restrict the admissions only up to 12 or 14 years of age. Despite all this, many a times, patients present very late with pediatric surgical index diseases like Hirschsprung's disease, anorectal anomalies, hepatobiliary disorders, lung pathologies, genitourinary requiring reconstructions and others. These have either been missed or mismanaged in the past. Due to their expertise, it is desirable that the pediatric surgeons should either accept the responsibility to treat index cases, irrespective of age, and operate upon them. Else, they should help their counterparts to achieve the best surgical results.

**RECENT ADVANCES**

Since 1980, the Stem cell research has taken a lead and is currently recognized as one of the main areas of interest to explore its potential in congenital anomalies, renal dysplasias, tumors, cirrhosis, testicular dysgenesis and many more. The very fact that the infant's bone marrow is quite rich with mononuclear cells (mostly hemopoetic and less of mesenchymal cells), which if modulated by appropriate regulators (unfortunately not well known till yet) may have the potential to repair or regenerate the damaged tissues in the body.

Minimal invasive surgery and endoscopy with much finer instruments have become popular to suite the pediatric surgical patients. However, their indications in newborns and infants still remain limited in general practice. Robotic surgery, though really useful and a preferred tool for deep pelvic surgery (e.g. radical prostectomy in adults and anorectal anomalies in children) has been used even for other procedures like pyeloplasty. Parents are aware of the global developments and demand for laparoscopy and even robotic surgery. These are becoming popular for use in pediatric surgical practice. Telesurgery has also become feasible with surgeons operating from distant places even across continents.

Laser technology has been applied to bronchial, esophageal and urethral valves, renal, ureteric and bladder stones and surface anomalies like hemangiomas. The harmonic scalpel has enabled liver resection, tumor surgery without much blood loss.

Most infants with biliary atresia would ultimately require Liver transplant (Ltp) in almost 80-90% children by 2-year of age, even after an initial successful porto-enterostomy. Currently, biliary atresia is the most common indication for Ltp, followed
by other indications like, tumors, trauma, and hepatic failure. However, the facility remains limited to developed nations, supported by the governmental or other program for an otherwise very expensive life long proposition for surgery and maintenance of immunosuppression. Though, renal transplant can now be performed even in smaller babies, the problem remains to find a suitable donor to fit in the recipient's small abdomen. With the ongoing research and interest in tissue engineering, it might just take another 5-10 years when the most of the organs in the body of the appropriate sizes and shapes would be made available on shelf for children also.

Indications of fetal surgery have now become well defined with the lessons learnt from the experiences during the past two decades. There are few conditions where fetal intervention can improve the morbidity and even the mortality. Small instruments assisted by minimal access surgery have been utilized for thoracic procedures, urinary tract decompression in babies with obstructive uropathy, ligation of the main vessel supplying the large tumors (e.g. Sacrococcygeal tumors), tracheal occlusion in babies with diaphragmatic hernia associated with lung hypoplasia and so on with the development of newer anesthetic agents and proper tocolysis, fetal surgery has been considered safe without much risks to both the fetus and the mother.

The management of pediatric tumors has been revolutionized both in investigations and in treatment. Positron Emission Tomography has been recognized as an important new modality of treatment. It is now possible to cure at least some of these if not all. Renal tumors, lymphomas, are a good example with almost 80-95% survival. Newer chemotherapeutic drugs and regimes are not only more effective but with less side effects also. Sarcomas need not have amputations any more. Radiotherapy is also considered only in selected cases if the chemotherapy is not sufficient. Intra-operative implants or brachytherapy can be considered in children with residual tumors, e.g. neuroblastoma, so as to have less of side effects usually associated with postoperative wider field of radiation. Detection of new microarrays may help in newer ways to classify tumors and detect their recurrences.

The electronic world of computers has not only improved the communication faster, easier and economical but also the skills amongst the experts. Many offices have already gone paperless. Telemedicine and teleconferencing has brought the whole world close to each other, enabling bilateral exchange of ideas from different centers and different parts of the world at an affordable cost.

PEDIATRIC SURGICAL SPECIALTY IN INDIA

The exact past of the specialty of Pediatric surgery is not known. However, in India, it may date back to ancient times. Sushruta, the father of Indian surgery and Plastic surgery had written large volumes of literature and recently retrieved from Turkey, may be as old as 3000 BC (Fig. 1.1). Others feel it is only 600 year BC and may well coincide with the Hippocratic era. Sushruta is known to have the knowledge about pediatric surgical conditions like anorectal malformations, intussusception, a condition resembling Hirschsprung's disease, bladder outlet obstruction in children, vesicoureteric reflux, vesical calculus, phimosis, congenital hydrocele, inguinal hernia and pelvic tumors. He had also reasoned the etiology of intersex due to non-dominance of either the sperm or the egg.

Sushruta also wrote, "Only the union of medicine and surgery constitutes the complete doctor."
doctor who lacks knowledge of one of these branches is like a bird with only one wing." Thus the need for collaboration between a pediatrician and pediatric surgeon is evident. He understood the high mortality in pediatric surgery in absence of anesthesia and antibiotics and warned that any surgeon should operate upon children only after obtaining due permission from king, lest it will amount to the offense of infanticide.

The pediatric surgical specialty in India, first established in 1965, as a section of Association of Surgeons of India (ASI), has a present strength of more than 800 members and collectively 30-40 pediatric surgeons are added each year from 23 teaching departments. After the improvement seen in the care of patients with trauma, malignancy and serious infections, the infrastructure for providing care to the surgical. Newborns is also improving with the survival of the newborns even with major malformations. Our specialty is very demanding and the facilities, including the trained faculty, nursing and technical staff is limited. The services are also restricted mostly to the urban areas. Most patients have to travel long hours even for short distances.

**National Scenario**

Our National Health Policy draft plan of 1983 was recently revised in the year 2002. The nation spends only 2.6% of its annual budget on health care. It increases to 5.2% if the expenditure incurred on providing preventive public health and hygiene is also included. The Government still has to focus on controlling the communicable diseases through various national health programs and treat malnutrition, diarrhea and infectious diseases on priority. Small pox has been eradicated. Polio is on the verge of eradication. There has been substantial drop in the total fertility rate and the infant mortality rate. Present population in India has already crossed 1 billion and we add 17-18 million newborns each year, almost equal to the existing population of Australia. The life expectancy has also increased from 36.7% in 1951 to 64.6% in year 2000.

Pediatric surgery is new and yet to be recognized for the role the specialty plays in providing quality care and reducing the national Infant Mortality Rate (IMR). Pediatric surgical services are presently limited only to the urban cities with very little or no pediatric facilities available in the rural sector. Also, almost 70-80% of pediatric surgical procedures are being performed by the general surgeons as the pediatric surgical specialists are not available in most centers or the medical colleges. It is aimed at developing pediatric surgery, in each and every Medical college in the country in the near future, and the facility needs to be extended later at the district level.

The main strength of pediatric surgery in India is the massive clinical work load dealing with more than 400 million children less than 14 years of age, constituting about 39% of population. This offers vast training opportunities to the residents in almost all aspects of surgical disciplines except open heart surgery and advanced neurosurgery.

**Teaching and Training**

The teaching program in pediatric surgery in India was started way back in 1969. It was only in 1972 that the American Board of Surgery was approved for the certification in Pediatric Surgery. This was followed by Canada and Great Britain in 1976. The Inter Collegiate Board of Royal Colleges in UK started its examination only in 1990s. India is proud of the postgraduate training program in pediatric surgery, following the British system, is now considered one of the best in the world. India, have not only the intense postdoctoral teaching program, dedicated curriculum and the syllabus but also have the expertise to offer in many sub-specialties.

**Challenges**

The clinical workload in the specialty is immense and is mostly directed to institutions, for seeking free, fair and seasoned service. The private sector is expensive especially for the newborn surgery and malignancy, remaining beyond the reach of the common man. The insurance cover is for less than 2% population. Antenatal care is limited and only 10-15% anomalies can be detected pre-natally. Folic acid prevention therapy is yet to take off. Challenging anomalies like spina bifida, extrophy bladder, gross hydrocephalus, large abdominal wall defects, multiple anomalies incompatible with life, require ethical considerations. Finally, the job opportunities even for the most qualified and the talented staff are also rare. This has contributed to the professional dissatisfaction and
sometimes even frustration amongst the younger generation opting for the specialty.

In a vast country like India, with lots of diversity in clinical workload, teaching and the research priorities, we have the following objectives:

1. To provide specialized pediatric surgical services to over 400 million pediatric population at an affordable cost and safety, ethically and professionally.
2. To provide rigorous and uniform training including sub-sections, at least in apex and centers of excellence.
3. To utilize the available limited financial resources to conduct only need based research to understand the common diseases in the region.

India being a vast country, all facilities are not likely to be available in each and every center. The quality of teaching and training also differs from place to place. Most our residents become quite trained and adequately competent after receiving the rigorous 3 year training. To meet any shortcoming, inter-departmental and the interstate exchanges have been established to widen their horizons and also keep the specialty vibrant and attractive. The talented faculty can excel in any field of medicine with proper planning and utilization of services.

In the recent past, the trend has been reversed. Not only the residents but also the faculty from developing and developed countries have been visiting key departments like that at AIIMS, New Delhi for higher training and patient care. This is only going to grow in future, with many teaching departments improving their teaching and training programs.

It is important that all postgraduate students in pediatric surgery are exposed to the research methodology to make them better teachers of tomorrow. Unfortunately, Animal experiments are conducted only in a few institutions in India. Recently, various Govt. and the non-Government organizations are objecting to the experiments on animals. This has seriously affected the ongoing animal experimental research programs in major institutions. However, animal research is essential, and these should be performed following the strict guidelines as laid down by various ethical committees. Alternately, experiments in the field of molecular biology, stem cell research and Tissue Engineering are quite exciting.

Antenatal diagnosis is still not very common and only 10-20% anomalies are being diagnosed, that to mostly after 20 weeks of gestation, offering limited scope for termination even for major defects. Organ transplantation remains a major challenge due to lack of facilities, shortage of donors and the high maintenance cost involved. India also has infrastructure and the well developed expertise in the field of endoscopy, urology, oncology and neonatal surgery but again only in the limited centers.

There is acute need to develop pediatric surgery in all Medical Colleges for teaching and patient care. Also, there should be at least one major tertiary care level center, one in each state. There should be apex centers at the national level to train the teachers and offer advanced surgery like transplant programs, conduct clinical and experimental research in the field of molecular biology, tissue engineering, stem cell therapy and others. These centers should be independent with complete autonomy for efficient delivery of advanced patient care, quality teaching and need based research.

Thus, Pediatric Surgery has come a long way in last few decades. It has taken a better shape, yet we have to go a long way to establish ourselves and the specialty, solve many hurdles, develop infrastructure and refine treatment methodologies suit ing to each nation.

It is not enough to begin. Continuance is necessary. The reason of failure in most cases is—lack of perseverance.

REFERENCES

Surgery of children has been known to be practiced since times immemorial. It is, however, only during the twentieth century after the 2nd World War that it was recognized as a distinct and independent entity and practiced exclusively by surgeons who felt attracted to treat conditions neglected or treated ineffectively by adult general surgeons. Before World War II there were very few surgeons who devoted their energies exclusively to the care of children. Breath-taking advances in science and technology during the last century almost over shadowed the development of the new specialty. The development of pediatric surgery after 1945 is therefore astonishing. It has been likened to the evolution of an Oak tree from an acorn, growing from humble beginnings to a well-recognized surgical specialty. Robert E Gross (Fig. 2.1) one of the founding fathers of pediatric surgery in North America had written in 1953 that “the care of the children requires a certain indefinable something which might well be called the ‘art’ of pediatric surgery; it cannot be quantitated or characterized any more than one can describe adequately the tints of Titian or the bold strokes of Michelangelo. This extra something is a priceless attribute which is most sought for in members of the visiting or house staff”.1 Willis Potts (Fig. 2.2), another pioneer of the newly emerging specialty in North America had in his inimitable style said in 1959 that pediatric surgery born of the lawfully wedded parents need and demand is now joining the family of specialties. After slow progress during infancy the specialty has grown into a lusty child howling for recognition and demanding a place at the table.

Pediatric surgery is surprisingly popular as a career because as compared to many other newer surgical specialties that have come up during the last 50 years the professional rewards are not as great nor the specialty as glamorous as Cardiac or Neurosurgery. Inspite of the fact that pediatric surgery is still struggling to gain recognition as a distinct entity in many developing countries as India, the number of candidates seeking admission to MCh training programs in our country is astounding. It is I believe,
the fascination of dealing with children, that grip those who care for them.

WHAT IS PEDIATRIC SURGERY?

Herbert E Coe (Fig. 2.3) possibly the first American to practice pure pediatric surgery at the Children’s Orthopedic Hospital in Seattle, addressing the 9th International Congress of Pediatrics at Montreal in July, 1959 had said, that Pediatric Surgery may be defined “as the application of sound surgical principles in the treatment of an organism which is in the most rapidly changing state of its entire lifespan. Pediatric Surgery is the surgery of evolution as contrasted with involution. It is the surgery of the transition period between the protected intrauterine existence and a world of an infinite number of more or less violent external stimuli, the period of adjustment of neuromuscular mechanism, of heat regulation, of nutrition, of fluid and electrolyte balance, where arithmetical computation of requirement based on those of 150 pound adults is completely fallacious. The patient frequently does not understand our language, cannot or will not cooperate and has emotional or mental reaction which are often unpredictable.”

Isidor Ravdin, the highest ranking Medical Officer in the US Army in India during the 2nd World War once used a mathematical equation when he claimed that “a Surgeon is a Physician and something more”.

A Surgeon = (A Physician)^SM

RAVDIN

Dr Henry Bahnson, in his presidential address before the American Association for Thoracic Surgeons, enlarged upon this metaphor and said “a Thoracic Surgeon is a Physician and something more” and raising the equation by another exponential power and something more.4

A Thoracic Surgeon = (A Physician)^SM^SM

BAHNSON

Judson Randolph while addressing the 16th annual meeting of the American Pediatric Surgical Association at Hawii in 1985 said that “when one considers the exacting technical requirements for surgery in 1000 G infant, it is not illogical to take Dr Bahnson’s analogy one step further: “a pediatric surgeon is a physician and something more and something more and something yet again.”

A Pediatric Surgeon = (A Physician)^SM^SM^SM

JUDSON RANDOLPH

RECORDED EARLY HISTORY OF PEDIATRIC SURGERY

Medical care of children has existed since time began. Old writings make it clear that it has included surgical procedures, Pediatrics as a medical specialty, however, did not come into existence before the middle of 19th century. Pediatric surgery distinct from surgery of the adult came much later. The Egyptian petroglyphs dating as far back as 2500 BC depict circumcision and surgery of the head and extremities. An Egyptian Papyrus dating back to 1450 BC is perhaps the oldest known treatise on pediatrics consisting of prescriptions and incantations for the protection of mothers and babies. But “The first consistent body of pediatric doctrine, particularly on hygiene and nutrition is in the Indian Sushruta, compiled in the 5th century BC; it describes about 120 surgical instruments”.6 Indian historians believe that there were two Sushrutas, a senior and a junior, and it would seem that the author of the original Sushruta samhita, flourished as early as 1000 BC and the later, the younger Sushruta, the author of most of the chapters in the present Sushruta samhita taught surgery in Kashi (Varanasi) during the 6th century BC. Sushruta samhita is the first ancient treatise, which advocated dissection of the human cadavers much against the prejudices, which must have flourished in his times. He is to be credited to be the first who described the removal of bladder stone by the perineal route. He described operations for anal fistula but his description

Fig. 2.3: Herbert E Coe
of repair of a cut nose by rotating a flap of skin from
the cheek was the most original concept. Other aspects
of plastic surgery dealt by Sushruta were repair of ear
lobules and lips and are described in meticulous
details.

Hippocrates (460-370 BC) considered to be the
Father of Medicine and Pediatrics described special
problems inherent in head injuries of children and gave
advice for the treatment of hematomas and fractures.7

Aulus Cornelius Celsus who wrote “De re Medica”
around 30 AD believed by Western historians as the
first classical medical work was in fact a compilation
from the Greek, included were a few passages
mentioning diseases in children stating that the
“children are required to be treated entirely differently
from adult”.8 He described tonsillectomy, uvulotomy,
fenotomy and the repair of the hare lip and nasal
defects.

One of the largest and most complete medical
encyclopedia written in the middle ages, Kitab at-
Tasrif was authored by Abu I - Quasim Khafaf, known
to historians by the distorted Latin name of Albucasis.
He was an Arab by descent. Cordoba in Spain where
he was born in 912, was famous all over Europe in
those days by its teachings of Islamic religion,
humanities, literature, pharmacology and medicine.
The encyclopedia comprised 30 volumes, the last one
dealing with surgery. Albucasis book on surgery was
considered by the developing European World to be
a basic work of reference for many centuries
throughout the renaissance. There were numerous
translations and editions of this famous work. Pediatric
surgery was known to Albucasis and the subjects
covered were cauterization of hare lip, care of hydro-
cephalus, removal of ranula, treatment of imperfect
urinary meatus and treatment of hypospadias. A
detailed description is given on circumcision of boys
and correction of their erroneous treatment.9

In 1465, Serafeddin Subuncuoglu published the
earliest known Pediatric surgical Atlas “Cerrahiye-I
ilhaniye” in Turkish describing surgical technique and
instruments. Serafeddin was born in Amasya in
Northern Turkey. This book contained many
miniature drawings concerning the operative
procedures. It is believed by many historians that
Serafeddin made only a faithful translation of Albucasis’ book of surgery, the only addition being the
miniatures depicting the surgical technique. This
has been contested and it has been claimed that the
book “contain not only the pictures or miniatures of
surgical and pediatric surgical procedures but also
many important and major new contributions to the
surgical literature originally described by Subuncuoglu himself.10

The first textbook in Pediatric Surgery is, however,
credited to the Swiss Surgeon Felix Wurtz published
experimental Treatise of surgery’ appeared with a
pediatric appendix including references to orthopedic
problems.11

PEDIATRIC SURGERY IN
THE NINETEENTH CENTURY

Nineteenth century saw an increasing interest in the
surgery of the children. This was due to many reasons.
Opening of hospitals exclusively for children,
publication of books and periodicals on the surgical
diseases of children, increasing interest in saving new
born babies suffering from medical and surgical
conditions and exciting individuals contributions of
surgeons and physicians in treating children. An
awareness was thus gradually generated amongst the
medical profession on surgery of children heralding
the beginning of Pediatric Surgery.

Europe is considered to be the cradle of Pediatric
Surgery. Many children’s hospitals came up all over
Europe mostly during the 1st half of the nineteenth
century. The first being the hospital des infant malades
in Paris in 1802. The World famous Hospital for Sick
Children Great Ormond Street was established in 1852.
In North America Hospitals for children came up
much later mostly during the latter part of the
nineteenth century. The famous Boston Children
Hospital modeled after the Hospital for Sick Children,
London, opened in 1882.

Pediatric Surgeons of the nineteenth century to a
large extent were engaged in orthopedic surgery.
Tuberculosis of bones, osteomyelitis, congenital
anomalies of bones like club foot, fractures and disloca-
tion of bones, and deformities of extremities due to
poliomyelitis were rampant in those days. “This
tradition persisted in certain countries like France,
where all Professors of Pediatric Surgery in Paris from
Kirmisson in 1901 to the great Ombradanne in 1923
were largely, although not entirely orthopedically
oriented.”12
Inspite of the fact that children's hospitals existed in most European countries during the 19th century, very few surgeons devoted their work only in children. The reasons were mostly economical. Many once appointed to the staff of children's hospitals were lured by the lucrative practice in adult surgery and tried their level best to leave. This phenomenon is seen even today in many parts of our country.

Many books exclusively on diseases of children were published during the nineteenth century in Europe and England. JN Coley published his ‘A practical treatise of children’ in 1846 in London. And between 1856 and 1877, there were atleast fifteen publications in English, French and Italian on the subject. One of the first textbooks of Pediatric Surgery in the English language “The Surgical Diseases of Children” was published by John Cooper Forester in 1860. Forester a Fellow of Royal College of Surgeons was an Assistant surgeon to Guys Hospital and Surgeon to the Royal Infirmary in London. In 1870, after fifteen years as Assistant Surgeon he became the Surgeon to the Guys Hospital in London. He favored the use of chloroform and felt that as it was safe there was no justification for inflicting pain in children needing surgery. By 1874 he had changed his views and preferred ether for babies. He was one of the few surgeons of his time who did tracheostomies in children and was the first to perform a gastrostomy for stricture of the esophagus in children. For stone bladder he made lateral perineal incision as advocated by Sushruta in India in the hoary past. He classified imperforate anus and described fistulous communication to vagina and urinary bladder. He was aware of the good results in low lesions and described a simple incision into the perineum. He had also advocated bringing the rectum down and suturing it to the skin. Forester’s book is largely descriptive but contains excellent lithographs reproducing in great detail many anomalies including hemangiomas of arm, lip, vulva and face.

A more detailed book on children’s surgery was compiled from a series of lectures given between 1840 and 1860 by MP Guersant, Honorary Surgeon of the Hospital des Enfants Malades, Paris. Richard Dunglison of Philadelphia translated the text from the French in 1873. Guersant described many congenital lesions like harelip, hypospadias and spina bifida. His description of congenital absence of the anus with fistula to an “abnormal position” indicated an increasing recognition of the various types of the malformation. He advocated making a puncture in the perineum, directing it to the side of the sacrum to avoid wounding the vagina or the bladder in cases of simple anal imperforate anus which we now refer to as “low anomaly”. He described various trocars and stents used to maintain the opening made in the perineum.

Prior to 1870 the management of sick babies did not constitute a problem at all. Since antiquity they were left to die. The Franco Prussian War took place in 1870-71 and this changed the attitudes of medical profession toward these babies. The reason was the enormous loss of human life on the French side and consequently the great reduction in the birth rate. The already weakened French nation could not sustain in the future against a victorious Germany more populous and much more fertile. Every life saved thus became an asset. It is not surprising therefore that the first improvements in the neonatal care came almost entirely from France. There were 3 main dangers to the neonates particularly the premature ones; hypothermia, infection and faulty feeding habits. All of these were systematically tackled. In 1878 Odite Martin, the Director of the Paris Zoo constructed a warming chamber for hatching of eggs. Tarnier, the Paris obstetrician was fascinated by the device. In close collaboration the two men built the first incubator heated by warm air which was installed in 1880 in the Paris Maternity Hospital. Isolating babies in special units controlled infection and careful sterilization of feeding bottles was successful in saving many a baby.

The first half of the nineteenth century witnessed the contribution of two eminent French Surgeons, a contribution which is considered a landmark in the evolution of surgical treatment of imperforate anus. In 1834, JN Roux operated on a case of imperforate anus through a midline longitudinal incision in the perineum. In 1835, JZ. Amussat operated on a girl using a T shaped incision. The rectum was pulled down to the perineum and stitched to the skin. This innovative procedure was heralded as the “great break through in the management of imperforate anus.

The latter half of the nineteenth century was an exciting time in the development of modern surgery. Ether anesthesia was introduced in 1846, the origin of surgical sepsis from bacteria discovered by Pasteur and its prevention by scrubbing the operative skin site
and scrupulous hand washing described by Lister. Billroth wrote about his success in gastric resection, esophageal surgery and bowel resection. Despite these advances, the general principles of surgical care established during the latter-half of the nineteenth century, almost uniformly benefited adult patient, and rarely if ever did a newborn with a major congenital anomaly or child with an acute surgical abdomen, large tumor and serious injury survive.15

Toward the close of nineteenth century the contribution of a pediatrician interested in surgical matters who often attended surgical operative procedures, exemplified the keen interest and knowledge of a pediatric surgeon. Harald Hirschsprung whose name is familiar to pediatricians and surgeons today was born in Copenhagen in 1830. He qualified MD in 1855 and was appointed the Chief Physician to the First Children’s Hospital in 1870. As a pediatrician Hirschsprung was interested in a wide range of neonatal problems. In 1886, he reported before the Society of Pediatricians in Berlin on “constipation in newborn due to dilatation and hypertrophy of the colon”. Although he failed to recognize the cause of congenital megacolon, a condition that bears his name even today, the contribution does not detract from his keen observation and far ranging interest in surgical matters. Earlier in 1861, he had described four cases of esophageal atresia with tracheoesophageal fistula occurring over a 7-month period in a town with a population of only 100,000. His report on cases of hypertrophic pyloric stenosis in 1887, established this condition as a distinct clinical entity. But perhaps his most imposing contribution was the use of hydrostatic reduction of ileocolic intussusception published in 1876. His results were so superior to previously published reports of surgical intervention that many doubted his conclusion. His final report in 1905 of 107 cases, substantiated a 35% mortality rate for a condition that up to that time was fatal in over 80% of cases. Hirschsprung’s observations regarding a number of potentially correctable surgical conditions gives him the distinction of being recognized as a modern day pediatric surgeon. His interest in surgical matters makes one suspect his unspoken desire to have been a Surgeon.

MODERN PEDIATRIC SURGERY

Modern pediatric surgery is largely the work of three generations of surgeons. The founders, notably William Ladd (Fig. 2.4) and Robert Gross in Boston and Sir Dennis Browne in London, a middle generation of 50-60 surgeons who were responsible for founding the surgical section of the American Academy of Pediatrics and the British Association of Pediatric Surgeons; and the third generation of very large number of surgeons all over the world.

Surgery of infants and children in the USA began with William Ladd. He is regarded as the Father of the Pediatric Surgery in North America. Born in 1880, he graduated from Harvard College in 1902 and Harvard Medical School in 1906 and joined the staff of the Boston Children’s Hospital in 1910. “On December 6, 1917, during World War I, a munition ship exploded in the harbor at Halifax, Nova Scotia, causing many casualties among whom were many children. A plea was made to physicians from Boston. William Ladd was among those who responded. It is said that this heart wrenching event helped influence Ladd to concentrate his efforts in the field of child surgery.19 In 1941 after nearly 15 years as Head of the Surgical Services at Children’s Hospital, he was honoured by the Medical School, the hospital and his colleagues and friends by the creation of the Ladd’s professorship of child surgery. He held this chair until his retirement in 1945. Not only he was recognized as the authority in pediatric surgery at Harvard but also he became the acknowledged leader throughout North America.

Ladd had an almost unique group of qualities in that he developed new and sound methods of surgical treatment; he was a superb teacher at all levels, from medical students to residents as well as to practicing medical and surgical community. The result of all these attributes was to attract an enthusiastic group of
trainees. Of his trainees by far the greatest is his former resident and immediate successor Robert E Gross. Gross followed directly in Ladd’s footsteps although more as a great innovator of surgery and as a teacher. His other trainees included Orvar Swenson (Fig. 2.5), H William Clatworthy and Everett Koop.

Robert Gross became surgeon in Chief at the Children’s Hospital, Boston in 1947, during his career he made great contributions in the field of pediatric surgery. In 1938, when he was Chief Surgical Resident, he successfully divided a patent ductus arteriosus. Unfortunately, the operation was done when Dr Ladd was on vacation. Ladd never forgave him for doing the operation when he was out of town. Thus began an estrangement that probably slowed the development of pediatric surgery more than we will acknowledge. Nevertheless Ladd and Gross published in 1941, the first American Textbook on Child Surgery “Abdominal surgery of infancy and childhood”. Because of the antagonism between the two, Ladd made it difficult as he possibly could for Gross to ascend to the chair that bore his name. It was only after two years of Ladd’s retirement in 1947 that Gross was finally appointed the Chief since his accomplishments were overwhelming and he was acclaimed internationally. In 1953, Gross published his matchless textbook, “The surgery of infancy and Childhood”.

The founder of Modern British Pediatric surgery Sir Dennis Browne was born in Australia where he studied medicine at the University of Sydney, New South Wales. He qualified in medicine in 1914 and having volunteered for the Australian Expeditionary Force spent the whole of 1914-18 world war in France as an Army Medical Officer. He came to England after the war and continued his surgical training at the London and Middlesex Hospital and trained in orthopedic surgery under Sir Robert Jones in Liverpool. Surgery of childhood always fascinated him and he therefore joined the staff of the Hospital for Sick Children, Great Ormond Street, London, as a registrar and a resident surgical officer. He was elected as a consultant surgeon to that hospital in 1928 and retired in 1957.

Dennis Browne was the first surgeon in England to confine his practice to children. After second world war the fame of his work spread all over the globe and young Pediatric Surgeons from all over the world came to him to learn. He was one of the founders and the first President of the British Association of Pediatric Surgeons.

Dennis Browne had a truly original mind and left his mark on virtually every branch of pediatric surgery. Among them one can recall his operations for harelip and cleft palate in plastic surgery, the operation for hypospadias and undescended testis in urology, his work on talipes equinovarus and congenital dislocation of hip in orthopedic surgery and his investigations and operations for anorectal malformation in Proctology. In 1957, the surgical section of the American Academy of Pediatrics awarded him the Ladd Medal for his services to Pediatric Surgery. In 1961, he was knighted.

CURRENT STATUS
It is amazing that in spite of the great struggle initially the specialty has grown up during the last 50 years all over the world and has shown signs of maturity and independence denied to them in the forties and fifties of the last century. Though independent pediatric surgical departments have come up and are well established in many medical institutions and universities all over the world there are disturbing trends which are likely to change the practice of pediatric surgery in future. The founding fathers and pediatric surgeons of yester years, were interested in orthopedic, in many a plastic procedures, treatment of congenital cardiac anomalies, and congenital malformations of central nervous system. Many of the pioneers in the treatment of cardiac anomalies started their professional career in pediatric surgery like Robert Gross and Willis Potts in North America,

The present day pediatric surgeons have gradually shied away from the management of facial anomalies like hare lip and cleft palate and malformations of central nervous system. The plastic and Maxillofacial surgeons have taken over the management of the former and neurosurgeons are now managing the latter. Many pediatric surgeons have duly recognized the increasing complexity of operative procedures for cardiac malformation and their management now is entirely in the hands of cardiac surgeons.

Another disturbing trend is the lack of interest of the present generation in the newly emerging subspecialties of transplant surgery and intrauterine fetal surgery.

There has also been a very rapid development of organ specialties in recent years. Specialties like urology, microvascular and transplant surgery have successfully made inroads into the specialty of pediatric surgery. The dangers of such a development have probably not been appreciated. Admission of children to highly specialized departments of urology, microvascular and transplant surgery, under the care of surgeons, and the supporting staff unaware of the special needs of sick children can often be disastrous. Pediatric surgeons of the future would have to either receive training in these sub-specialties which obviously is likely to lengthen the course of their training or practice in a field which is already shrunk by the fragmentation of the specialty. Both these alternatives are difficult to choose. Newer knowledge and complexity of the surgical procedures of the newly coming up sub-specialties will make it difficult for many to master the complicated procedures.

In recent years, the popularity of laparoscopic surgery in adults has stimulated the pediatric surgeons to adopt this newly emerging specialty in their own field. It is inevitable that in the foreseeable future, laparoscopic surgery will also become a major and important component of our specialty.

THE INDIAN SCENARIO

Pediatric surgery as a specialty is only about 40 years old in India. Essentially it is no different than the development of this specialty in other countries. In the fifties of the last century very few general surgeons were interested in the surgical diseases of children particularly the severe congenital anomalies. The result was that nearly all such babies either died in the hospitals they were admitted to or were sent home to die.

In those days there were only a few surgeons who were exclusively practicing pediatric surgery in India. Prof UC Chakraborty of Calcutta Medical College, Dr Raman Nair (Fig. 2.6) at Trivandrum Medical College and Prof O Anjaneyulu at Niloufer Hospital at Hyderabad were perhaps the only ones in the whole country. Two other distinguished general surgeons of that era namely Dr Arthur E Desa at Bombay and Col RD Ayyar at Delhi who were interested in children surgery did more for the development of Pediatric Surgery in the fifties and sixties of the last century than any other surgeon of the day by their encouragement and moral support to the young talented surgeons. Both of them were influential in the Health Services of the country and helped behind the scenes to promote and establish independent pediatric surgical centers in the country. Encouraged by the guiding spirit of surgeons like Arthur Desa and Col Ayyar a number of young surgeons therefore, decided to practice surgery exclusively in children. Many of them went abroad for training in the specialty since there were hardly any facilities in the country. They had heard and read about the great masters like Dennis Browne in London, William E Ladd, Robert E Gross and Orvar Swenson in Boston, Will Potts in Chicago, C Everett Koop in Philadelphia and some others in Canada and Australia and to these masters or their successors our young surgeons went. After varying periods of training they returned home with great hopes of settling down to practice the new specialty.

Fig. 2.6: Raman Nair, Calicut
Many of them were soon disillusioned, as they were not received with open arms as they expected. In fact there was a stiff resistance not only from the Health administrators but also from the general surgeons. The general surgeons felt threatened that their specialty already fragmented by the newer specialties of cardiac, neuro and plastic surgery could not accept further fragmentation.

Two very significant developments took place at this point of time in initiating the process of development of the new specialty. One was the formation of an independent pediatric surgery section within the frame work of Association of Surgeons of India in 1964 and the other was the institution of Postgraduate degree in Pediatric surgery at the University of Madras in 1966.

It was during the Silver Jubilee Conference of Association of Surgeons of India (ASI) at Mumbai in December 1964, that Dr RK Gandhi (Fig. 2.7) of Mumbai thought of putting up a proposal for establishing an independent pediatric surgery section within the ASI, Dr Gandhi hurriedly cornered like minded youngsters who had returned from abroad after training in Pediatric surgery to seek their opinion. About 30 young surgeons enthusiastically received the suggestion and it was decided to put up a proposal before the General Body Meeting. Dr KK Gandhi, Dr T Dorairajan from Madurai, drafted the proposal with the help of late Dr MS Ramakrishnan (Fig. 2.8) of Madras. The resolution was presented before the General Body Meeting of the ASI. The proposal, as expected, encountered stiff opposition from the surgeons but was finally adopted after a strong plea made by one of the past Presidents of the ASI late Prof. BN Sinha.20

The institution of a postgraduate course at the University level leading to a degree in the specialty was the other noteworthy event, which had a vast impact in the development of the specialty. The late Prof MS Ramakrishnan was able to plead for such a course at the Madras University and because of his efforts, this University was the first in the country to institute such a course in 1966. The first MCh degree in the country was awarded in 1968. Gradually other Universities and Postgraduate Institutions followed suit and by the end of the 1972, as many as seven Institutions were awarding MCh degrees in Pediatric surgery. Starting of such courses gave an academic recognition and professional status to the specialty and helped train pediatric surgeons within the country. As a consequence the flow of surgeons going out of the country for higher training in pediatric surgery virtually dried up and till 1998 as many as 500 Pediatric Surgeons had been trained at various centers in the country.

Besides these two significant and fortuitous events, I believe there was an additional element, which made Pediatric surgery a popular, and a dynamic specialty. It was the pioneering spirit of a handful of young surgeons of those days. The contributions made by Prof RK Gandhi and Prof SS Deshmukh from Mumbai, Prof MS Rama Krishnan and Prof T Dorairajan from Tamil Nadu, Prof Raman Nair from Trivandrum, Prof Subir K Chatterjee (Fig. 2.9) from Kolkata, Prof Purushottam Upadhyaya (Fig. 2.10) from New Delhi, Prof IC Pathak from Chandigarh (Fig. 2.11), Prof KC Sogani from Jaipur (Fig. 2.12) and Prof Meera Bai from Hyderabad are legendary.
Pediatric Surgeons which gave them an opportunity of having a voice in several policy decisions. It is a remarkable historical fact that three of these pioneer pediatric surgeons of the country namely Prof MS Rama Krishnan from Chennai, RK Gandhi from Mumbai and T Dorairajan from Madurai were elected Presidents of the ASI in 1979-80 and 1981 respectively. Prof SS Deshmukh from Mumbai joined their illustrious company a few years later.

At the meeting of the Pacific Association of Pediatric Surgeons in Tokyo in 1972, the first meeting of the Asian Pediatric Surgeons was also held and elected adhoc office bearers to formalize the Association. Two of the three crucial offices were secured by Prof MS Ramakrishnan as founder Vice President and Prof RK Gandhi as founder Secretary General. India managed to maintain its pre-eminence by continued representations and occupying key positions in the Asian Association of Pediatric Surgeons. Prof RK Gandhi was its President from 1980-82, Prof P Upadhyaya was the President for the years 1984-86 and Prof SK Chatterjee was the Vice President for the years 1986-88.

The individual contributions of some of these pioneers during the early days of pediatric surgery in the country have been no less significant. Prof Upadhyaya’s work on splenic trauma, inventing the first low priced indigenous shunt valve for the management of hydrocephalus and innovative new surgical techniques for the treatment of rectal atresia and anterior perineal anus has been internationally recognized. He was the first surgeon to successfully separate conjoined twins in the country in 1969 and established a neonatal ICU, the first of its kind in the country in 1971 at the AIIMS, New Delhi. Prof Subir
Chatterji was the first one in the country to save a baby with esophageal atresia in 1964 and also separated successfully two sets of conjoint twins in the mid-eighties. He is the author of a popular book “Anorectal malformation” published in 1993 and is the founding Chief Editor of the “Journal of the Indian Association of Pediatric Surgeons” since 1995. Prof Pathak and his associates from Chandigarh drew the attention of Pediatric surgeons to a peculiar variant of anorectal Malformation, now popularly known as “Pouch Colon” for the first time in 1972. This anomaly since then has been found to be common in the northern belt of the country and large series have been reported from this geographical area during the last 35 years.

The present day leaders of the specialty in various Medical Institutions in the country are the students of these first generation Pediatric Surgeons. They have not only maintained the high standards of competence laid down by their teachers but have by their diligence and hard work improved and expanded the specialty in all aspects of patient care, training and research. The future of Pediatric Surgery I believe is in their hands and in turn in the hands of their students.

The progress made by the specialty during the last three decades has been tremendous both by individual surgeons as well as the Pediatric Surgical Centers in some parts of the country. These centres have raised the standards of surgical care of children and many of them compare favorably with the best centers in the world. It must, however, be emphasized that these are isolated islands of excellence. India is a big country and we are still woefully short of well established centers in most parts of the country. Presently, there are 21 teaching departments of Pediatric surgery in the country producing about 30 pediatric surgeons each year.

What is the lot of pediatric surgeon in the country that we have trained during the last 30 years? I understand it is not very happy situation. In a recent survey conducted by Dr KL Narasimhan and his colleagues from the Postgraduate Institute of Medical Education and Research, Chandigarh, it was found that the trained and qualified pediatric surgeons in the country were a dissatisfied lot. Only 50 percent of them were economically satisfied. Nearly 1/4th had to resort to general adult surgery work to augment their income. Nearly two thirds felt the need for a change in the training program. It was the opinion of many of the Pediatric Surgeons that uniform curriculum, better hands-on experience and a rotation through 2-3 centers of training in the country was desirable. It was found that the cities were overcrowded with pediatric surgeons and there were very few and insufficient numbers in the rural areas. It was also the opinion of many that majority of general surgeons had inadequate training to operate on children and there was a need for better cooperation with pediatricians.

I hope the present day leaders of the profession in our specialty would take note of this dissatisfaction amongst the practitioners of this specialty and make efforts to rectify the deficiencies in our training programs. It does not brook any delay and sooner we address these inadequacies better it will be for our specialty.

REFERENCES

7. Mettler LC, Mettler FA. History of Medicine, Correlative text, arranged according to subjects, Philadelphia, Blakiston 1947.
We are presently in the era of Molecular Medicine and for a busy Pediatric Surgeon it is difficult to be updated on molecular biology concepts and applications. For better understanding of the following text, it is imperative to understand the commonly used terms in Molecular Medicine. Therefore, the glossary given at the end of this chapter has commonly referred terms.

There are several pediatric surgical conditions where we encounter defects at the genetic and the molecular level. For example, duodenal atresia may be seen in Down's syndrome, which is one of the commonest chromosomal abnormality. There are numerous other situations, where study of molecular biology may enhance our basic understanding of the disease, structure diagnostic tests, and identify appropriate molecular therapeutic targets. The DNA for molecular diagnosis may be obtained from a variety of living tissues including peripheral and umbilical blood lymphocytes, epithelial cells lining the buccal mucosa, chorionic villus and amniotic fluid. The principal limitation in using these molecular techniques for diagnosis is the heterogeneity of genetic changes that underlie the inherited disorder.

The gene is the basic unit of heredity and contains the information for a particular protein and/or RNA (ribonucleic acid) molecule. This gene consists of a continuous stretch of DNA (deoxyribonucleic acid), which in turn forms part of a larger microscopically visible genetic unit associated with acidic and basic proteins, the chromosome. Even bacteria and virus require thousands of different genes and their products to carry out its biological function.

The term gene was first used by Danish geneticist Wilhelm Johannsen in 1911. Thomas Hunt Morgan predicted that these genes were carried on chromosomes. The three-dimensional structure of DNA was elucidated in 1953 in an exciting way by James Dewey Watson and Francis Harry Compton Crick in collaboration with Maurice Hugh Frederick Wilkins and Rosalind Franklin. They demonstrated (using X-ray diffraction studies) that DNA existed as a double helix consisting of 2 polynucleotide chains held together by hydrogen bonds. The key components of the DNA molecule with respect to its role as the carrier of transmissible information were the four nitrogenous bases which were the alphabets of heredity and reproduction - A, T, G, C - and it was the sequence of the bases along one of the two polynucleotide chains (the coding strand) that carried the information in the form of a genetic code, and was the essential blueprint of life.

The two complementary strands of the double helix are held together by specific number of hydrogen bonds (with low bond energy) between A-T and G-C (Table 3.1). The complementary nature of the two strands ensures that the information stored within a gene can be transmitted to the next generation by the process of DNA replication with complete fidelity.

Genes are the blueprints for all RNA and protein molecules within a cell. Some genes encode RNA as the final product (genes for r RNA, t RNA, sn RNA) whereas others encode polypeptide chains, which are synthesized by way of the intermediate m RNA. These blueprints may be modified by mutation, which alters the genetic information encoded by the gene through alteration of the base sequence of the DNA.

The genetic information stored within a gene is downloaded in a couple of sequential processes: transcription, whereby a linear portion of the gene is copied into a single-stranded RNA molecule, and
translation of the information into a functional protein molecule (Fig. 3.1). At the ribosome the coded genetic message in mRNA is translated into an equivalent string of covalently linked amino acid, a polypeptide chain.

The flow of genetic information from DNA to RNA to protein is highly regulated in all cell types. The process of gene expression is highly regulated, thus ensuring that the cell does not spend excessive energy in synthesizing a gene product until that product is required by the cell.

With the advent of the DNA cloning technology, and DNA sequencing methodologies, scientists were ultimately able to unfold the organization of the gene to the level of the single base pair.

A typical eukaryotic gene (Fig. 3.2) consists of the coding region (exon) and the non-coding region (intron or the selfish DNA). The coding region contains the genetic code that is read by the translational setup in the cytoplasm and is defined by the initiation codon (normally, AUG, codes for methionine, and GUG, codes for valine) and one or other of the three termination codons (UAA, UGA and UAG). The nitrogenous sequences in introns appear to have no role in gene expression per se (Figs 3.3 and 3.4) and are discarded during the process of primary RNA transcript (RNA splicing). In the 3 billion base pairs of the human genome, there are about 30,000 - 40,000 genes and the coding region is less than 5%. The number of genes may be just over twice the number in Drosophila or Cenorhabditis. The promoter region is required to promote the enzyme RNA polymerase to bind to the gene at the correct position with respect to the region that needs to be transcribed, i.e. the transcription unit.

Genes that encode polypeptides are generally present in one or two copies per haploid genome, that is they are single-copy genes, whereas genes encoding tRNA, rRNA and histones are often present in multiple copies to ensure that sufficient gene product is available to the cell.
As mentioned earlier, DNA is a linear polymer of 4 different building blocks (nucleotides) of which the variable parts are adenine(A), guanine(G), cytosine(C), thymine(T). Proteins are linear polymers of 20 different amino acids. The amino acid sequence of a protein must be encoded by the sequences of bases in the corresponding DNA. The four-letter alphabet of DNA is correlated with the 20 letter alphabet of amino acid by a 3-letter nonoverlapping code. Each consecutive triplet of bases in RNA is called a codon. The codon is unpunctuated and correct translation of a sequence depends on the starting at the right place so that the sequence is read in the correct reading frame. tRNA is the adaptor molecule - within its nucleotide sequence is a 3 nucleotide anticodon which binds to a particular codon and at its 3’ end it carries the appropriate amino acid. The aminoacyl t RNA synthetase are responsible for attaching the correct amino acid to the corresponding t RNA. 61 of the 64 (4 to the power 3) codons correspond to an amino acid. AUG/GUG are chain initiating signals (start codon). Most amino acids (excepting methionine and tryptophan) are encoded by more than one triplet. This is called degeneracy of the codon. Synonymous codons defining the same amino acid differ only by the last base (wobble hypothesis). With few exceptions, the genetic code is universal and eukaryotic genes can be accurately transcribed in Escherichia coli. This forms the basis of recombinant DNA technology, resulting in a directed and predetermined alteration in the genotype of an organism.

An organism's characteristics are specified by its genetic information represented as a precise nucleic acid sequence, the sum total of this information being its genome. Genome organization is related to the functional demands placed upon it by the organism's biological characteristics. Definition of the complete nucleic acid sequence of an organism's genome is expected to identify its every gene product, their relative arrangements and organization, and the sequences required for controlled gene expression and replication, thus leading to a much greater understanding of the organism's biology.

The goal of genetics and molecular biology is to study the structure and function of genes and genomes. Although it is relatively easy to isolate DNA from living tissue, DNA in a test tube looks like a mass of mucus. How could it be possible to isolate a single gene from this tangled mass of DNA threads? Recombinant DNA technology provided us the technique for just doing that.

Gene isolation is important because it enables us to determine the nucleotide sequence and reflect on the internal landmarks (introns, etc), and also enable us to predict the function of the gene. For example, it was know from pedigree analysis that cystic fibrosis is inherited as an autosomal recessive disorder. However, the function of the gene product (CFTR) was known only after the gene was isolated and sequenced.

**MAKING RECOMBINANT DNA**

The basic procedure comprises of extracting and cutting DNA from a donor genome into fragments containing from one to several genes and allow these fragments to insert themselves individually into opened - up small autonomously replicating DNA molecules such as plasmids. These small circular DNA molecules act as carriers, or vectors, for the DNA fragments (Fig. 3.4). The vector molecules with their inserts are called recombinant DNA because they consist of unique combination of DNA from the donor genome (which can be from any organism) with vector DNA from a completely different source (bacterial plasmid or viruses). The recombinant DNA is then used to transform bacterial cells, and it is common for single vector molecule to find their way into individual bacterial cells. Bacterial cells are plated and allowed to grow into colonies. An individual transformed cell with a single recombinant vector will divide into a colony with millions of cells, all carrying the same recombinant vector. This colony containing a very large population of identical DNA inserts is called a DNA clone. Thus, cloning allows the amplification and recovery of a specific DNA segment from a large, complex DNA sample such as a genome. The clone with the specific gene of interest is isolated in bulk and subjected to analyses.

For cloning, the plasmid DNA can be isolated by the differential binding of ethidium bromide to the circular plasmid DNA, making it denser than the chromosomal DNA, and the plasmids form a distinct band on centrifugation in cesium chloride gradient and separated out, to be used as cloning vectors. Phage lambda can also be used as a vector for cloning.

All DNA molecules, from viral to human, have restriction-enzyme target sites purely by chance and may
be cut into defined fragments of a size suitable for cloning. For example, the restriction enzyme Eco RI (obtained from *E coli*) can cut the following 6-nucleotide pair sequences in DNA of any organism:

5' - GAATTC - 3'
3' - CTTAAG - 5'

The segment is a DNA *palindrome* with similar sequences in antiparallel orientation (for, e.g. the statement - Madam, in Eden, I'm Adam - reads the same when read from either direction). This enzyme cleaves between G and A, leaving single stranded sticky ends with enhanced cohesiveness, which can from recombinant DNA.

The donor DNA and vector DNA after cleavage by restriction enzymes (and leaving sticky ends) are mixed in a test tube to form fusion DNA molecules. Once introduced into a bacterial cell, the *chimeric molecule* (Fig. 3.5) undergoes enormous proliferation (the plasmid has a replication origin) and the donor DNA is automatically replicated along with the vector.

**Salient Characteristics of Vector**

1. Small manipulable molecule
2. Prolific replication capacity
3. Possess restriction site.

For example - plasmid, phage lambda, cosmid, yeast artificial chromosome (YAC), bacterial artificial chromosome (BAC) (can carry 45 kb DNA insert). Special vectors called *expression vectors*, may detect a specific cloned gene, by detecting their protein products expressed in the bacterial cell.

The next step is collection of clones in a genomic library or a c DNA (*complementary DNA*) library. The advantage of c DNA is that it is made from mRNA using *reverse transcriptase* and is devoid of upstream and downstream regulatory sequences and introns. A genomic library is useful during cloning an entire genome.

**Pulsed field gel electrophoresis (PFGE)** may be used to construct a *chromosome specific library*. The library may further be probed using a DNA probe, which, when denatured, will complementarily bind to the single strand of the denatured library transferred onto a nitrocellulose membrane. The sequence of probe DNA can be made from several sources. The probe is usually labeled by radioactive agent or fluorescent dye and the signal subsequently detected.

Information about a gene’s position in the genome may be used to bypass the tenacious work of assaying an entire library to find the clone of interest. **Positional cloning** is a term that can be applied to any method that makes use of such an information. A common
starting point is the availability of another cloned gene or other markers known to be closely linked to the gene being sought. The linked markers acts as the departure point in a process called chromosome walking, that will terminate at the target gene. Cloned DNA has several uses. They may be used as a probe, or can be used to find a specific nucleic acid in a mixture.

There are several ways of fractionating DNA (Figs 3.6 and 3.7, Table 3.2). The most extensively used method is gel electrophoresis. If a mixture of linear DNA molecules is placed in a well cut into an agarose gel and the well is placed near the cathode (negative electrode) of an electric field, the molecules will move through the gel to the anode (positive electrode) at speeds dependent on their size. If there are distinct size classes in the mixture, these classes will form distinct bands on the gel. The bands can be visualized by staining the DNA with ethidium bromide which causes the DNA to fluoresce in ultraviolet light. If bands are well separated, then purified bands can be cut from the gel and the purified DNA sample can be recovered from the gel matrix. Thus, DNA electrophoresis can be either diagnostic or preparative.

Polyacrylamide gels are most effective for separating small fragments of DNA (5-500 bp), and they can resolve DNA fragments that differ in size by 1 bp. Agarose gels have a lower resolving power but a greater range of separation (200 bp - 50 kbp).

Detecting specific nucleic acid sequence uses a technique called hybridization. After electrophoresis, the gel is placed in buffer and covered by a nitrocellulose filter and a stack of paper towels. The fragments are denatured to single strands so that they can stick to filter. They are carried to the filter by the buffer. The filter is then removed and incubated with

*Fig. 3.6: Southern Blotting*

*Fig. 3.7: Blot transfer techniques*
a radioactively labelled single stranded probe that is complementary to the targeted sequence. Unbound probe is washed away, and X-ray film is exposed to the filter. Because the radioactive probe has hybridized only with its complementary restriction fragments, the film will be exposed only in bands corresponding to those fragments. Comparison of these bands with labelled markers revels the number and size of the fragments in which the targeted sequences are found. This procedure is called Southern blotting (Fig. 3.6) named after E M Southern, when DNA is transferred to the nitrocellulose paper and Northern blotting when RNA is transferred (Fig. 3.7).

A parallel technique called Western blotting has been developed to transfer electrophoretically fractionated protein from a gel and then to visualize with antibodies (polyclonal, prepared from animals, or monoclonal, prepared by hybridoma technology). Proteins can be separated based on molecular weight by technique of SDS - PAGE (polyacrylamide gel electrophoresis). SDS (sodium dodecyl sulfate) coats the protein, gives them a negative charge, and facilitates migration in an electric field. The proteins are denatured in the presence of SDS and the migration is made smooth. After electrophoresis, the specimen is detected by staining with silver, Sypro Ruby or Coomassie blue, or by performing Western blotting (Western blot increases the preciseness of detection).

Further analysis after cloning is to characterize the structure and function of that gene. The DNA sequencing now most commonly used was developed by Fred Sanger (Fig. 3.8). His method is based on DNA synthesis in the presence of dideoxynucleotides, which differs from normal deoxynucleotides in that they lack a 3'-OH group. The dideoxynucleotide triphosphates (ddNTPs) can be incorporated into a growing chain, but when incorporated, they terminate synthesis because they lack the 3'-OH group necessary to bind to the next nucleotide triphosphate. Each of the four reaction tube is prepared with single stranded DNA template for the sequence of intent, DNA polymerase and primers. Each tube receives different ddNTP, and 4 normal d NTP. In any given tube, various truncated chain lengths will be produced, each corresponding to the point of insertion of dd NTP. These lengths are in turn clear indications of where the bases complementary to the dd NTPs are in the template strand. The fragments can be visualized by electrophoresis of the 4 samples in 4 lanes on an acrylamide gel, where the fragments form bands. The base sequence can be determined by scanning up the gel, encompassing all four lanes, and recording which ever base occupies the terminus in the next band. Instead of radioactive labels, fluorescent dyes can be tagged to the oligonucleotide probes and automated sequencing performed. The data is fed into computers, and based on the open reading frames (ORFs), the prospective candidate genes are predicted.

Newer advances like reverse genetics (gene knockout) and organism containing introduced foreign DNA (transgenics) will provide wonderful tools for research at baseline levels. The latest excitement is genomics: Structural Genomics, characterizing the physical nature of the whole Genome and Functional Genomics, characterizing the transcriptosome (the entire range of transcripts produced by an organism) and the proteome (the entire array of encoded proteins).

Now, how do we analyze small amounts of DNA sample? Polymerase chain reaction provides for the amplification of this sample and facilitates its analysis by techniques elucidated in this chapter. The polymerase chain reaction (PCR), the repetitive bi-directional DNA synthesis via primer extension of a...
region of nucleic acid, is simple in design and has revolutionized molecular biology. After 25 cycles, there is a 10 (5) fold increase in DNA. PCR amplification of a template requires two oligonucleotide primers, the four dNTPs, Mg\(^{2+}\) ion in molar excess of dNTPs, and a thermostable DNA polymerase to perform DNA synthesis. The reaction samples are usually between 20 and 100 microliters.

There are 3 distinct steps of PCR cycle (Fig. 3.9):

a. **Denaturation of template:** Reaction is heated to 92 - 96 degree Celsius. The time required usually depends on complexity, thermal cycler, geometry of tube and the volume of reaction.

b. **Primer annealing:** After denaturation, the oligonucleotide primers hybridize to their complementary single stranded sequences. The temperature of this step varies between 37-65 degree celsius, depending on the homology of the primers for the target sequence as well as the base composition of the oligonucleotide. Primers are present at a significantly higher concentration than the target DNA, and are shorter in length; as a result, they hybridize to their complementary sequences at an annealing rate much faster than the target DNA duplex can reanneal. Optimization of annealing temperature begins with the calculation of Tm value of the primer-template pairs

\[
T_m = 4(G+C) + 2(A+T)
\]

c. **DNA synthesis by a thermostable DNA polymerase:** This is carried out at 72 degrees Celsius. Thermostable Taq polymerase is often used for this step. The time required to copy the template fully depends on the length of the PCR product. Because of the nature of the PCR it is critical that the only DNA that enters the reaction is the template added by the investigator. Thus, PCR must be performed in a DNA free, clean environment. DNA generated by previous amplification of the same target sequence can cause carryover contamination and adequate precaution should be taken about this to avoid false positive results. An ideal PCR would have high specificity, fidelity and yield.

Virtually all forms of DNA and RNA are suitable substrates for PCR. They include genomic, plasmid, and phage DNA, previously amplified DNA, c DNA, and m RNA. Typically, 0.1-1 microgram of mammalian genomic DNA is utilized per PCR. Samples prepared

by standard molecular methodologies are sufficiently pure for PCR. Now, rapid isolation of DNA may be done from whole blood spot, whole blood, and whole tissue with the aid of Genereleaser. The suspension is composed of 20% suspension of an activated hydrophilic proprietary polymer in aqueous 0.01 M Tris-HCl, 0.05 M KCl, 10% DMSO, pH 7.4-7.6. The hydrophilic polymer aids in cell disruption and serves as a nucleation site for precipitation and absorption of proteins.

PCR can also simultaneously amplify multiple loci in the human dystrophin gene. Multiplex PCR has been widely used in linkage analysis, template quantitation, and genetic disease diagnosis.

After performing PCR, the PCR product may be detected using agarose gel electrophoresis. The appearance of a discrete band of the correct size suggests a successful reaction. Following PCR, a portion of the reaction is subjected to digestion with the appropriate restriction enzyme and electrophoresed to detect the DNA fragments of the predicted size. An oligonucleotide probe that hybridizes to the template and is located between the two primers employed in PCR may be used to detect the PCR product. This probe can be used to detect the PCR product after transfer to a solid support (Southern Blotting). Other approaches to the detection of PCR product include systems using a nonradioactive ELISA-based format.

The amplification and quantitation of specific RNA species can be performed by reverse transcriptase-PCR (RT-PCR). This can detect or measure a defined RNA species, ranging from mRNAs for gene products to levels of viral RNA in plasma (e.g. hepatitis C virus, HIV, etc). Quality RNA template is converted to complementary DNA using RT, which is then subjected to PCR. This method can also be used for studying gene expression. Single nucleotide polymorphism (SNP) is the commonest type of polymorphism in the genome where variation is at only one nucleotide. It is detected by PCR using a common primer at one end and a variable primer at the other end, 3’ end of which anneals to the polymorphic base. Depending on the base at that position, only one of the variable primers will successfully amplify the locus and determine the base at that position. Using fluorescent probes and Real Time PCR, SNPs can be detected during PCR without running a gel. Once the linkage between a particular polymorphism with a disease or phenotype is established, it can be used as an inexpensive way of determining susceptibility to the disease and predict the probability of the disease in the offspring arising from a given match. The DNA obtained from polar body, blastomere or blastocyst biopsy during preimplantation diagnosis may be studied by PCR, gene sequencing or in situ hybridization, or the protein and enzymes identified and assayed.

PCR (polymerase chain reaction) has gained much importance in diagnostics. This highly sensitive molecular technique permits amplification of DNA without cloning that can be analyzed for gene alteration by techniques such as single stranded conformation polymorphism, denaturing gradient gel electrophoresis, etc. For example, single stranded conformation polymorphism (SSCP) have been used to detect genetic defects in sodium channels and resultant prolonged QT interval in sudden infant death syndrome (SIDS).

PCR and fluorescence in situ hybridization (FISH) have surpassed other non-isotopic in situ hybridization techniques (NISH) and have proved to be very powerful in the detection of genetic alterations. Oligonucleotide-primed in situ DNA synthesis (PRINS), an alternative procedure to conventional in situ hybridization, and direct incorporation of labelled nucleotides by PCR greatly improve the detection of small DNA probes, thus rendering a high sensitivity to these procedures.

FISH have been particularly useful in identifying microdeletions. For example, FISH has been used to diagnose Prader-Willi syndrome/Angelman syndrome, Miller-Deiker syndrome, etc. It is a precise technique for localization of single sequences within metaphase chromosome. The contrast enhancement of diaminophenylindole (DAPI) banded chromosome images permit the direct visualization of fluorescent signal on G-like bands. A variety of cDNA or genomic probe is used for the purpose. Some tissues, like amniotic fluid cells, chorionic villus and fetal blood are particularly refractile to hypotonic treatment, colcemid arrest, and yield chromosomes of unsatisfactory morphology. So, interphase FISH can be used to study these cells, especially for facilitating prenatal diagnosis. Interphase FISH has also been used to study minimal residual disease in cancer patients, diagnosis and prognostication of cancer, and
assessment of radiation induced damage. FISH can also detect the microdeletions in chromosome 22 in velocardiofacial syndrome.

**Multiplex FISH** uses digital images acquired separately for each fluorochrome using a charged couple device camera and analysed using an image analysis software. FISH can also be used to detect nuclear RNA. **Spectral karyotyping (SKY)** can be used for precise identification of chromosomes involved in complex arrangements. Digital fluorescence ratio (FR) may be used to quantify and discriminate fluorescent probes. **Comparative genomic hybridization (CGH)** is an analytical technique based on FISH and FR measurements that allow us to compare cytogenetically the entire genome of malignant and normal cells, as well as to assess gain and loss of DNA in tumor cells.

There are several other upcoming techniques in molecular biology which have broadened our horizon. **Denaturing high performance liquid chromatography (DHPLC)** can detect single nucleotide substitutions, small deletions, insertions, genotyping, LOH determination and gene expression analysis. **Serial analysis of gene expression (SAGE)** is a computer based technique for analysis of gene expression, and may be useful in studying the gene products of many tumors, including pancreatic cancer. There are several other techniques for detecting known and unknown mutations, which are helpful in academic and diagnostic purpose.

DNA chips have revolutionized genetics in the same way that semiconductor chips have revolutionized the information industry a few years back. DNA chips are samples of DNA laid out in regimented arrays bound to a glass chip the size of a microscope cover slip. Robotic machines with multiple printing tips resembling miniature fountain pen nibs deliver microscopic droplets of DNA solution to specific positions (addresses) on the chip. The DNA is dried and treated so that it will bind to the glass. Thousands of samples can be applied to one chip. The arrays of DNA are known cDNAs from different genes. For probing, fluorescent label is used, and the binding of probe molecules to the glass chip is optically monitored automatically by laser beams.

The need for dedication at bedside, appropriate observation, analysis and holistic approach to patient care has no alternative in practice of medicine. There are several diseases including cancer, autoimmune diseases and congenital malformation, whose pathogenesis and evolution are still in the grey zone. Basic medical research has enormous prospects in finding the molecular aspects and the cellular susceptibility to such conditions. However, in a country like India, the tools of biotechnology may be directed at present for improving food supplies, development of basic vaccines and diagnostic agents for infectious diseases. Also, the heterogeneous population of India is a big genetic laboratory in itself. Thus, the need for integration of the concepts of molecular biology in surgical sciences is justified.

**GLOSSARY**

Allele: One of the two alternative forms of a DNA sequence, each one inherited from father and mother.

Anticodon: A trinucleotide sequence on a transfer RNA which is complementary to codon that is present on messenger RNA.

Base pairing: The bond between adenine and thymine or guanine and cytosine of a double stranded DNA.

Bacteriophage: Virus that infects a bacteria.

Clone: Colony of cells descended from a single ancestral cell. In a noun sense it means — a population of recombinant DNA molecules all of them carrying the same inserted genetic code. To clone (as a verb) means to use *in vitro* recombination techniques to insert a particular gene or other DNA sequence into a vector molecule.

Cloning vector: It is used to carry foreign DNA molecule.

Coding sequence: Portion of a DNA that specifies a particular amino acid sequence, many of such would result in a particular protein.

Codon: A triplet of nucleotides in messenger RNA that specifies a particular amino acid. Each protein would have a specific ladder of amino acids.

Complementary: Each strand of the human DNA is said to be complementary to the another strand of DNA as it is base paired with hydrogen bonds.

Complementary DNA: DNA complement of an RNA sequence. This is synthesized by the enzyme RNA-primed DNA polymerase of reverse transcriptase. The single stranded DNA product of this enzyme may be converted into the double stranded form by DNA-primed DNA polymerase and inserted into a suitable vector to make a complementary DNA clone.

DNA finger printing: This is a method to generate a pattern of DNA restriction fragments that are unique to an individual. DNA from blood, semen etc is isolated and fragmented with enzyme - restriction endonuclease. That is further separated and documented by gel electrophoresis. Fragments of a specific nucleotide sequence are detected by hybridization with an appropriate DNA probe to produce the unique pattern.

DNA polymerase: This enzyme synthesizes DNA by copying a template strand.

DNA topoisomerase: This enzyme alters DNA by change in the supercoiling of double stranded DNA. In single stranded DNA it is capable of converting it to rings or knots.

Electrophoresis: A technique that separates DNA/RNA/protein based on ionic solute's differential migration after application of electric field.

Endonuclease: Enzymes that cleave nucleic acids at specific positions within the chain.

Euchromatin: Lightly staining regions of chromosomes that contain less condensed chromatin.
Exon: Expressed region of a gene. This encodes a protein as opposed to intron.

Fluorescence in situ hybridization (FISH): A method to label DNA probes for in situ hybridization utilizing non-isotropic fluorochrome.

Gene: A segment of DNA involved in a specific RNA molecule or a specific protein.

Heterochromatin: Condensed chromatin in certain chromosome regions that do not contain actively transcribed genes.

Heterozygote: Individual with two different alleles (genes) at a single locus.

Histones: Proteins found in the nuclei of all eukaryotic cells where they are complexed to DNA. These may act as a non-specific repressors of gene transcription.

Homologous chromosome: Chromosomes that pair with each other. They contain most of the same genes from a common ancestor.

Homozygote: An individual with two identical alleles (genes) at a single locus.

Hybridization: Annealing of a labelled nucleic acid probe to DNA or RNA for detecting the particular nucleic acid sequence.

Intron: Part of the gene that is not represented in the protein product. This means intron sequences are transcribed into RNA and then excised - intron splicing - before translation of RNA to protein.

Karyotype: Chromosomal number, size and morphology etc detected by light microscopy by stains.

Linkage: Tendency to inherit together two or more nonallelic genes or DNA markers than is to be expected by independent assortment. Genes/DNA markers are linked because they are sufficiently close to each other on the same chromosome.

Microarray: Chip technology for profiling of function of many genes or for screening for multiple genetic abnormalities.

Mutation: Change in the nucleotide sequence or arrangement of DNA

Northern blot: A method for studying RNA; RNA is transferred from an agarose gel to a nitrocellulose filter, on which the RNA can be detected using a specific probe.

Operon: Set of coordinately controlled genes adjacent to one another in the genome.

Palindrome: The sequence of double stranded DNA that is the same when read in opposite direction; e.g. "NURSES RUN"

Plasmid: Small circular DNA present outside the chromosome and replicates independent of the host DNA; responsible for conferring antibiotic resistance in bacteria; is used extensively as a vector in recombinant DNA technology.

Polymerase chain reaction: This discovery by Kary Mullis has opened several new vistas. This utilizes thermostable enzymes for repeated copying of the two strands of DNA (of a particular gene) and ultimately amplifies it. The large amount makes it easy for analysis of the DNA.

Polymorphism: Occurrence of 2 or more alleles at a specific locus in frequencies greater than can be explained by mutations alone; polymorphisms are common in introns.

Positional cloning: Cloning a gene purely based on its map position without knowing about the function

Probe: Probe is used to detect the presence of a specific fragment of DNA or RNA.

Promoter: Site located upstream of gene where RNA polymerase II and transcription factors assemble so that gene can be transcribed into functional mRNA molecule; contains TATA box, CAAT box, or GC box.

Reading frame: In a mRNA molecule, the exact nucleotide at which translation begins determines which one of three possible reading frames will be used during translation, since adjacent groups of three nucleotides are passed by the translation of machinery. Insertions or deletions of nucleotides that are not multiples of three shift the reading frame of mRNA to encode an entirely different protein with a different function.

Recombinant DNA: A fusion DNA resulting from insertion of a sequence of nucleotides into a separate molecule of DNA; the technology has been widely used for production of vaccine and other biologically useful substances. For example recombinant collagen is now being used as Vasostat to seal bleeding vessels and thus perform sutureless surgery.

Restriction enzyme: A bacterial endonuclease which cleaves both strands of DNA at very specific sites of the base sequence (4-10 base pairs).

sn RNA: Small nuclear RNA.

Southern blot: Used for detection of DNA.

Splicing: The removal of introns from RNA followed by the ligation of the exons; splicing involves some RNA molecules which act as enzymes (ribozymes).

Sticky ended DNA: Complementary single strands with high affinity for each other.

Transcription: DNA-directed synthesis of RNA using RNA polymerase enzyme.

Transgenic: Introduction of new DNA into germ cells by direct injection into the nucleus of ovum.

Translation: Synthesis of protein on a mRNA template.

Transposon: Mobile DNA sequences that jump from one place in the genome to another, e.g. Alu and LINE -1 sequences. Transposable elements affect the genetic variability.

Vector: A plasmid or bacteriophage in which foreign DNA can be introduced for cloning.

Western blot: An immunoblot transfer technique for detecting protein.

Growth is observed in measurable units postnatally as increase in length/height, skull circumference and weight. It stretches from:

a. Conception— intrauterine growth period to infancy (Most rapid growth period— > 70% of total human brain growth is completed),
b. Followed by a long phase of slow juvenile growth, and
c. Finally by 10-12 years in girls and 12-15 years in boys there is initiation of puberty – adolescent growth spurt lasting for 2.5-3.0 years (in this phase girls gain 25-26 cm and boys 28-30 cm in height).

TOOLs FOR ASSESSMENT OF GROWTH AND NUTRITIONAL STATUS

Intrauterine Assessment

Ninth week of gestation onward growth is measured as crown-rump and crown-heel length, later as biparietal and occipitoparietal measurements of skull using ultrasonography.

Infancy—Childhood—Adolescence

Anthropometric tools can be used not only for growth monitoring but also for nutritional status assessment. It is the repeated measurement only that can give the clue on assessment of growth. For minimizing errors measurements should be taken preferably by the trained workers; using accurate techniques and standardized instruments. The knowledge of exact age is very essential to evaluate growth in a child. The measurements used for growth monitoring are, skull circumference, height and weight.

For assessment of nutritional status midarm circumference is another good measurement. Skin fold thickness is useful in assessment of thinness and obesity in later years of childhood, particularly adolescence. In this age group to diagnose overweight/obesity and thinness the internationally used index is BMI weight kg/height meter.

Head Circumference

A very important growth measure, it enlarges rapidly in hydrocephalus/raised intracranial tension. Small head size with little gain in circumference with palpable ridge on suture(s) could be diagnostic of craniosenosis.

In infants and small children it can be measured in the lap of the mother/caretaker. On older children it can be measured with head in Frankfort plane (see measurement of height) with arms relaxed and legs apart. A fiber glass tape (nonstretchable) is passed over the occipital protuberance of the head at the back and most anterior protuberance at the front, tightly so as to compress the hair. Some recommend that tape be passed over glabella in front and occiput at the back. The objective is to record maximum of the head circumference. Measure twice to ensure the correct reading.

Stature (Length/height)

In children below 2 years of age recumbent length on an infantometer be accurately measured by two persons. Infantometer has an horizontal board with scale markings; two side perpendicular boards of which one is sliding allows child in lying position (Supine), with child’s knees extended firmly and feet
are flexed at right angles to the lower legs for proper measurement (accuracy 0.1 cm). The upright sliding feet sideboard is moved to closely touch the heels (without shoe and shock) and length is recorded. Height is measured (For children above 2 years of age), on a vertical-measuring rod called anthropometric rod, it has a flat small horizontal arm to be fixed on head for exact measurement.

**Weight**

The child should be weighed in minimal (Standard weight) clothing. The weighing scale should be checked for zero error each time the subject is weighed. Placing known weight everyday can check it. The weighing scales used commonly are (i) beam balance, (ii) spring balance and (iii) electronic scale. The beam balances are more sturdy, but heavy to carry. The lighter spring balances are easy to carry but likely to give fallacious reading, due to elasticity of spring, if proper care is not taken in its maintenance. Electronic weighing scale gives reading upto 10 gm, but it should also be tested before use against a known weight.

There are beam-weighing scales with fitted anthropometric rod. Child with standard minimum clothing without shoe and shocks stands with feet parallel on the even flat platform, stretching upward to the fullest, arms hanging on the sides; buttocks and heels touching against the rod. The head should be held comfortable, erect, with lower border of the orbit of the eye in the same horizontal plane as the external canal of the ear (Frankfort plane). The headpiece (flat small horizontal arm) of the measuring device should be gently lowered to make contact with the top of the head. The measure should be calibrated unto 175 cm with markings of 0.1 cm.

**Arm Circumference**

Midarm circumference is recorded midway between tip of acromian process and olecranon. The tape is passed around the arm at the marked level, but no pressure is applied.

Measurement in the age group 1-6 years changes < 1.0 cm. The following cut off are accepted by the WHO to diagnose under/malnutrition

- > 13.5 cm — Normal
- 12.5 - 13.4 cm — Mild to moderate
- < 12.4 cm — Severe.

**Skin Fold Thickness (SFT)**

Half of body fat is located directly under the skin. Measurement of skinfold gives the estimate of the body fat. Triceps and biceps SFT measure peripheral fat and subscapular and suprailiac SFT measure central fat.

**Growth in Head Circumference (Cm)**

In normal full-term child.

The increment is 2 cm/month in first 3 month; 1 cm/month between 3 - 6 month; 0.5 cm/month between 9-12 month. Thereafter gain in head circumference is very slow, only 5 cm after first birth day to 12 years of age (Tables 4.1 and 4.2 give percentiles for head circumference for boys and girls – Birth until 6 years of age). Figure 4.1 shows percentile curves for boys. These can be used for girls also as data (Tables 4.1 and 4.2) do not show much difference.

Tables 4.1 and 4.2 are based on data published by the author in 1992 and 1994 that were the results of a large multicenter survey of growth and development of Indian Children. Though various studies have tried to formulate reference data in the past, but in all

Indian Pediatrics 1994;31:377 (Agarwal and Agarwal)
these studies, the sample size was very small and they were more regional rather than representative of the whole country.3,6

Skull circumference is important in pediatric surgical practice: The causes of variations are:

**Large Head**
Big infant, familial feature, hydrancephaly, hydrocephalus (progressive or arrested), subdural effusion, cerebral tumor, storage diseases megacephaly (abnormal storages of substances within the brain parenchyma- lysosomal diseases, e.g. Tay-Sachs, gangliosidosis, mucopolysacchridosis chondrodystrophies, metachromatic leucodystrophies, etc.

**Small Head**
Small infant, familial, microcephaly- skull size below 2 SD (primary brain growth failure), craniostenosis (ridge is palpable on the suture line).

**Head Circumference in Pre-term Babies**

**Length/Height Growth**
At birth length is 50 cm it becomes 73-75 cm by first birth day; 86-87 cm by 2nd year and 100 cm at 4 years of age. Until puberty sets in gain in length (height velocity) is 5-7 cm every year. If gain is less than 4 cm/year possibility of growth hormone deficiency be kept in mind. Percentile growth curves for height given in Figure 4.2 are for children up to 36 months of age (same curve can be used for girls) and in Figures 4.3A and B for children up to 12 years of age. By the age of 12 years ‘Puberty’ sets in majority of girls and in some boys. Therefore, percentiles in relation to sexual maturity rating are given in Tables 4.3 and 4.4. These figures and tables will assist us in plotting the child’s measured value and if the value is closer to the 50th

![Fig. 4.2: Shows percentiles for length/height of children < 90% value of the 50th percentile value are “stunted” (chronic undernutrition)](image)

![Fig. 4.3A: Agarwal’s growth curves (Percentile curves for height and weight on affluent in Indian children)](image)
Fig. 4.3B: Agarwal's growth curves (Percentiles for height and weight in Indian affluent children)

Fig. 4.4: Height-velocity Chart for boys and girls (Indian Pediatr 1994;31:377)

Fig. 4.5: Growth and nutrition assessment: The inset graph has 50th centile weight as 100% of weight and lines for 90%, 75% and 60% are to identify normal in weight for age (> 90%), grade I (< 90–75%), grade II (< 75–60%) and < 60% are in grade III. Gomez's classification for malnutrition (Birth-3 years) Indian pediatr 31:377-412, 1994. Weight, height, skull and mid-arm centiles for boys and girls are very close, thus the graphs can be used for girls, also

Gomez et al 1956, J Trop Pediatr Env Ch Hlth. 2:77
(Used by the National Nutrition Monitoring Bureau in India)

What are Percentile Growth Curves?

To follow a child regularly percentile growth curves are used. The percentile refers to the position of an individual on a given reference distribution. The percentiles are calculated for 3rd, 10th, 25th, 50th, 75th, 90th and 97th etc; the data between 3rd and 97th include 94% children (this covers children within +2 SD from the mean). The 50th percentile value for any age indicates that 50% values lie above and remaining 50% below this value. In case there is gaussian distribution mean and median values will be the same.

Weight Gain

Birth weight is around 3.0 kg, it doubles by 5 months of age (wt = 6.0 kg) and trebles (wt = 9.0 kg) on first birthday. At 2 yr of age it is 4 times (wt = 12 kg) of the birth wt. It becomes five times at 3 yr (wt = 15 kg) and 6 times (wt = 18 kg) at 5 year of age. The percentile growth curves for children up to 36 months and 12 year of age are in Figure 4.5. In the Figure, the nutritional status curve is inset to grade the malnutrition according to Gomez et al (Table 4.5).

The National Child Health Survey (NCHS) percentiles available for American children are also given in Tables 4.6 A and B. Our children have similar height as those of Japanese, Thai, Hongkong—thus closer to Asian children. But are shorter than Caucasian children from Europe and USA.

Sexual Maturity

This can be assessed by using Tanner’s criteria given in Tables 4.7 and 4.8.

DEVELOPMENTAL MILESTONES

Control of body movements is thru the coordinated activities of nerves, nerve centers and the muscles. These motor movements develop in a definite sequence the direction being cephalocaudal. The first step in gross motor development is head control, involving the neck muscles. It is development of spinal muscle coordination that makes child sit with straight back instead of a round one. Child develops coordinated movements of hands, allowing him to crawl, followed by the leg movement, e.g. standing and walking. The development is proximodistal also, e.g. movement coordination develops first in trunk muscle followed by shoulder, arm, hand and fingers. The aimless movements of arms and legs of the first six months are replaced by the specific movements of locomotion and manipulation. In surgical practice – ‘Neck holding, sitting, standing, walking’ are easy to observe. The gross motor, fine motor (Manipulation), vision and hearing (personal social) and language development are summarized in Table 4.9.

ESSENTIAL MILESTONES

4–6 weeks: Smiles, vocalises 1-2 weeks later.
12–16 weeks: Head control/holds objects placed in hands converses with mother
12–20 weeks: Hand regard
20 weeks: Goes for objects and gets them
26 weeks: Transfers objects from one hand to another
28–30 weeks: Sits unaided
9–10 months: Index finger approach (Points index finger to the object).

REFERENCES

Billions of years ago the life started in the sea as unicellular organism and the cell was surrounded by the sea water. The sea water protected the cells as a shell. In human beings the extracellular fluid (ECF) compartment has the composition of fluids similar to that of sea water and it protects the cells. Primary disturbances in fluid and electrolytes affect mainly the extracellular compartment. Though minor disturbances in the extracellular environment are compensated by renal and other mechanisms, gross changes in ECF lead ultimately lead to alterations in the intracellular fluid (ICF). This may affect the cell function and cell survival depending upon the severity of the deleterious changes.

Fluid and electrolyte imbalances occur much more quickly in children than in adults. Newborn babies, infants and children present unique problems in managing fluids and electrolytes. Differences in the rate of metabolism and body surface area are two unique aspects of them that contribute to special circumstances. Children and adults obviously are different in size, but children are not miniature adults. A child’s body composition and homeostatic controls differ from those of an adult very much. The younger the child, the greater the differences and it posed the greater challenge to manage. Fluid and electrolyte requirements vary, not only with the size of a patient, but also with the child’s age and clinical condition. The pediatric surgeon needs to be alert to the potential problems of these children and this would have a tremendous effect on patient outcome. It is necessary to be alert to fluid and electrolyte imbalance so they necessary intervention could be instituted before the situation turns out to be too critical.

**FLUID BALANCE**

Fluid is well balanced in all living organisms by nature. “Fluid balance” refers to total body water, which stays constant with consistent distribution among the main fluid compartments - that is ECF, ICF and interstitial fluid. Water and electrolytes are balanced together and each one of them in each compartment is important and all of them together determine the fluid equilibrium. The ICF and ECF composition is shown in Table 5.1.

In summary, the body is comprised two fluid compartments – ECF and ICF. The ECF has extracellular fluid compartment, which is intravascular fluid (plasma) and extravascular or interstitial fluid (lymph and cerebral spinal fluid). For these the major electrolyte is sodium (Na⁺). The ICF is within cell walls, and here the major electrolyte is potassium (K⁺). Water balance is maintained in the body in an almost constant amount, and under normal circumstances, water taken in is close to the amount of urine excreted in a 24-hour period. The water in food and from oxidation balances the water lost in feces and evaporation. These auto-regulated events keep the body’s fluids in balance.

The premature infant’s body is approximately 90% water, the newborn infant’s body is 70-80% water; and the adult’s body is approximately 60% water. By the time a child is almost 3 years old, the total body water is approximately 60%. However, although an infant has more total body water than an adult, the infant is not protected from excessive fluid loss. In fact, the opposite is true. An infant may exchange half his extracellular fluid daily, whereas an adult may exchange only one sixth in the same day. This means the infant has a greater fluid requirement and is able to keep only a small amount of fluids in reserve. Any increase in fluid loss can quickly cause an infant to become dehydrated. Insensible water losses (fluids lost through the skin and lungs) are higher for infants and children than for adults. Because an infant has relatively greater body surface area than does an adult, an infant will lose more insensible fluids. For example, compared to an older child, a premature infant has almost five times as much body surface area in relation to its weight; the newborn has three times the body surface area. Consequently, any situation that causes an increase in loss of water and electrolytes through the skin threatens the body fluid balance of the infant and small child to a greater degree than it would an older child or adult. Insensible water losses may increase as much as 50-70 ml for each degree Celsius above normal body temperature in an infant. Fever increases insensible water losses by about 0.42 ml/kg/degree Celsius for each degree above 37°C. It also is important to consider any additional sources of fluid loss that can increase evaporation losses through the skin, such as the use of radiant heat warmers or phototherapy lights.

**MAINTENANCE FLUID THERAPY**

Maintenance fluids provide water and electrolytes equal to those lost during normal activities, such as breathing, urination, stool formation, and regulating body temperature. Holliday and Segar devised a formula in 1957 that is still used to estimate maintenance water requirements. It is important to keep in mind that the amounts calculated from the formula does not take into consideration the increase or decrease in water excretion secondary to illnesses. Also, it is important to keep in mind those maintenance fluid needs to be supplemented with deficits. For this it is imperative to assess whether the baby already has deficits. Assessment skills are important for the pediatric surgeon to recognize subtle clues before an infant or child gets into serious fluid and electrolyte imbalance. Assessing physical data, the results of laboratory tests, body weight, and intake and output charts are some of the important aspects in this regard.

**PHYSICAL ASSESSMENT**

When child is dehydrated, extracellular fluid volume decreases, which leads to a decrease in peripheral circulation. As circulation becomes compromised, skin color changes from normal to pale. Capillary filling time also increases. Skin turgor will be dry, and tenting of the skin may be noticed. A decrease in the production of secretions may also be noted. As fluid volume decreases small arterioles vasoconstrict to keep blood flow to vital organs resulting in cool extremities. The mouth is a good place to assess fluid deficit. Watch for a decrease in saliva, dry lips and nares, and cracked mucous membranes. The tongue may become red, rough, dry, and wrinkled. Pulse rate is another sensitive indicator of fluid status. If a pulse rate is greater than 160 beats per minute (bpm) for infants and 120 bpm for children, hypovolemia should be strongly suspected. Fontanels of infants will be depressed with a moderate fluid deficit. Fluid volume deficit causes a mild metabolic acidosis. Children often will hyperventilate to compensate for the acidosis. An increased respiratory rate will increase insensible water loss, worsening the fluid volume deficit. Blood pressure is the last vital sign to show changes and
should not be relied on as an assessment indicator of dehydration.

LABORATORY DATA

Laboratory values and physical assessment data are necessary for diagnosing and treating fluid and electrolyte imbalances. Normal serum laboratory value ranges may differ from one laboratory to another, so it is imperative to keep in mind the values of the local laboratory. Common normal values for this purpose are given in Table 5.2.

BODY WEIGHT

Body weight is an important variable in guiding diagnosis and treatment. An accurate baseline weight is essential. Frequent follow-up weight measurements are critical to the treatment of an infant or child with a fluid and electrolyte imbalance.

INTAKE AND OUTPUT CHARTS

Calculating and documenting accurate intake and output are critically important. Though these charts are maintained by the nurses, pediatric surgeon should cross check and utilize them for calculating the fluid and electrolyte requirements of the baby. The number, consistency, and character of stools must be documented. Urine, emesis, gastric suctioning, and wound drainage also should be included in output amounts.

OVERVIEW OF ELECTROLYTES

The most crucial electrolytes for all cell life are potassium (K⁺), sodium (Na⁺), and chloride (Cl⁻). Another electrolyte to be closely monitored in children is calcium. Although not an electrolyte, serum glucose plays an important role in the hemodynamic monitoring of the pediatric patient. Electrolytes are lost in different amounts with normal body fluids, except insensible losses. For example, more potassium is lost in stool than are sodium and chloride. To effectively monitor infants and children, we need a basic knowledge of important electrolytes and signs and symptoms of imbalances. The normal values along with important biochemical parameters are listed in Table 5.2.

**Sodium**

Sodium is the most abundant electrolyte in extracellular fluid. When a decrease in serum sodium concentration (hyponatremia) produces an acute decrease in intravascular osmolality, free water moves from the intravascular to the interstitial space until the osmolality of the compartments are the same. Thus, an acute decrease in serum sodium will result in an acute shift, which may lead to significant cerebral edema.

Sodium concentration of extracellular fluid profoundly influences the kidneys’ regulation of body water and electrolyte status. For example, when sodium concentration falls, the kidneys promote water excretion under the influence of aldosterone. When sodium concentration increases, the release of antidiuretic hormone causes the kidneys to retain more water and dilute the sodium to normal levels.\(^{10}\) Hyponatremia is associated with acute respiratory distress in infants with bronchopulmonary dysplasia. Other causes of hyponatremia include gastrointestinal fluid losses coupled with increase water replacement, adrenal insufficiency, water enemas, potent diuretic therapy, and factors predisposing to syndrome of inappropriate anti-diuretic hormone secretion from drugs, tumors, or central nervous system disorders. Signs and symptoms of hyponatremia are apprehension, headache, abdominal cramps, convulsions, oliguria or anuria, diarrhea, muscle twitching or weakness, increased deep tendon reflexes, lethargy or confusion, tachycardia, and cold clammy skin. Hypernatremia may be caused by an excessive intake
of sodium or an increased water loss related to sodium loss. Signs and symptoms are dry, sticky mucous membranes; flushed skin; intense thirst; rough and dry tongue; irritability when stimulated; firm tissue turgor; and coma. When treating hypernatremia, eliminate the cause of excess intake, if possible; give infusates to dilute the serum level; and monitor closely.

**Hyponatremia**

The causes and laboratory data of hyponatremia is summarized in the Table 5.3.

**Treatment**

It is important to look for the losses and replace the losses appropriately. The original cause for the hyponatremia needs to be treated. If there is an increase in the body weight along with the hyponatremia, fluid restriction is recommended.

**Syndrome of Inappropriate Antidiuretic Hormone (SIADH) Secretion**

Conditions associated CNS disease or injury (head injury, meningitis, subarachnoid hemorrhage, meningoencephalitis, brain tumors, neurosurgery may result in SIADH.

The treatment includes normovolemia with fluid restriction, to maintain normovolemia and an addition of diuretic (e.g., furosemide). It needs administration of insensible fluid losses plus isotonic fluid to replace hourly urine output.

**Hypernatremia**

The causes and laboratory data of hypernatremia is summarized in Table 5.4.

**Clinical Management**

Predominantly neurological symptoms: Lethargy, weakness, altered mental status, irritability, and seizures. Additional symptoms may include muscle cramps, depressed deep tendon reflexes, and respiratory failure. Treatment includes, replacement of free water losses based on calculations in present text and treat the cause. Natriuretic agent may be considered if there is an increased weight.

**Potassium**

Potassium is the predominant intracellular electrolyte. Potassium activates several enzymatic reactions, helps regulate acid-base balance, influences kidney function and structure, and maintains neuromuscular
excitability. Potassium exists normally in the serum in a narrow range (3.5 mEq/l - 5.5 mEq/l), thus small deviations in either direction can have disastrous consequences. Even for children who are only mildly ill, a potassium imbalance can quickly become surprisingly severe. Fortunately, potassium levels usually stay within normal limits, despite a great fluctuation in fluid and electrolyte intake. There may be a reciprocal relation between sodium and potassium: A large intake of sodium increases the loss of potassium and vice versa. The kidneys are the main compensatory and regulatory mechanism responsible for this hemodynamic state. Potassium is the electrolyte most affected by intestinal illness such as diarrhea. Children have a reservoir of potassium in their extracellular fluid that the body uses when needed. Thus, when a drop in the serum potassium (intracellular) level is observed, the pediatric surgeon can assume the extracellular supply is gone, and the child could be headed for serious trouble. Adults are at risk for cardiac arrhythmias when their potassium levels drop below 3.5 mEq/l. However, children do not usually show cardiac symptoms until their level is below 3.0 mEq/l.

**Hyperkalemia**

Hyperkalemia is a dangerous electrolyte disturbance because of the potential for cardiac arrest. Hyperkalemia may result from excessive intake (particularly intravenously), changes in acid-base balance, cell destruction (releases intracellular potassium), or reduced renal excretion (such as renal failure). This is summarized in Table 5.5. Hyperkalemia is a common, but poorly understood, problem in premature infants, with an incidence reported as high as 60% of all infants of very low birth weight. Signs may appear within the first 6 hours of life. Hyperkalemia may also represent an intravascular shift of potassium ions that occurs in acidosis or it may be associated with renal failure. If the serum potassium level does not decrease during rehydration, renal failure should be suspected. Signs and symptoms of hyperkalemia include tall T-waves and prolonged P-R intervals. Ventricular arrhythmias or ventricular fibrillation can occur anytime. These following measures are recommended to manage hyperkalemia:

1. Administer calcium gluconate to alter cardiac effects.
2. Decrease serum K⁺ by increasing extracellular volume.
3. Decrease serum K⁺ by sending it into the cells (sodium bicarbonate, insulin, glucose) and
4. Remove excessive serum K⁺ (with the administration of sodium polystyrene sulfonate).

The following is the algorithm for management of hyperkalemia (Fig. 5.1).

![Fig. 5.1: Management of hyperkalemia in children](mebooksfree.com)
**Hypokalemia**

Hypokalemia also is a dangerous situation. Pediatric patients in danger of becoming hypokalemic are those with large gastrointestinal losses, such as from protracted vomiting, prolonged gastric suctioning, or diarrhea. Patients receiving chronic loop or thiazide diuretics also are at risk because of potassium loss. Other common causes of hypokalemia include shifts into the cell that may occur with TPN, alkalosis, or excessive secretion or administration of insulin (Table 5.6). Signs and symptoms include thirst, malaise, muscle weakness, tremors, diminished reflexes, tachycardia, hypotension, and myocardial irritability. Treatment is the administration of potassium, either parenterally or orally. The clinical manifestations are summarized in Table 5.7.

**Calcium**

Infants and children are more prone to hypocalcemia than adult patients. When an infant is stressed, more growth hormone is secreted, which results in increased deposits of calcium in the bone. Because of low stores, the infant often is unable to keep up with the demand to deposit calcium in bones. The result is systemic hypocalcemia. Hypocalcemia also may be caused by acute pancreatitis, excessive infusion of citrated blood, malabsorption syndrome. Cow’s milk given to newborns, alkalosis, hyperphosphatemia, hypomagnesemia, and vitamin D deficiency are also in the list. Signs and symptoms are tingling of fingers and toes, tetany, abdominal cramps, muscle cramps, and seizures. Infusions of calcium gluconate are administered to correct this electrolyte imbalance. Hypercalcemia usually is the result of immobilization, excessive use of diuretics, or malignant neoplastic disease. Signs and symptoms include constipation, dehydration, and dry mouth, polyuria, and muscle hypotonicity. Cardiac arrest is possible in severe hypercalcemia. Treatment includes decreasing the serum calcium level by administering IV fluids and promoting renal excretion. Calcium disequilibrium is summarized below.

**Hypocalcemia**

Hypocalcemia can be caused by pancreatitis, malabsorption states (malnutrition), hypoparathyroidism (decreased parathyroid hormone (PTH) levels or ineffective PTH response), vitamin D deficiency, hyperphosphatemia (i.e. secondary to excessive use of sodium phosphate enemas), drug therapy (anticonvulsants, cimetidine, aminoglycosides, Ca++ - channel blockers), hypomagnesemia/hypermagnesemia, maternal hyperparathyroidism if patient is a neonate, Calcitriol (activated vitamin D) insufficiency, tumor lysis syndrome. Clinical features include — Tetany, neuromuscular irritability with weakness, paresthesias, fatigue, cramping, altered mental status, seizures, laryngospasm and cardiac dysrhythmias, ECG changes (prolonged QT interval), Trousseau’s sign—carpopedal spasm after arterial occlusion of an extremity for 3 minutes and Chvostek’s sign—muscle twitching with percussion of facial
nerve. Treatment in acute setting includes the administration of, calcium gluconate, or calcium chloride intravenously but slowly in a diluted form.

Hypercalcemia

Hypercalcemia is caused by hyperparathyroidism, vitamin D intoxication, excessive exogenous calcium administration, some malignancy cases, prolonged immobilization, with the use of some diuretics (thiazides), granulomatous disease (i.e., sarcoidosis) and hyperthyroidism. Clinical features include weakness, irritability, lethargy, seizures, coma, abdominal cramping, anorexia, nausea, vomiting, polyuria, polydipsia, renal calculi, pancreatitis and ECG changes (shortened QT interval). Management includes the following:

1. Treat the underlying disease.
2. Hydrate to increase urine output and Ca^{2+} excretion.
3. Diuresis with furosemide.
4. Consider hemodialysis for severe or refractory cases.
5. Steroids may be indicated in malignancy, granulomatous disease, and vitamin D toxicity to decrease vitamin D and Ca^{2+} absorption.
6. For severe or persistently elevated Ca^{2+} give calcitonin or bisphosphonate.

Chloride

Chloride imbalances are seen as acid-base disturbances. For homeostasis, blood pH, the patient's arterial carbon dioxide tension (PaCO₂), and serum bicarbonate concentrations must be in balance. Any disturbance in that balance tells the body to immediately compensate. For example, a child loses a great deal of bicarbonate in diarrhea, which lowers the serum bicarbonate level. The body responds by increasing alveolar ventilation, which lowers PaCO₂. If the diarrhea is not severe, the blood pH will remain normal because the homeostasis-compensatory mechanism has worked.

Acid-base imbalances are classified as metabolic, respiratory, or mixed, depending on which concentration (PaCO₂ or bicarbonate) has been disturbed. Metabolic acidosis usually occurs in pediatric patients because they lose too much bicarbonate in diarrheal stools. High fevers or ketosis of starvation (such as failure to thrive or neoplastic disease) also cause increased metabolic rates that change the acid-base balance. Metabolic alkalosis in pediatric patients usually is related to loss of acid from vomiting or excessive gastric suction. Alkalosis is a common occurrence in children on diuretic therapy attributable to losses of Na⁺, Cl⁻, and water without a proportional loss of bicarbonate.

DEHYDRATION

Being alert for developing dehydration is an important aspect of caring for infants and children. Dehydration often is characterized as mild, moderate, or severe. In children, dehydration usually is attributable to vomiting or diarrhea.

The clinical signs and symptoms of classic dehydration are the result of extracellular fluid volume depletion: Hypovolemia and decreased tissue perfusion. The child usually is lethargic. Hands and feet are cold and may be cyanotic because of constriction of peripheral arterioles caused by hypovolemia. Tachycardia and other responses to hypovolemia are the body's efforts to keep cardiac output supported. Dehydrated patients occasionally are mildly febrile, although young infants may be hypothermic. Oliguria may be present, and the urine osmolality usually is high unless renal failure is present.

Types of Dehydration

Isotonic Dehydration (Isonatremic)
Electrolyte and water deficits are approximately equal. This is the most common dehydration in children and may be life threatening. The child with isotonic dehydration has signs and symptoms characteristic of hypovolemic shock.

Hypotonic Dehydration (Hyponatremia)
Electrolyte losses are greater than water losses. Hypotonic dehydration also presents with signs and symptoms of hypovolemia.

Hypertonic Dehydration (Hypernatremic)
Hypertonatremic dehydration is caused by water losses that are greater than electrolyte losses or large
electrolyte intake. Gastroenteritis, vomiting, and diarrhea in children usually leads to hypernatremic dehydration. Burns, high fever, diabetes insipidus, aggressive diuresis, and diabetic ketoacidosis also may produce fluid loss that is more than sodium loss. Hypernatremic dehydration also occurs in infants with diarrhea who are given fluids by mouth that contain large amounts of solute and in children receiving high protein nasogastric tube feedings that place an excessive solute load on the kidneys.

**Degree of Dehydration**

Treatment of dehydration is determined by the degree of the dehydration. This has been elaborated in the following section (fluid deficits).

**Rehydration**

Intravenous fluids remain the treatment of choice for fluid volume deficit in children as well as adults. The ability to select from different types of fluids and customize the infusion prescription to the patient's needs is a large part of ensuring positive patient outcomes. However, there is an alternative therapy for some patients after their conditions have been stabilized with IV treatments.

**Oral Rehydration Solutions**

Intravenous rehydration is commonly used to replace lost fluids and electrolytes. After initial stabilization, oral rehydration solutions may be used in the hospital or home setting.

Oral solutions are successful in treating many children with isotonic, hypotonic, or hypertonic dehydration. Vomiting is not a contraindication. A child who is vomiting should be given frequent, small doses of oral rehydration solutions. After successful IV rehydration, oral rehydration solutions may be used during the maintenance fluid therapy phase. Alternating an IV solution with a low-sodium fluid, such as water, breast milk, lactose-free formula or half-strength lactose containing formula, is an effective treatment plan.

**Diarrhea**

Generally, diarrhea is present when there is an increase in stool frequency accompanied by increased water content. The impact of diarrhea changes with its severity, duration, associated symptoms, the age of the child, and the child's nutritional status.

Chronic diarrhea usually is secondary to chronic conditions, such as malabsorption syndromes, inflammatory bowel disease, immune deficiency, food allergy, lactose intolerance, and chronic, nonspecific diarrhea. Chronic diarrhea also may be the result of inadequate management of acute infectious diarrhea.

**Water Intoxication (Acute Symptomatic Hyponatremia)**

Water intoxication, or water overload, is observed less often than dehydration. However, it is important to be aware that water intoxication can occur and be alert of the possibility in certain situations. Infants are especially vulnerable to fluid overload. Because their thirst mechanism is not well developed, they are unable to turn off fluid intake appropriately. Decreased glomerular filtration rate prevents their immature kidneys from excreting more fluid when faced with an increased water load. Consequently, infants are unable to excrete a water overload effectively. The immediate danger of water intoxication is from brain swelling. Infants with water intoxication have a serum sodium level of less than 130 mEq/l. Hyponatremia not associated with dehydration results from an infant having too much water in proportion to sodium. The infant with water intoxication has too much water parenterally, orally, or by enema. Another factor is a history of diarrhea. It is not unusual to discover that the infant has been given inappropriate fluids (such as dilute low-solute formulas, water, juices, tea, or soft drinks) to keep the infant from become dehydrated. Water intoxication also can occur during acute IV fluid overloading, too rapid dialysis, or with too rapid reduction of glucose levels in diabetic ketoacidosis. Administration of improperly prepared formula is another common cause of water intoxication. Families who cannot afford to buy formula may dilute the formula to increase the volume or may substitute water for the formula. In addition, water sometimes is used for pacification. Water intoxication may occur in infants who receive overly vigorous hydration during a febrile illness.
When we order for fluids for a patient, we have to make sure that we answer the following three questions:
1. How much fluid to give?
2. What fluid to give?
3. How to give?

**HOW MUCH FLUID TO GIVE?**

This depends on the maintenance requirements and the deficits.

**Maintenance Requirements**

Maintenance requirements stem from basal metabolism. Metabolism produces two by-products: Heat and Solute. Most by-products are taken out of the body. Heat dissipation through insensible losses and solute excretion in urine each can be considered as representing 50% of maintenance needs. In the management of children who have anuric renal failure, maintenance fluid needs decrease by 50% because the only fluids that need to be replaced are insensible losses. This can be calculated by the following methods.

**Holiday and Segar Method**

The Holliday and Segar method (Table 5.8) estimated caloric expenditure in fixed weight categories; it assumes that for each 100 calories metabolized, 100 mL of H₂O will be required. For each 100 kcal expended, about 50 mL of fluid is required to provide for skin, respiratory tract, and basal stool losses, and 55-65 ml of fluid is required for the kidneys to excrete an ultra-filtrate of plasma at 300 mOsmL without having to concentrate the urine. This method is not suitable for neonates. It generally overestimates fluid needs in neonates compared with the caloric expenditure method.

**Caloric Expenditure Method**

The caloric expenditure method is based on the understanding that water and electrolyte requirements more accurately parallel caloric expenditure. For this standard basal calorie (SBC) expenditure as approximated by resting energy expenditure is calculated, and then adjustments by various factors (e.g. fever, activity) is done. For each 100 calories metabolized in 24 hours, the average patient will need 100-120 mL H₂O, 2-4 mEq Na⁺, and 2-3 mEq K⁺.

**Body Surface Area (BSA) Method**

The BSA method is based on the assumption that caloric expenditure is related to body surface area. It is not recommended for infants. In this method, water requirements are 1500 mL/m²/24 hr, Na⁺ requirements are 30-50 mEq/m²/24 hr and K⁺ requirements are 20-40 mEq/m²/24 hr. The surface area can be calculated by the following formula:

\[
\text{Surface area} = \frac{[4w + 7]}{[w + 90]}
\]

For example, the correct fluid requirement of a child of 10 years old with a body weight of 25 kg would be:
- For the first 10 kg = 10 × 4 ml/h = 40 ml/h
- Plus
- For the second 10 kg = 10 × 2 ml/h = 20 ml/h
- Plus
- For the last 5 kg = 5 × 1 ml/h = 5 ml/h
- So, the total would be 40 + 20 + 5 = 65 ml/h

**Table 5.8: Holliday and Segar method of fluid requirement estimation**

<table>
<thead>

</tr>
<tr>
<td>Second 10 kg</td>
<td>50</td>
<td>2</td>
</tr>
<tr>
<td>Each additional kg</td>
<td>20</td>
<td>1</td>
</tr>
</tbody>
</table>

For example, the correct fluid requirement of a child of 10 years old with a body weight of 25 kg would be:
- For the first 10 kg = 10 × 4 ml/h = 40 ml/h
- Plus
- For the second 10 kg = 10 × 2 ml/h = 20 ml/h
- Plus
- For the last 5 kg = 5 × 1 ml/h = 5 ml/h
- So, the total would be 40 + 20 + 5 = 65 ml/h

Since the calculation of surface area in the ward on the weight basis is difficult, a method has been evolved to administer fluid based only on weight. Hence Holliday and Segar method is the most popular method to calculate the fluid requirements.
Deficits

Assessment of the deficits may be done by calculated assessment and clinical assessment. To this the ongoing losses need to be added up.

Calculated Assessment

The most precise method of assessing fluid deficit is based on preillness weight:

Fluid deficit (L) = Preillness weight (kg) - Present weight (kg)

Percentage of dehydration = [(preillness weight - illness weight)/pre illness weight] × 100%

If the accurate weight is not known, the clinical observation as described below is used.

Clinical Assessment

This requires a good clinical examination. Table 5.9 elaborates this.

Ongoing Losses

In pediatric surgical practice, this constitutes an important component of the fluid calculations. The following table (Table 5.10) would give an idea about the losses and this needs to kept in mind during the calculation.

Role of ECF and ICF

Na⁺ deficit is the amount of Na⁺ that was lost from the Na⁺ containing ECF compartment during the dehydration period. Na⁺ deficit (mEq) = fluid deficit (L) × proportion from ECF × Na⁺ concentration (mEq/L) in ECF. (Intracellular Na⁺ is negligible as a proportion of total; therefore, it can be disregarded).

K⁺ deficit is the amount of K⁺ that was lost from the K⁺ containing ICF compartment during the dehydration period. K⁺ deficit (mEq) = fluid deficit (L) × proportion from ICF × K⁺ concentration (mEq/L) in ICF. (Extracellular K⁺ is negligible as a proportion of total; therefore it can be disregarded).

Role of Distribution Factor

Electrolyte deficits (in excess of ECF/ICF electrolyte losses).

mEq required = (CD – CP) × fd × wt

where, CD = concentration desired (mEq/L), CP = concentration present (mEq/L), Fd = distribution factor as fraction of body weight (L/kg).

The FD of HCO₃ is 0.4 - 0.5, Cl⁻ is 0.2 - 0.3 and Na⁺ × 0.6 - 0.7.

WHAT FLUID TO GIVE?

Fluids are classified into:
1. Electrolytes such as NaCl, KCl, NaHCO₃, CaCl₂.

2. Non-electrolytes like glucose, fructose, and mannitol.

Electrolytes are solutions which contain electrically charged particles and they are always in electroneutrality. The positively charged ions (Ca\(^+\) ions) are equivalent to the negatively charged ions (anions). For example, 0.9% NaCl has Na: 154 mEq/L and Cl: 154 mEq/L. Blood is an electrolyte and its major biochemical parameters pertinent to this chapter are tabulated in Table 5.2.

Chemical substances can also be expressed as millimoles. A mole is atomic weight in grams. A millimole is one thousandth of a mole. In a monovalent ion like sodium one millimole is equivalent to one milli equivalent. In a divalent ion like calcium one millimole is equivalent to 2 milli equivalents.

In the SI system of units the concentration of substances of known and exact composition will be expressed as moles/liter whereas substances of ill defined composition such as protein will continue to be expressed by weight in milligrams/liter (Table 5.11).

### Tonicity of Solutions

A solution is described as isotonic or iso-osmotic if it has the same tonicity or osmolality of the blood. For example, 0.9% NaCl is isotonic with blood. However, it is not physiological since it contains more chloride than the blood.

</table>

There is a balance of chlorides and bicarbonates in the blood. If the chloride level goes up as in Hyperchloremic acidosis, the bicarbonate level comes down. Hence administration of large amounts of 0.9 NaCl to patients who lose more chlorides than sodium in diarrhea develop hyperchloremic acidosis. Ringer’s lactate solution on the other hand is physiological. The chloride content is only 102 mEq/L and bicarbonates are formed from metabolization of lactate ions.

The composition of various well known fluids is shown in Table 5.12.

It is preferable to use acetate salt than lactate as acetate ions are metabolized at the peripheral tissues and muscles. They require less oxygen for metabolism into CO\(_2\) and bicarbonate ions. This is important especially if shock is present. In Ringer’s lactate a part of the lactate is converted into glycogen by the liver hence the available bicarbonate is less. Ringer’s Lactate is superior to isotonic saline and acetated ringer is preferable to lactated ringers solution. In shock 0.9% normal saline mixed with sodabicarbonate can also be used. Multiple electrolyte solutions are now available in the market like Isolyte P. (Pediatric maintenance) Isolyte M, Isolyte G and Isolyte R. It is necessary to make sure what they contain. Salient features of these are noted below.\(^{13-16}\)

Isolyte M (half isotonic): Contains Na 40 mEq/l, K 35 mEq/l. It is a potassium rich solution. Isolyte P is one-third isotonic and sodium poor solution. It contains 26 mEq of Na per liter of solution. Normal saline, 0.9% NaCl, has more chlorides than chlorides in the blood.

### Ringer’s Lactate (Isotonic)

Lactate has to be metabolized to bicarbonate, it has low potassium. Unless specified it does not contain any sugar-glucose.

### Isolyte G

Gastric replacement solution has an acidifying solution containing ammonium chloride as the acidifying salt. NH\(_4\)Cl is contraindicated in patients with cirrhosis liver or any liver dysfunction, azotemia, congestive cardiac failure. It can precipitate metabolic acidosis if given in large amounts. Most often Isolyte G is given for metabolic alkalosis which can be treated better by sodium chloride and potassium chloride solutions.
In actual practice Isolyte G is used as the gastric replacement fluid when the gastric aspirate is bile stained. Bile is an alkaline solution and isolyte G which is an acid solution should not be used as the replacement solution.

**Potassium Containing Solutions**

The commercially available ampoules are 15% KCl. It is highly concentrated solution and unless it is adequately diluted it can kill the patient. Each ml provides 2 mEq of K and 2 mEq of chloride. 2 ml of the above solution diluted with 100 ml of dextrose or normal saline will give a concentration of 40 mEq/liter and is the safe limit. At no time the concentration of the K in the solution should exceed 80 mEq/liter (40 ml of 15% KCl in 1000 ml) but even this concentration has to be given under strict monitoring of the vital functions. The safe limit is 40 mEq/liter (20 ml of 15% KCl in 1000 ml of fluid). The isolyte M gives 40 mEq/liter of K and is one of the potassium rich solutions available in the market within the safe limits of administration. The basic rule is even in severe hypokalemia, not more than 20 mEq of K should be given in an hour.

**Alkaline Solutions**

Sodium bicarbonate is available in the market as a hypertonic solution. It is available as 7.5% solution and should be used adequately diluted. One-sixth molar (isotonic) sodium lactate can be used instead of bicarbonate if there is no fluid restriction in the administration of fluids. However, the lactate has to be metabolized into bicarbonate in the liver and hence cannot be used in liver dysfunction or in shock, since the metabolism of the lactic acid is impaired. THAM (Tromethamine) has been used in metabolic acidosis. It is an amino alcohol and has side effects if large amounts are used. It can produce severe hypoglycemia, hyperkalemia and is not available in India.

Amongst the volume expanders that are available pooled plasma is a good physiological expander. However, it carries the risk of hepatitis unless it is stored at 34°C for six months. Plasmonate contains human plasma protein fraction and heat treated to destroy the hepatitis virus. Patients with low serum albumin level can be treated with albumin containing solutions which are salt free. Dextrose 5% in water if used as volume expander, it will be distributed evenly in all ICF and ECF. Three liters of 5% dextrose will be needed to expand the ECF by one liter. One liter of

isotonic saline will expand the ECF by one liter. But because of their relative size one liter of isotonic saline will expand the plasma volume by one quarter of liter. Plasma, whole blood or plasma expanders—all these will expand the plasma volume by one liter. Albumin is also a plasma expander but diffuses into interstitial fluid in clinical practice.

**PREOPERATIVE FLUID NEEDS**

During surgery, isotonic fluids are the most preferred and recommended fluids. For minor procedures 6 ml/kg/h, for moderate procedures, 8 ml/kg/h and for major procedures 10-15 ml/kg/h is the fluid recommended.17

**HOW TO GIVE FLUIDS?**

This is very important in fluid administration of neonates or when the fluid used is diluents to give certain drugs like dopamine. One conventional drop is equivalent to 4 micro drops. Algorithm for dehydration correction is shown below (Fig. 5.2).

**ACID-BASE DISTURBANCES**

**Introduction**

An acid is a hydrogen ion donor where as a base is hydrogen ion acceptor. The strength of an acid depends on the concentration of hydrogen ions and the degree with which it dissociates. The hydrogen ion power is expressed as pH (Puissance hydrogen).
Blood pH

Normal range of plasma pH is 7.36 - 7.44. The extreme range of pH compatible with life is 6.7 - 7.9. It is acidosis if the pH is below 7.36 and it is alkalosis if the pH is above 7.44.

**pH Calculation**

\[
\text{pH} = \left[ 6.1 + \log (\text{HCO}_3^-) \right] \text{ divided by } \left[ \text{H}_2\text{CO}_3 + \text{CO}_2 \right]
\]

This can be rewritten by stating that the pH is equivalent to the bicarbonate–carbonic acid ratio. Relationship of pH and hydrogen ion concentration expressed as nanomole. Since hydrogen ion concentration in the plasma is very small it is measured in terms of nano equivalents (or nanomole). The following table gives the values of Hydrogen ion concentrations at different pH (Table 5.13). It will be observed from the Table that the hydrogen ion concentration is 40 nanomole at 7.4 pH of the blood. But it increases two fold when the pH is 7.1 (80 nanomole). But similar increase in pH-7.7 does not reduce the hydrogen ion. It is obvious that the changes in hydrogen ion concentration are profound in acidosis.\(^{18,19}\)

**Chemical and Physiological Regulation of the pH of Body**

The following mechanisms regulate the acid base balance:

1. Chemical buffers (immediate).
2. Respiratory buffers (slow).
3. Renal buffers (slowest).

Chemical buffers react with strong acids and bases formed within the body or which enter the body. The three buffers are:

1. Bicarbonate carbonic acid system.
2. The phosphate buffer system.
3. Protein and hemoglobin buffer system.

The respiratory buffer system deals primarily with the carbon dioxide elimination and regulation which in turn determines the blood carbonic acid. The partial pressure of the CO2 is one of important parameters in acid base status of the individual. The kidneys are the most important buffering mechanism and not only compensate the buffering deficiencies in the chemical and respiratory system but it also eliminates certain acids that cannot be buffered by other systems like sulphuric and phosphoric acids produced by the protein catabolism.

**Base Excess**

This represents the amount of strong base or acid per liter of blood which has been added as a result of metabolic disturbances. This describes the presence of an excess base or a deficit of base. Positive values indicate an excess of base negative values indicate a deficit of base. The normal value for base excess is 0 (+2.5 to –2.5) mEq/L.

**Standard Bicarbonate**

Standard bicarbonate represents the concentration in plasma of blood which has been equilibrated at PCO2 of 40 mm of Hg with oxygen to saturate the hemoglobin. The normal values of standard bicarbonate is 24 mEq/l. If actual bicarbonate is higher than standard bicarbonate it will indicates respiratory acidosis. If actual bicarbonate is lower than standard bicarbonate it will indicate respiratory alkalosis.

**Disturbances in Acid-Base Balance**

1. Respiratory acidosis (that is, ventilatory failure). The drop in pH is explained by the change in PaCO2.
2. Respiratory alkalosis (that is, alveolar hyperventilation)—the decreased PaCO2 explains the increased pH.
3. Metabolic acidosis: Reduced pH not explained by increased PaCO2. It is usually associated with an increased anion gap due to the accumulation of renal acids, lactic acids, and ketoacids (from diabetes or starvation).
4. Metabolic alkalosis: Raised pH out of proportion to changes in PaCO2. It is associated with hypokalemia, volume contraction, or exogenous alkali administration.
Relation between pH and PaCO₂

Acute changes in PaCO₂ result in predictable changes in pH (the negative log of hydrogen ion concentration) and plasma carbonic acid. This represents the respiratory acid base change. Although the relation is not completely linear, within clinically relevant ranges it is sufficiently linear to allow the following guideline to estimate the degrees of abnormality resulting from acute changes in PaCO₂:

- For every increase in PaCO₂ of 20 mm Hg (2.6 kPa) above normal the pH falls by 0.1.
- For every decrease of PaCO₂ of 10 mm Hg (1.3 kPa) below normal the pH rises by 0.1. Any change in pH outside these parameters is therefore, metabolic in origin.

Anion Gap Concept

Cells exist in a state of electroneutrality with major and minor cations balanced by similar anions. The anion gap is an artificial disparity between the concentrations of the major plasma cations and anions routinely measured—normally sodium, chloride, and bicarbonate. The anion gap is calculated as Na⁺-(Cl⁻ + HCO₃⁻).

The anion gap is normally 8-16 mmol/l, of which 11 mmol/l is typically due to albumin. A decreased anion gap is usually caused by hypoalbuminemia or severe hemodilution. Less commonly, it occurs as a result of an increase in minor cation concentrations such as in hypercalcemia or hypermagnesemia. Increased anion gap acidosis is caused by dehydration and by any process that increases the concentrations of the minor anions, lactate, ketones, and renal acids, along with treatment with drugs given as organic salts such as penicillin, salicylates, and with methanol and ethylene glycol. Rarely an increased anion gap may result from decreased minor cation concentrations such as calcium and magnesium. Metabolic acidosis without an increased anion gap is typically associated with an increase in plasma chloride concentrations; chloride ions replace plasma bicarbonate. Hyperchloremic acidosis is usually caused by gastrointestinal loss or renal wasting of bicarbonate.

Definitions

Serum Osmolality

Number of particles per liter. Can be calculated as follows:

\[ 2 \times [Na^+] + \text{glucose (mg/dL)/18} + \text{BUN (mg/dL)/2.8} \]

Normal range: 275-295 mOsm/L.

Serum Osmolar Gap

Calculated serum osmolality - laboratory measured osmolality.

May be elevated in some anion gap acidosis, but a markedly elevated osmolar gap in the setting of an anion gap acidosis is highly suggestive of acute methanol or ethylene glycol intoxication.

Anion gap (AG)

Represents anions other than bicarbonate and chloride required to balance the positive charge of Na⁺, K⁺ is considered negligible in AG calculations. Clinically, it is calculated as follows:

\[ AG = Na^+ - (Cl^- + HCO_3^-) \]

(Normal: 12 mEq/L ± 2 mEq/L)

Rules for Determining Primary Acid-Base Disorders

1. Determine the pH: The body does not fully compensate for primary acid-base disorders; therefore, the primary disturbance will shift the pH away from 7.40. Examine the pCO₂ and HCO₃ to determine whether the primary disturbance is a metabolic acidosis/alkalosis or respiratory acidosis/alkalosis.

2. Calculate the anion gap: if the anion gap is > 20 mmol/L, there is a primary metabolic acidosis regardless of pH or serum bicarbonate concentration (The body does not generate a large anion gap to compensate for a primary disorder).

3. Calculate the excess anion Gap (i.e. "ΔGap" or "Gap-Gap"):

\[ Δ\text{Gap} = [\text{calculated anion gap} - \text{normal anion gap (i.e., 12 mmol/L)]} + \text{measured HCO}_3^- \]

If the ΔGap is greater than a normal serum bicarbonate concentration (>30 mmol/L), there is an underlying metabolic alkalosis.

If the ΔGap is less than a normal bicarbonate concentration (< 23 mmol/L), there is an underlying nonunion gap metabolic acidosis (1 mmol of unmeasured acid titrates 1 mmol of bicarbonate)

\[ (+Δ \text{anion gap} = -Δ \text{[HCO}_3^-]) \]

All this is summarized in the Flow chart (Fig. 5.3.)
Fig. 5.3: Flow chart for determination of primary acid-base disorders

- **Determine the pH**
  - pH < 7.40
  - pH ≥ 7.40

- **Acidosis**
  - $\text{HCO}_3^- < 22$  
  - $\text{PCO}_2 > 45$

- **Metabolic acidosis**

- **Respiratory acidosis**
  - Impaired lung motion: hemothorax, pneumothorax
  - Acute airway obstruction
  - Upper airway, laryngospasm, bronchospasm
  - Severe pneumonia or pulmonary edema
  - Thoracic cage injury: flail chest
  - Ventilator dysfunction
  - Central hypoventilation
  - COPD
  - Chronic lung disease, BPD
  - CNS depression: Drugs, CNS event

- **Metabolic acidosis**
  - Increased acid production (noncarboxylic acid)
  - l-Hydroxybutyric acid and acetoacetic acid production.
  - Insulin deficiency (diabetic ketoacidosis)
  - Starvation or fasting
  - Increased lactic acid production
  - Inborn errors of metabolism (i.e., carbohydrates, urea, cycle, amino acids, organic acids)
  - Tissue hypoxia
  - Sepsis
  - Exercise
  - Ethanol ingestion
  - Methanol ingestion
  - Ethylene glycol ingestion
  - Paraldehyde intoxication
  - Systemic diseases (e.g., leukemia, diabetes mellitus, cirrhosis, pancreatitis)
  - Increased short-chain fatty acids (acetate, propionate, butyrate, d-lactate) from colonic fermentation
  - Viral gastroenteritis
  - Other causes of carbohydrate malabsorption
  - Drugs
  - Salicylates intoxication
  - NSAID intoxication
  - Increased sulfuric acid
  - Decreased acid excretion
  - Acute and chronic renal failure

- **Respiratory alkalosis**
  - Mechanical ventilation
  - Seizures
  - Anxiety
  - Hypoxia
  - Lung disease with or without hypoxia
  - CNS disease
  - Drug use: salicylates, catecholamines, progesterone
  - Pregnancy
  - Hepatic encephalopathy

- **Alkalosis**
  - $\text{CO}_2 < 35$
  - $\text{HCO}_3^- > 26$

- **Metabolic alkalosis**
  - (Measure urine chloride levels)
  - Volume contraction with H+ loss
    - Low urinary chloride
    - Vomiting
    - Gastric suction
    - Pseudourea therapy
    - Positively ill patients

- **Increased urinary H+ excretion**
  - (Normal or high urinary chloride)
  - Excess mineralocorticoid activity
  - Cushing’s syndrome
  - Conn’s syndrome
  - Lactate ingestion
  - Increased rennin states
  - Current diuretic usage
  - Excess alkali administration
  - Refeeding alkalosis
  - Exogenous steroids

**Anion gap metabolic acidosis**

- Increased acid production (noncarboxylic acid)
- l-Hydroxybutyric acid and acetoacetic acid production.
- Insulin deficiency (diabetic ketoacidosis)
- Starvation or fasting
- Increased lactic acid production
- Inborn errors of metabolism (i.e., carbohydrates, urea, cycle, amino acids, organic acids)
- Tissue hypoxia
- Sepsis
- Exercise
- Ethanol ingestion
- Methanol ingestion
- Ethylene glycol ingestion
- Paraldehyde intoxication
- Systemic diseases (e.g., leukemia, diabetes mellitus, cirrhosis, pancreatitis)
- Increased short-chain fatty acids (acetate, propionate, butyrate, d-lactate) from colonic fermentation
- Viral gastroenteritis
- Other causes of carbohydrate malabsorption
- Drugs
- Salicylates intoxication
- NSAID intoxication
- Increased sulfuric acid
- Decreased acid excretion
- Acute and chronic renal failure

**Nonunion gap metabolic acidosis**

- Gastrointestinal loss of bicarbonate
- Ureteral sigmoidostomy or ileal loop conduit
- Diarrhea (secretory)
- Fistula or drainage of the small bowel or pancreas
- Surgery for necrotizing enterocolitis
- Ileal ileal pouch
- Use of anion exchange resins in presence of renal impairment
- Renal bicarbonate loss
- Carbonic anhydrase inhibitors (Diamox)
- Renal tubular acidosis, especially type II
- Early renal failure
- Aldosterone inhibitors
- Other causes
  - Administration of HCl, NH₃, Cl, arginine, or lysine hydrochloride
  - Hyper-alimentation

Shock in Children—Surgeon’s Perspective

The clinical syndrome of shock is one of the most life threatening problems faced by the treating doctor in the critical care unit. Shock is an acute complex state of circulatory dysfunction that results due to the discrepancy in oxygen need and supply. The metabolic demands of body are not met leading to multiple organ failure and death. Although untreated shock carries a very high mortality, yet with early diagnosis and prompt management, the mortality is considerably reduced.

PATHOPHYSIOLOGY

Normal circulatory function is maintained by the complex interplay between cardiac output and systemic vascular resistance. Cardiac output is the most important determinant of tissue perfusion. Delivery of oxygen to tissue (DO₂) is a direct function of cardiac output and arterial oxygen content CaO₂₁.

\[ \text{DO}_2 = \text{CO} \times \text{CaO}_2 \]

Where \( \text{CO} = \text{HR} \times \text{SV} \) (HR-heart rate, SV-stroke volume)

\[ \text{CaO}_2 = (\text{Hgb} \times 1.39 \times \text{SaO}_2) + (0.003 \times \text{PaO}_2) \]

Thus inadequate oxygen delivery can result from either limitation or misdistribution of blood flow or due to increased oxygen demand (fever, sepsis etc). When oxygen delivery fails to meet cellular oxygen demands, patient goes in a state of shock and various compensatory mechanisms are activated. There are three phases of shock, namely:

a. Compensated
b. Uncompensated
c. Irreversible.

Compensated Shock

In compensated shock, vital organ function is maintained by various intrinsic hemostatic mechanisms. Hence, blood pressure, cardiac function and urine output may appear to be normal. Thus, early stages of all types of shock may be difficult to identify and requires a high index of clinical suspicion.

The compensatory mechanisms aim to increase the intravascular volume and blood pressure. Various compensatory mechanisms are triggered by the baroreceptors, chemoreceptors and by renin angiotensin system (RAS).

Baroreceptors

Stretch receptors are located in the atria and in the carotids. The carotid sinuses, aortic arch receptors, receptors in the walls of right and left atria (at the entrance of the superior and inferior venae cava) and in the pulmonary circulation, monitor the arterial circulation. They are stimulated by distension of these structures in which they are located and so they discharge at increased rate when the pressure in these structures rises. Their afferent fibers pass via the glosopharyngeal and vagus nerves to the medulla. Most of them end in the nucleus of the tractus solitarius (NTS), and the excitatory transmitter they secrete is probably glutamate.² Impulses generated by stimulation of baroreceptors excite the vagal innervation of the heart, producing vasodilatation, bradycardia and decrease in cardiac output. Hypotension causes decreased in stretching of these receptors leading to diminished firing of impulses which results in increased sympathetic activity and decreased vagal discharge of heart.
Increased sympathetic discharge causes increased cardiac contractility and vasoconstriction starting from small venules, veins and progressing to arterioles of skin, subcutaneous fat, muscle, splanchnic vessels and kidney. The vessels last to be affected are those of heart and brain.

Chemoreceptors

Chemoreceptors are located in the carotid and aortic bodies. Afferents from the chemoreceptors exert their main effect on respiration, but they also have affect on vasomotor area. Shock leads to tissue anoxia due to inadequate local perfusion, thereby stimulating the chemoreceptors. The cardiovascular response to chemoreceptor stimulation consists of peripheral vasoconstriction.

Renin Angiotensin Aldosterone System (RAAS)

Renal hypoperfusion, in shock leads to stimulation of renin angiotensin aldosterone system (RAAS), as shown in Figure 6.1.

Decompensated Shock

If these early compensatory mechanisms are not enough, shock progresses on to a decompensated state. In uncompensated shock the effects of cellular ischemia with associated release of vasoactive and inflammatory mediators begins to affect the microcirculation and the child shows sign of brain, kidney and cardiovascular compromise.

Irreversible Shock

Terminal or irreversible shock implies damage to the vital organs of such magnitude has occurred, that death occurs even if therapy returns cardiovascular measurement to normal levels.

PATHOGENESIS AND MULTISYSTEM EFFECT OF SHOCK

Shock is a multisystem disease. Initially the body tries to compensate it by various mechanisms as mentioned earlier. If, however, intravascular volume loss, surpasses the body's compensatory mechanisms, then decompensation appears with profound ischemia and anaerobic metabolism.

Due to anaerobic metabolism and hypoxia the capillary endothelium gets damaged with exudation of proteins and fluids from circulation. This not only worsens the state of hypovolemia but also stimulate microcirculatory dysfunction, release of biochemical and vasoactive mediators, leading to multiple organ failure and death.3 Mortality in shock has been related to multiple organ system involvement. Lung, kidney, GIT and heart are the most common organs to be involved initially. If one system is involved mortality is 30-50%, with 2 system involvement it increases to 50-60%, with 3 systems involvement it rises further to 60-80% and with 4 or > systems more than four involvement, mortality is 100%.4

Microcirculatory dysfunction is common to all type of shock. It is characterized by maldistribution of capillary blood flow, altered capillary permeability and mechanical obstruction of capillary beds with cellular debris (aggregation of platelets and granulocytes). Anaerobic metabolism in shock leads to accumulation of lactic acid. The resultant metabolic acidosis causes efflux of intracellular potassium into ECF (leading to hyperkalemia) and an influx of sodium and calcium with an obligate influx of water into the cells. This cellular swelling further potentiates the cellular dysfunction.
Biochemical Mediators in Shock

Biochemical mediators play an important role in the development and continuation of all types of shock. These vasoactive mediators are usually endogenous (host derived), primarily from cells of nervous and hemopoetic system. In septic shock these mediators are released in response to exposure to microbial products (e.g. endotoxin) and play a primary role in initiating shock. In hypovolemic and cardiogenic shock, they are released secondarily in response to ischemic cellular injury.

These biochemical mediators are vasoactive and exert their effect by induction of severe vasoconstriction and vasospasm, induction of platelet aggregation, increased capillary permeability and thrombus formation, as shown in Table 6.1.

Inflammatory Mediators in Shock

Endogenous inflammatory mediators are the major culprits in the pathogenesis of septic shock. The most potent stimulus for the activation of the inflammatory cascade is the outer cell membrane of gram-negative bacteria, lipopolysaccharide antigen also called endotoxin. Once in blood stream the LPS, attaches to a plasma protein called LPS binding protein (LBP). This complex LPS-LPB binds to CD14 receptors on the surface of monocytes/macrophages which leads to stimulation of tumor necrosis factor (TNF) and interleukin 1 (IL-1). TNF is capable of inducing a broad range of vasoactive and inflammatory mediators. Treatment of shock with anti-TNF antibodies has been attempted with mixed results. The various inflammatory mediators in shock are as described in Table 6.2.

Nitric Oxide

Literature reports increased level of nitric oxide in circulatory shock. After exposure to TNF and IL1 variety of cells like macrophages, vascular endothelium, vascular smooth muscle, hepatocyte and cardiac myocytes are induced to produce increased nitric oxide. Nitric oxide causes vasodilatation, vascular hyporesponsiveness and hypotension. Trials are ongoing to determine whether drugs that inhibit nitric oxide production may be helpful in controlling shock.

Complement Activation

Tumor necrosis factor (TNF) and bacterial antigens activate the complement system. Vasoactive affects are seen with C3 and C5 fragments which promote the release of histamine and other vasoactive mediators, producing vasodilatation, increased capillary permeability and platelet aggregation leading to blockage of capillaries.

Myocardial Depressant Factor

All types of shock are accompanied with myocardial dysfunction of varying severities. Investigations have revealed that a small peptide called myocardial depressant factor (MDF) is released by the pancreas when they are ischemic and hypoperfused. MDF acts directly on myocardial tissue causing a negative inotropic effect.

SYSTEMIC EFFECT OF SHOCK

Shock, if uncorrected can affect almost all the systems of body like respiratory, renal, hepatic, gastrointestinal, cardiac, CNS and endocrinal.

Respiratory: Respiratory failure is a frequent complication of shock. It may be due to dysfunction of alveolar endothelial interface (ARDS) or due to respiratory muscle fatigue. Management options include increasing the inspired oxygen and positive pressure ventilation in selected cases.

Renal: Shock syndromes may be associated with renal failure. The shock related renal failure syndromes are usually due to pre-renal causes. Acute tubular necrosis can however, result if the ischemic results are continued for too long. Renal failures associated with shock are mostly oliguric, but, one should remember that high output renal failure can also occur in these patients.

Renal support for these patients consists of volume augmentation, diuretics (e.g. frusemide, mannitol) and low dose dopamine (3-5 μg/kg/min).

Hepatic and gastrointestinal tract: Prolonged hypoperfusion and stress in shock can lead to hepatic dysfunction, GIT bleeding, ileus and bacterial translocation. It is usually recommended that patients with shock should receive prophylactic H2-receptors blockers in order to prevent stress ulcers.

Another devastating condition which can occur in shock syndrome is acute nonocclusive mesenteric ischemia. This is characterized by prolonged splanchnic vasoconstriction, intestinal mucosal hypoxia, acidosis, mesenteric ischemia, transmural necrosis of bowel, bacterial translocation, sepsis and eventually multisystem organ dysfunction. Prevention of gut ischemia is advocated to prevent bacterial translocation.

Cardiac: Myocardial dysfunction, both due to hypoxia, hypovolemia and myocardial depressant factor is known to occur in all shock syndromes.

Coagulation abnormalities: Disseminated intravascular coagulation (DIC) can occur to various extents in all forms of shock. DIC is usually secondary to intravascular thrombosis which is induced in response to activation of TNF and platelet aggregation factor. Replacement therapy specifically for various absent clotting factors, vitamin K, fresh frozen plasma, and cryoprecipitate and platelet transfusion are some of the advisable management options for these patients.

Endocrine: Multiple endocrine problems may arise and complicate the management of shock in children like problems with fluid electrolyte, mineral balance and calcium homeostasis.
CNS: Shock if prolonged for too long can lead to cerebral anoxia, altered sensorium and mental obtundation.

CLASSIFICATION OF SHOCK

For purpose of description, shock can be classified into following four major categories.

a. Hypovolemic Shock

<table>
<thead>
<tr>
<th>Hemorrhagic</th>
<th>Non-hemorrhagic</th>

<td>Diabetes insipidus</td>
</tr>
</tbody>
</table>

b. Septic shock

c. Distributive shock

e.g. Anaphylaxis
Neurogenic shock
Drug toxicity

d. Cardiogenic shock

Cardiac insufficiency

e.g. Myocarditis
Cardiomyopathy, dysrhythmias
Metabolic: hypoxia, hypoglycemia
Congenital heart disease
Drug intoxication, e.g. anthracycline
β-blocker, tricyclic antidepressant
Cardiac surgery

Obstructive lesions

e.g. Pericardial tamponade
Tension pneumothorax
Pulmonary embolism,
Aortic stenosis
Pneumopericardium
Critical pulmonary stenosis

Various Types of Shock can be Remembered by the Mnemonic as follows:4

S - Sepsis
H - Hypovolemia (intrinsic/extrinsic, hemorrhagic/nonhemorrhagic)
O - Obstructive (e.g. cardiac tamponade, tension pneumothorax, massive pulmonary embolism)
C - Cardiogenic (primary pump failure)
K - Kinetic/distributive.

Diagnosis and Monitoring of Shock

Early diagnosis of shock requires a high index of suspicion. Identification of a full blown case of shock with hypotension, cold extremities and poor peripheral perfusion are usually suggestive of a decompensated shock.

Clinical assessment usually begins with a proper history taking. History of excessive fluid loss because of trauma, diarrhea, vomiting, burns etc is suggestive of hypovolemic shock. It is important to elicit details of environmental exposure, previous medical problems, allergies and potential drug ingestion. Septic shock is suspected in a child with history of fever, features suggestive of infection and circulatory collapse. Previous history of disorders such as congenital heart disease offers clue to the etiology.

On clinical examination features of decreased perfusion are assessed. Decreased perfusion affects the temperature, capillary filling time and vital organ function. Cold extremities with peripheral core temperature of > 2 °C indicates decreased perfusion to skin.

Impaired capillary filling time is a more sensitive indicator of poor peripheral tissue perfusion. The refill is determined by blanching an area over face, sternum, and forehead by firm compression with finger tip for > 5 seconds, and then noting the time for the blanching to disappear. Normally it should be < 3 sec, if it is > 5 seconds, it is a nonspecific indicator of tissue hypoperfusion.

Hypoperfusion of vital organs may manifest as oliguria (renal hypoperfusion) or altered sensorium (CNS hypoperfusion). Urine output measurement is one of the most important indicator for shock. In children urine output of < 1 ml/kg/hr is considered as oliguria.

Most significant physical findings in shock result from autonomic response to stress. It must be emphasized that "hypotension is not the sine qua non of shock". BP may be recorded as normal in early phases of shock. A rough estimate of minimal acceptable systolic BP in children is: systolic BP (mm Hg) = 70 + [age (yrs) × 2]. Hypotension, if present,
strongly supports the diagnosis of shock. Initially the pulse pressure is decreased, later both systolic and diastolic pressure fall.

In children, tachycardia occurs early and is the sole determinant of cardiac output. Respiratory rate may also be increased in shock due to metabolic acidosis (Kussmaul’s respiration). However, one should remember that respiratory rates and heart rate vary considerably with age as shown in Table 6.3.

It has to be emphasized that acute volume deficiency of us little as 10% may cause tachycardia while a gradual loss of 10-15% of volume produces minimal changes. However, hypotension may not occur until there is volume loss of 30% or more. Hemodynamic variables in different shock status are as shown in Table 6.4.

MONITORING THE PATIENT OF SHOCK

All children with shock are best managed in a pediatric intensive care unit (PICU). The aim of monitoring is to detect the alternation, in the physiological status and to assess the response of intervention.

It is noteworthy, that clinical monitoring is most crucial in the management of shock. It is probably, the most sensitive and effective monitoring technique. Clinical monitoring must include repeated and careful examination of the following parameters:
1. Color-pink/dusky/blue
2. Temperature – skin, core
3. Pulse rate
4. Respiratory rate
5. Capillary filling time
6. Blood pressure
7. Level of consciousness
8. Urine output (intake-output changes) (one should aim for urine output of >1-2 ml/kg/hr.

Based on these clinical parameters, shock can be categorized in compensated, decompensated and irreversible shock as shown in Table 6.5.

INVASIVE MONITORING

This is also sometimes required in management of shock. It includes the following:

a. CVP measurement (central venous pressure monitoring).
b. PCWP measurement (pulmonary capillary wedge pressure monitoring).
c. Arterial blood gas analysis.

CVP Measurement

The role of CVP monitoring in management of shock in basically in patients with myocardial compromise or renal failure, in order to avoid volume overload. In
pure hypovolemic shock it is unlikely that CVP measurement may add anything significant to careful evaluation of peripheral perfusion, BP, HR and urine output. CVP monitoring also helps the surgeon to differentiate between hypovolemic and septic shock.

CVP catheter can be placed via the external or internal jugular, femoral, basilic or subclavian vein. Before using CVP measurement, it is essential to confirm the position of the tip of catheter in the right atrium. Normal CVP is described as > 10 mm Hg (5-8 mm Hg) and it reflects intravascular volume, right ventricular contractibility and right ventricular pressure. CVP should not be taken as a guide of left ventricular function. Poor correlation has been reported between CVP and pulmonary artery occlusion pressure. Reported complication of internal jugular or subclavian vein catheterization include bleeding, pneumothorax, hemothorax, chylothorax, pericardial tamponade, in advent arterial puncture, dysrhythmias, sepsis and thrombosis. Complications of indwelling catheter occur in approximately in 5% of children mostly < 5 year of age. Line sepsis is reported as 1.4 septic episodes per 100 catheterization. Line patency can be prolonged with continuous infusion of a solution containing 0.25-1U/ml of heparin.

### Arterial Blood Gas Analysis

Arterial blood gases should be frequently monitored in patients with shock. It helps in determining the adequacy of ventilation and also about tissue perfusion. In shock patients usually have metabolic acidosis (lactate acidosis) with increased anion gap. The best treatment for such patient is restoration of intravascular volume.

### Therapeutic Approach

Management of shock irrespective of the causes is aimed at optimizing the vital organ perfusion and in correcting the metabolic abnormalities due to tissue hypoperfusion. However, for proper treatment of shock, determining the etiology and management of the underlying cause is mandatory. Certain therapies are however common to all the forms of shock. They are as follows:

a. **Correction of hypoxemia:** All patients with shock should receive supplemental oxygen. Endotracheal intubation and mechanical ventilation is, however, not, needed in all cases of shock. This is only indicated under following circumstances:

   i. Patients with non-cardiac pulmonary edema (ARDS).
   ii. Respiratory fatigue (decreased respiratory muscle function).
   iii. Children with cardiogenic shock and pulmonary edema.

   Intubation and intermittent positive pressure ventilation aids myocardial function by improving pulmonary compliance, decreasing intrapulmonary shunting and by decreasing after load.

### Pulmonary Artery Swan-Ganz Catheter

Pulmonary artery catheters are required in the management of cardiogenic shock and in cases of refractory shock resistant to usual forms of treatment. Swan-Ganz catheters are currently used for pulmonary artery catheterization. They have a proximal side hole to monitor right aerial pressure, a thermostar to estimate cardiac output by thermodilution, as well as an end hole to measure pulmonary artery pressure. When the balloon is inflated the pulmonary artery wedge pressure (PAWP) which is as reflection of left atrial pressure can also be recorded.

Insertion of such catheter is usually done either from the left subclavian or right internal jugular vein, using the Seldinger’s technique. Normal PAWL is 2-8 mm Hg. Reported complications with these catheters are minimal in children.
b. **Fluid therapy:** In all patients of shock intravenous access should be established at the earliest. Initially percutaneous peripheral IV cannulation should be tried. In case of failure, central veins like femoral, saphenous or internal jugular should be tried. If such attempts are unsuccessful the intraosseous route should be resorted to without wasting time for performing cut down. If unfortunately the child sustains a cardiopulmonary arrest before establishment of IV access then resuscitative drugs like epinephrine and atropine can be given via endotracheal tube. In children less than 5 years old, needle placement into the marrow space of the medial portion of proximal tibia, angulated away from the growth plate and 1-2 inches below the tibial tuberosity, is indicated. In older children, needle placement 1-2 inches above the medial marrow is indicated. Veiasoo et al found that intraosseous route is helpful in resuscitation of hypovolemic shock. Intravenous fluids, blood products, bicarbonates are among the other drugs that can be given using this technique. He also showed that efficacy of intraosseous route is comparable to central and peripheral intravenous routes.

Initial fluid for all types of shock is crystalloid, i.e. Ringer’s lactate or normal saline. Subsequently, depending on the cause of shock fluid can be changed as described later, e.g. in dehydration crystalloid is continued, in sepsis or trauma blood products or colloids are given judiciously. Initial bolus of crystalloid in shock is 20 ml/kg over 6-10 min. On reassessment if peripheral perfusion and BP improves and the patient passes urine, maintenance fluids should be continued. If, however, patients fails to pass urine or hypotension persist then a repeat bolus of 20 ml/kg of crystalloid is given. If anuria still persists, another bolus of 20 ml/kg is advisable before further interventions. Thus, it is apparent that upto 60 ml/kg of fluid can be administered while managing patients with shock, hypotension and anuria. Beyond this, CVP monitoring should be instituted and cardiac status should be evaluated before giving further fluid therapy as mentioned later. Further treatment of shock is specific to the type of shock and is mentioned with them.

---

**HYPOVOLEMIC SHOCK**

Hypovolemic shock is the most common cause of shock in infants and children. There is decrease in intravascular blood volume, leading to a decrease in preload, thereby causing fall in stroke volume and cardiac output. Various etiological factors leading to hypovolemic shock are mentioned earlier in the classification of shock.

Acute loss of 10-15% of the circulatory blood volume may be well tolerated in healthy children. Based on the amount of blood volume loss hypovolemic shock can be classified into three classes as shown in Table 6.6. Class I shock or early hypovolemic shock are characterized by normal BP and normal heart rate. With continued loss of blood volume as in class II and III shock, fluid loss surpasses body’s compensatory abilities and signs of circulatory and organ dysfunctions appears.

**Therapy of Hypovolemic Shock**

Initial treatment of hypovolemic shock is similar regardless to etiology and includes establishment of adequate oxygenation, ventilation and restoration of circulatory blood volume as mentioned earlier. Initial volume resuscitation is with crystalloids (Ringer’s lactate or 0.9% sodium chloride) as shown in Figure 6.2.

**Use of Colloids in Hypovolemic Shock**

Administration of colloids in hypovolemic shock is a controversial issue. Colloids may be used after the

---

| **Table 6.6: Classification of hypovolemic shock** |
|-----------------|-----------------|-----------------|-----------------|-----------------|
| **Blood loss %** | Class I | Class II | Class III | Class IV |
| <15 | 15-30 | 30-40 | >40% |
| 100 | 100-120 | 120-140 | >140 |
| Pulse pressure | N | ↓ | ↓ | ↓ |
| CFT | N | Delayed | Delayed | Delayed |
| RR/min | N (14-20) | 20-30 | 30-40 | >40 |
| UO ml/hr | >30 | 20-30 | 5-15 | Negligible |
| Mental status | N, thirsty | Slightly anxious | Confusion | Lethargy |

HR-heart rate, BP-blood pressure, CFT-capillary filling time, RR-respiratory rate, UO-urine output
A child has received 60 ml/kg of crystalloid and continues to have ongoing fluid loss. Colloids like 5% albumin or hydroxyethyl starch may allow for more rapid volume expansion and may decrease the amount of interstitial edema. However, a meta-analysis of several clinical studies concluded that hypovolemic shock should be managed with crystalloid resuscitation as colloid administration leads to increased intravascular volume at the expense of interstitial fluid.

**Use of Blood and Blood Substitutes**

Hemorrhagic variety of hypovolemic shock warrants blood transfusion, especially if blood volume lost is > 15%. Type specific cross matched blood should be arranged for these patients. Failing which they can receive type specific uncross matched blood, and if even this is not available then in emergency setting, as a life saving measure, they can be transfused 0 negative blood.

Recently artificial blood substitutes like perfluorocarbons (PFC), perfluorodecalin and highly purified stoma free hemoglobin (SFH) have also been tried in the management of patients with acute blood loss.

**Role of Vasopressors in Hypovolemic Shock**

Vasopressors are not indicated in the treatment of uncomplicated hypovolemic shock. Vasopressors raise blood pressure by increasing peripheral vascular resistance which is already elevated in hypovolemic shock. Thus, these agents aggravate the deleterious effect of hypovolemic shock and as such are unwarranted in these patients.

---

**Fig. 6.2: Fluid management in hypovolemic shock**

- **Assess heart rate, blood pressure, capillary filling time, urine output**
  - **Improvement**
  - **No improvement**

- **Hypovolemia**
  - Replace the rest of fluid (Maintenance fluid)

- **In hemorrhagic shock if blood loss is 10-15%**
  - Give blood

- **Over 10-20 minutes**
  - Repeat infusion 20 ml/kg crystalloid

- **CVP < 10 mm Hg**
  - 10-20 ml/kg crystalloid
  - Re-evaluate

- **CVP > 10 mm Hg**
  - Insert PCWP catheter
  - Inotropic agents
  - After load reduction
  - Re-evaluate

- **Causes**
  - Unrecognized
  - Pneumothorax
  - Pleural effusion
  - Myocardial Dysfunction
  - Adrenocortical Insufficiency
  - Ongoing blood loss

- **Repeat infusion of 20 ml/kg Crystalloid over 20 minutes**
  - No improvement (unresponsive shock)
    - Put CVP line
    - Assess cardiac function
    - CXR
Role of Positioning in Hypovolemic Shock

Most first aid courses teach that patients in shock should be placed in the head down position (Trendelenburg). Although, this position is efficacious in neurogenic shock yet its role in hypovolemic shock has not been of much advantage.

Role of MAST Garment In Hypovolemic Shock

Military antishock trousers (MAST) are mentioned in the management of hypovolemic shock to be condemned. MAST causes compression of inferior vena cava, impairs ventricular function, decreases blood supply to gastrointestinal and abdominal viscera and is known to cause compartment syndrome in limbs. Because of these disadvantages, MAST is no longer used in the management of hypovolemic shock. It may, however, have some role in the management of bleeding pelvic fracture.

Use of Analgesics and Antibiotics in Hypovolemic Shock

Analgesics are needed for reducing pain in these patients. Analgesics should not be administered by intramuscular or subcutaneous routes as due to reduced blood supply to these structures, these drugs would not reach the systemic circulation. However, once the circulation gets improved the doses previously administered are suddenly reabsorbed and may result in profound sedations which may be life threatening.

Antibiotics were used in the treatment of hypovolemic shock for many years and were thought to exert a protective mechanism against the ravages of hypovolemia. Subsequent data, however, fails to support this hypothesis. Presently there is no role for the use of prophylactic antibiotics in these patients. Antibiotics are advocated only in presence of contaminated and infected wounds.

Role of Steroids in Management of Hypovolemic Shock

Routine use of steroids in management of hypovolemic shock is not indicated. Only in patients with Addison’s disorders and post-adrenalectomy states who present with hypovolemic shock, steroids can be used. The use of steroids in complicated unresponsive shock states remains controversial.

Monitoring

Response to treatment in hypovolemic shock is determined by continuous monitoring of heart rate, blood pressure, peripheral perfusion, saturation (SaO₂) and urine output.

If the patient develops unresponsive shock then following causes should be ruled out:
- Unsuspected loss of blood in chest and or abdomen.
- Associated unrecognized pneumothorax, or pericardial effusion
- Myocardial dysfunction
- Acute adrenocortical insufficiency
- Pulmonary hypertension

Therefore, in these unresponsive patients special monitoring like CVP (central venous pressure) and pulmonary capillary wedge pressures are required as mentioned earlier.

SEPTIC SHOCK

Sepsis and septic shock are among the leading causes of mortality in children. Septic shock is often a combination of multiple problems like hypovolemia, maldistribution of blood flow, myocardial depression and cellular derangements that makes cells and tissues unable to utilize the substrates delivered to them.

The definitions used for the description of sepsis are highly variable. In order to resolve this ambiguity the American College of Chest Physicians and Society for Critical Care Medicine (1991) have stated following definitions of sepsis and its related syndromes and they are universally accepted. They are as follows:

a. Sepsis (systemic inflammatory response syndrome): It is the systemic response to infection. Two or more of the following conditions manifests this systemic response-
   - Temperature > 38 °C or < 36 °C
   - Heart rate > 2 SD than normal
   - Respiratory rate > 2 SD above normal
   - WBC count >12,000 cells/ml³, < 4000 cells/ml³ or band count >10%

b. Severe sepsis: Sepsis associated with organ dysfunction, hypoperfusion or hypotension.
c. **Septic shock:** Sepsis with hypotension despite adequate fluid resuscitation along with the presence of perfusion abnormalities, which includes lactic acidosis, oliguria and or an acute alteration in mental status.

Septic shock is usually highly fatal with a reported mortality in neonates of around 20% and in older children it ranges from 10 - 50%.  

Although bacteria, virus, fungi and parasite may result in septic shock, yet the most common organisms causing septic shock are gram-negative organisms, e.g. *E. Coli*, *Klebsiella pneumoniae*, *Enterobacter* and *Pseudomonas aeruginosa*. The most common source of gram-negative bacteria is the genitourinary system, followed by respiratory tract and alimentary tract (especially biliary tract). Gram-positive bacteria responsible for septic shock include *Staphylococci*, *Pneumococcus* and *Neisseria meningitidis*. *Staphylococci* are common isolates in nosocomial sepsis and in sepsis secondary to indwelling vascular catheters. Besides these organisms sometimes anaerobic organisms are also implicated in sepsis especially after abdominal surgeries.

### Pathophysiology

The pathophysiology of septic shock is as described earlier in the chapter. Lipopolysaccharide (LPS) antigen of endotoxin binds to lipopolysaccharide binding protein (LBP). This LPS-LBP complex than attach to CD14 receptors on macrophages and leads to stimulation of fibrinolytic system, coagulation system, complement system, vasoactive and biochemical mediators resulting in vasodilatation, increased capillary permeability and myocardial dysfunction. Endotoxin, tumor necrosis factor and interleukins stimulate nitric oxide synthetase in macrophages and vascular smooth muscle cells leading to profound peripheral vasodilatation. Various causes have been attributed to myocardial dysfunction that is seen in septic shock. Some of those mechanisms are as follows:

i. Myocardial ischemia due to shock
ii. Defective myocardial calcium metabolism
iii. Presence of cardioinhibitory substances in circulation like myocardial depressant factor (MDF), histamine, endorphins, complement, interleukins and prostaglandins.

iv. Endocardial endothelial injury

v. Nitric oxide production by endocardium/myocardium.

Thus, it is important to note that myocardial dysfunction appears to occur not only in preterminally sick patients but also in the early stages of septic shock.

Endotoxin also activates the intrinsic coagulation cascade along with fibrinolytic system. Platelets are activated, natural anticoagulant like antithrombin 3; protein C and protein S are depleted leading to disseminated intravascular coagulation (DIC). Adrenal insufficiency is common in children with septic shock. In a study by Hatherill et al adrenal insufficiency is documented in 52% of children with septic shock.

### Clinical Features of Septic Shock

Early stages of septic shock (early septic shock) are characterized by an elevated or a normal cardiac output decreased systemic vascular resistance, widened pulse pressure with warm extremities and a normal BP. This phase is also called pink shock or warm shock. If, sepsis is uncorrected then these patients progress on to a classical pale shock characterized by hypotension, decreased cardiac output and metabolic acidosis. The features of early and late septic shock are elaborated in Table 6.3.

### Investigations

Laboratory work up for patients of septic shock includes the following:

1. Hb, TLC, DLC: Total leukocyte count (TLC) >12,000 or < 4000 cells/ml, blood count of > 10%, vaculolation of neutrophils, toxic granules and presence of dohle bodies are suggestive of sepsis.
2. Acute phase reactants, ESR, C-reactive protein, platelet count.
3. Coagulation profile - With the occurrence of DIC in sepsis platelet count decreases and PT, APTT prolong. (PT - prothrombin time, APTT - activated partial thromboplastin time).
5. Blood, urine and cultures from all the catheters and IV line is also required. CSF analysis may be required in selected patients to rule out associated meningitis.
6. Procalcitonin is a new diagnostic tool in the management of septic shock. It is a polypeptide, which is present in plasma at concentration of 0.5 mg/ml. It is markedly increased in invasive bacterial infections. It is not elevated in viral and in non-invasive bacterial colorization. Harbath S et al revealed the mean concentration of procalcitonin in SIRS (0.6 ng/ml), sepsis (3.5 ng/ml), severe sepsis (6.2 ng/ml) and in septic shock as (21.3 ng/ml). The sensitivity of procalcitonin is 97% and specificity is 78%. Serial estimation of serum procalcitonin can be used to monitor the response of infection to antimicrobials.

7. Polymerase chain reaction (PCR): PCR has been found to be more sensitive than blood cultures in detecting bactremia.

**Therapy**

Initial treatment of septic shock includes establishment of adequate oxygenation, ventilation and fluid management as mentioned earlier.

**Fluid Therapy**

Crystalloids (Ringer’s lactate or isotonic saline) are the preferred fluid of choice in septic shock. However, in these patients signs of volume overload should be closely monitored with the help of central venous pressure (CVP). Judicious use of colloids and blood products to maintain hemoglobin, clotting factors and colloid oncotic pressure is also advocated for these patients. Colloids may be used after the child has received 60 ml/kg of crystalloids. 5% albumin in saline is used in dose of 5 ml/kg in septic shock. So far no additional benefit has been documented with its use. Hemodynamic monitoring is required to prevent pulmonary edema, which is known to occur with its excessive use.

**Antibiotics**

Before putting the patient of septic shock on broad-spectrum antibiotics, cultures of blood, urine and any other potentially infected site should be sent. Broad-spectrum antibiotics covering gram-positive, gram-negative and anaerobic bacteria can be started empirically in these patients; depending on the bacterial flora of the hospital or nursery.

**Cardiovascular Support – Role of Vasopressors**

Vasopressor agents are indicated if cardiac output remains low despite adequate fluid infusion, as predicted by CVP of >10 mm Hg or if the child develops pulmonary edema. Some of the commonly used vasopressors in management of septic shock are dopamine, dobutamine, epinephrine and isoproterenol.

**Dopamine:** Dopamine is the most commonly used vasopressor agent in shock. It stimulates α, β and dopaminergic receptors at varying dose. At low dose (3-5 µg/kg/min) it improves renal perfusion by selectively stimulating the dopaminergic receptors of renal and mesenteric vessels. At dose of 5-10 µg/kg/min it stimulates β-receptors along with dopaminergic receptors, thereby having direct inotropic affect on heart. At higher doses (>10 µg/kg/min) it acts mainly on a receptors and causes systemic vasoconstriction. In management of septic shock it is usually used in dose of 3-5 µg/kg/min or uptil 10 µg/kg/min.

**Dobutamine:** Dobutamine acts on β-receptors and causes an inotropic effect on heart. Besides improving myocardial contractility, it causes peripheral and pulmonary vasodilatation. Therefore, dobutamine should be used in the patients only after they have been infused with adequate amount of fluid, otherwise significant vasodilatation and intrapulmonary shunting, caused by dobutamine can lead to fall in cardiac output. It is usually used in doses of 1-20 µg/kg/min.

**Epinephrine:** Epinephrine is the reserve inotrope to be preferred as last choice in cases where there is no response to other inotropes. It acts on α and β 1, 2 receptors resulting in increased cardiac output, heart rate and blood pressure. The potential complications of epinephrine are ventricular tachyarrhythmias and renal ischemia.

**Norepinephrine and Isoproterenol:** In patients with low peripheral vascular resistance as in anaphylaxis and septic shock, enhancing peripheral vascular tone with nor epinephrine may be beneficial. However, the potential vasoconstrictor effect of norepinephrine requires careful hemodynamic monitoring. Isoproterenol is best reserved for patients requiring potent inotropic stimulation especially in conjunction with pulmonary vasodilatation.
Renal Support in Septic Shock

Renal support is essential to avoid renal failure in hypoperfusion states. Fluid therapy and use of low dose dopamine (3-5 μg/kg/min) improves renal blood flow. If there is oliguria/anuria even after fluid management and CVP is >10 mm Hg then loop diuretics (frusemide) can be given in dose of 1-2 mg/kg. If, however patient goes in a state of renal failure then peritoneal or hemodialysis is required.

Nutritional Support in Septic Shock

Parenteral or enteral nutrition should begin as soon as cardiovascular stability is achieved. Many surgeons advocate the early use of minimal enteral nutrition (MEN) to prevent gut mucosal atrophy and bacterial translocation.20

Role of Steroids in Management of Septic Shock

Several large trials have failed to show the beneficial effect of steroids in treatment of septic shock.21 Current studies suggest that replacement therapy with hydrocortisone may alleviate the symptoms of SIRS.

Newer Management Strategies in Septic Shock

With better understanding of the pathophysiology of sepsis and septic shock, new management strategies have been proposed and are presently under trial. They are as follows:

Antiendotoxin Antibody

Monoclonal antibody against bacterial endotoxin may be helpful in preventing the stimulation of various immunological pathways in sepsis. Trials with murine monoclonal antibody E5 have not shown encouraging results.22

Anti-TNF Antibody

Monoclonal antibodies against tumor necrosis factor (TNF) have been tried in the management of septic shock. Afelimomab, the murine monoclonal antibody against TNFα has been tried and phase I results have revealed a sustained rise of blood pressure.23

Lenercept

Lenercept is the human recombinant p55 tumor necrosis factor receptor immunoglobulin G1 fusion protein. It decreases the effect of TNF by blocking its receptor protein. Abraham E et al tried it in 1342 patients with severe sepsis and found that mortality in Lenercept group is 27% as against 28% in placebo group.24

Activated Protein C

Recombinant human activated protein C (rh APC) has antithrombotic, anti-inflammatory and profibrinolytic properties. Trials have been conducted with rh APC in patients with severe sepsis, and they have shown an absolute reduction in risk of death by 6.1% but its use is associated with increased risk of bleeding.25

Antithrombin III

Antithrombin III inhibits thrombin, intrinsic and extrinsic clotting cascade, besides having anti-inflammatory properties. Warren BL et al administered antithrombin III in patients with severe sepsis and septic shock and found that overall mortality was not much different in the treated and placebo group.26

Tissue Factor Inhibitor

Tissue factor inhibitor (TFI) inhibits the action of tissue factor, factor 10A and factor 7A, thus affecting both the intrinsic and extrinsic pathways. Kemme MJ et al showed a dose dependent reduction of thrombin with TFI.27

Intravenous Immunoglobulin

Intravenous immunoglobulins (monoclonal or polyclonal) are used as an adjunctive therapy in septic shock. The Cochrane database reviewed 27 studies of use of IV immunoglobulins in septic shock and found that beneficial effect were apparent in children who received polyclonal immunoglobulins.28 Mortality did not decrease in children who received monoclonal antibodies.

Nitric Oxide Synthase Inhibitor

Nitric oxide synthase inhibitor, N (G)-methyl-L-arginine hydrochloride (546 C88) has been tried in
patients with septic shock (1-20 mg/kg/hr) along with norepinephrine and dobutamine. Usage of 54C88 is associated with 60-80% reduction of requirement of NE to control hypotension.

**Angiotensin II**

Yunge et al used angiotensin II in two children with septic shock who remained hypotensive despite fluid management and high dose of conventional inotropes and vasopressors. In both cases angiotensin II could stabilize the blood pressure and both the patients survived the septic shock. Thereby, proving the beneficial effect of angiotensin II in septic shock.

**Recombinant Granulocyte Colony Stimulating Factor (rh G-CSF)**

Rh G-CSF has been used as a prophylactic agent in some trials with encouraging results. However, larger studies are needed to document the benefit of rh G-CSF (Filgrastim) in severe sepsis.

**Vasopressin**

Some workers have advocated the use of vasopressin infusion in dose of 0.01-0.04 U/min in patients with septic shock refractory to other agents.

**Pentoxyfylline**

Pentoxyfylline inhibits cytokine-mediated inflammation. Lauterbach R et al infused pentoxyfylline in dose of 5 mg/kg/hr for 6 hrs for 6 days in 100 premature babies with sepsis, and found that 1 out of 40 patients died in pentoxyfylline group as compared to 6 out of 38 in placebo group. Also in pentoxyfylline group complication of DIC, anuria and metabolic acidosis were less common.

**High Volume Hemofiltration (HVH)**

HVH can be used in septic shock for supporting hemodynamics and also for removing complements, cytokines, interleukins and other activated inflammatory reactants. In study conducted by Cole et al use of HVH has shown to decrease the requirement of vasopressors in septic shock.

**Management of Complications Related to Septic Shock**

The following complications are known to occur in the course of septic shock:

**Adult Respiratory Distress Syndrome (ARDS) or Shock Lung**

The inflammatory mediators increase the pulmonary capillary permeability resulting in pulmonary edema, and capillary thrombi, leading to ventilation perfusion mismatch. It manifests clinically with hypoxemia, hypocarbia, and metabolic acidosis. Early mechanical ventilation with PEEP is recommended for supporting respiratory function.

**Disseminated Intravascular Coagulation (DIC)**

Septic child may present either with thrombocytopenia in the initial stage of sepsis or with DIC in the late stage with bleeding from multiple sites. In such patients platelet counts, BT, CT, PT, APTT should be assessed. In these patients blood transfusion, fresh frozen plasma (FFP) and platelet transfusions may be required along with vitamin K supplementation.

**Gastrointestinal, Renal and Cardiac Related Complications**

Shock can lead to stress ulceration in the fundus and body of stomach. They can be prevented and treated with H2 blockers. Renal and cardiac support also needs to be given in these patients as mentioned earlier.

**Conclusion**

Inspite of advance in the management of septic shock, mortality continues to be high (10-50%) and the main cornerstone of treatment continues to be antibiotics and cardiovascular support.

**DISTRIBUTIVE SHOCK**

It results from maldistribution of blood flow to the tissue. The important causes are anaphylaxis, neurogenic shock and drug over dosage (spine/ epidural anesthesia).

Anaphylactic shock: Results in previously sensitized host when an antigen reacts with fixed IgE antibody, thereby, triggering mast cells, eosinophil,
complement and vasoactive mediators, leading to widespread vasodilatation decreased venous return, increased capillary permeability and shock. Treatment consists of IV fluid administration, along with steroid (+) vasopressor.

Management of neurogenic shock consist of positioning the patient in head low position, IV fluid and vasopressors.

CARDIOGENIC SHOCK
Cardiac shock is the pathophysiological state in which abnormality of cardiac function is responsible for the failure of the cardiovascular system to meet the metabolic demand of body. This disease mainly comes in the jurisdiction of physicians. Therefore, a detailed description of this entity is beyond the scope of this book. We shall briefly mention an outline of management in these patients.

Cardiogenic shock can be caused by multiple etiologies as mentioned earlier in the classification of shock. Early recognition of congestive heart failure or cardiac shock in infancy requires a high index of suspicion. The initial workup of these patients is as shown below:

**History**
1. Excessive respiratory effort
2. Prolonged feeding time
3. Poor weight gain
4. Excessive sweating
5. Frequent respiratory tract infections

**Physical Examination**
1. Tachycardia/Tachypnea
2. Gallop rhythm
3. Cold extremities, weak peripheral pules
4. Wheezing, rales
5. Cyanosis
6. Diaphoresis
7. Hepatomegaly
8. Neck vein distension
9. Peripheral edema
10. Hypotension

**Investigation**
1. Chest X-ray
   - Cardiomegaly

In contrast to hypovolemic shock, compensatory mechanisms can have a deleterious effect in patients with cardiogenic shock as shown below:

a. Increased systemic vascular resistance causes increased myocardial after load. This along with increased heart rate and contractility raises the myocardial oxygen demand and ischemia.

b. The diastolic filling is impaired because of tachycardia leading to decrease in myocardial perfusion.

c. Fluid retention causes increase in preload, pulmonary congestion and hypoxemia.

d. Increased myocardial demand of oxygen and other subtractions in setting of decreased perfusion leads to worsening of ischemia.

**Therapy**
General principles in the management of cardiogenic shock are as shown below:

1. Minimize myocardial oxygen demands
   - Intubation, mechanical ventilation
   - Maintain normal temperature
   - Provide sedation
   - Correct anemia

2. Maximize myocardial performance
   - Correct dysrythmias
   - Optimize preload
   - Salt + water restriction
   - Diuretics, vasodilatation

3. Improve myocardial contractility
   - Provide oxygen
   - Ventilation
   - Correct acidosis and other metabolic abnormalities
   - Inotropic drugs (Digitalis, amrinone, milirone)

4. Reduce after load
   - Sedation
   - Vasodilator

**Inotropic Agents used in Cardiogenic Shock**
The catecholamines like norepinephrine, epinephrine, dopamine, dobutamine and isoproterenol are some of the most potent positive inotropic agents. Digitalis...
glycosides augment myocardial contractility but because of narrow therapeutic to toxic ratio, their use in patients with cardiogenic shock should be avoided. Newer drugs Amrinone and Milirone decrease myocardial intracellular cAMP degradation by inhibiting phosphodiesterase type III, thus augmenting myocardial contractility. Amrinone is administered intravenously (a bolus of 1-3 mg/kg our 1-3 min followed by continuous infusion of 1-20 mg/kg/min).

After Load Reduction
Nitroprusside is more potent than nitroglycerin as afterload reducing agents. Nitroglycerin is a more potent arterial vasodilator effect.

Cardiac Obstructive Shock
Obstructive shock is caused by the inability to produce adequate cardiac output despite normal intravascular volume and myocardial function. The various causative factors have been enumerated earlier in the chapter. Out of the various causes cardiac tamponade and tension pneumothorax are of relevance in a surgical setting.

Cardiac Tamponade
Cardiac compression caused by accumulation of fluid, blood or gas in pericardium

Clinical features are characterized by Becks triad
- Hypotension
- Increased jugular venous pressure
- Silent heart (barely audible hearts sound).

Besides these signs patient also has pulsus paradoxus and pericardial rub. Echocardiography is confirmatory. Emergency management consists of pericardiocentesis in an unstable patient. Pericardiocentesis is usually done by a subxiphoid approach on left side in 6th intercostals space monitored by echocardiography.

Definitive treatment of cardiac tamponade is removal of pericardial fluid by surgical drainage.

PROGNOSIS IN SHOCK
Aggressive management of shock especially hypovolemia can be quite rewarding. However, septic shock still continue to have a high mortality rate of around 50%. Adverse outcome is anticipated in following situations:
1. Multiple organ failure
2. Major myocardial damage
3. DIC
4. Renal failure
5. Respiratory failure
6. Uncontrolled sepsis.

Thus, to conclude early detection, immediate intervention, close monitoring and systemic approach to reverse the pathophysiological abnormalities are the key points in the successful management of shock.

REFERENCES
Transfusion of blood and its components requires careful consideration in children as a result of continuous anatomical and physiological developments. A correct diagnosis is essential for proper choice and use of various components. The weight and age of the patient determines the transfusion requirements and risks of complications. Potential problems often arises because of the small intravascular volume and difficulty in administration of larger amounts blood products if the concentrates are not available. Premature infants and neonates under the age of four months present unique problems in pediatric transfusion therapy. Premature infants are often over transfused. With the better understanding of the pathophysiological changes and advances in the management of critically ill newborns have necessitated changes in the blood banks policies and preparation of smaller units. The administration of blood components have been altered to suit their special needs. Appropriate pediatric transfusion practice requires the understanding of neonatal physiology.

A full-term neonate has an average blood volume of 85 ml/kg and a premature infant has about 100-110 ml/kg of the body weight. The blood volume reduces after birth as a result of transudation of the plasma. A newborn cannot compensate for volume depletion or over transfusion as well as an adult can because of limited cardiovascular adaptive capabilities. Normal hemoglobin (Hb) level in the neonates varies between 16-18 g/dL and normal levels varies significantly. Neonatal hemoglobin is not able to deliver oxygen to tissues as effectively as an adult hemoglobin. The bone marrow shows poor response to anemia, primarily due to low erythropoietin level and poor reticulocyte response to anemia.

Metabolic problems may arise as a result of immature kidneys which has poor capability of excreting potassium and acid and/or calcium loads. Similarly, acidosis or hypocalcemia may occur because of immature liver which cannot metabolize citrate efficiently.

BLOOD COMPONENTS

The various blood components used for pediatric transfusion are shown in Table 7.1. All these components can be leucodepleted, irradiated or saline washed as per requirements.

Red Blood Cells (RBCs)

There are marked differences in transfusion practices in children and adults:
1. Children require relatively small quantities of blood and blood products, usually 10-15 ml/kg body weight of and thus require only fraction of unit.

2. Repeated blood sampling, even of small quantities, can lead to volume depletion in a neonate. Some times red cell transfusions are needed following iatrogenic blood loss for laboratory tests and blood gas analysis. It is generally recommended that micromethods should be used for various investigations such as biochemical parameters, blood gas analysis blood cultures etc. specially for neonates and infants.

3. Since neonates have maternal antibodies, in addition to their own, until the age of 3-6 months, therefore, it is preferable that red cells intended for transfusion should be crossmatched with the mother’s serum, as well.

Currently the knowledge of hematopoiesis during neonatal, perinatal period and that of response to RBC (i.e. packed red cells) transfusion is limited. The tissue need for oxygen cannot be measured directly and presence of high fetal hemoglobin cannot release the oxygen to tissues as freely as adults. Therefore, the indications for red cell transfusions are not well defined. However, packed red cell transfusions in presence of cardiorespiratory failure secondly to anemia is unquestioned. Role of packed red cell transfusion in situations such as poor weight gain, respiratory difficulties, apnea, patent ductus arteriosus or maintenance of a predetermined blood hemoglobin concentration etc. remains controversial.

The concept of ‘fresh’ red cells needs to be clarified. Freshness is a vague form as its definition is variable. Platelets and factor VIII are lost within 48 hours of storage at 4°C. There is an increase in potassium and ammonia along with a reduction in pH after 5-7 days of storage. Blood less than 5 days old is often used for large volume transfusions, e.g. exchange transfusion in neonates. Blood less than 5 days old ensures that the plasma electrolyte concentration is within tolerable limits for infants and is now considered as fresh blood.

Indications for Red Cell Transfusions

The indications of red cell transfusion are given in Table 7.2. Pediatricians can modify them according to the general condition of the patient and their hospital transfusion practices.

Neonates

Physiologic Anemia of Infancy

The anemia, resulting from the decrease in red cell mass due to physiological factors during the first eight weeks of life is termed as “physiologic anemia of infancy.” Hemoglobin values in term infant fall to about 11±2g/dL by 8 weeks of age. The erythropoietin (EPO) response to anemia is relatively diminished and the drop in hemoglobin is variable, with the lowest values (9±2g/dL). Clinical trials with recombinant human erythropoietin (rhEPO) for the physiological anemia of infancy have been encouraging.

Hb < 10 g/dL, if Symptomatic

In neonates, particularly with respiratory distress, red cell transfusions should correct systemic hypoxia, improve peripheral oxygen delivery and assure adequate oxygen perfusion. The adequacy of transfusion is assessed by hemoglobin level or hematocrit.

Hb <13.0 g/dL, in Cardiopulmonary Disease

Neonates requiring oxygen and ventilator support for longer period should be transfused red cells containing adult hemoglobin. It will provide satisfactory oxygen delivery during the period of illness associated with diminished pulmonary function. It has been recommended that hemoglobin should be maintained above 13.0 g/dl. This level of hemoglobin ensures optimal oxygen delivery in severe cardiac disease with cyanosis or congestive heart failure while in patients...
with patients ductus arteriosus the rise in hemoglobin levels following red cell transfusion has been found to be useful as it increases pulmonary vascular resistance which enhances the ductal closure and alleviates high output failure. Red cell transfusion should be given slowly and should be monitored closely as transfusion may transiently increase blood volume leading to cardiac failure.

**Hb < 10 g/dL in Infants with Failure to Thrive**

Anemia is one of the several possible causes for growth failure, especially in presence of other signs of distress (e.g. tachycardia, respiratory difficulty, less vigorous cry and activity and poor sucking). RBC transfusion is recommended in infants having anemia with growth failure, if Hb level is less than 10 g/dL in the absence of other causes for poor weight gain.

**Replacement of Iatrogenic Blood Loss**

Red blood cells transfusion for iatrogenic blood loss account for about 90% of transfusions during the neonatal period. Repeated blood sampling may be necessary for laboratory monitoring in the intensive care unit. Therefore, it is recommended that only minimal necessary investigations should be undertaken. Secondly these investigation should be done by micromethods to prevent anemia. It is generally advised that red cells should be replaced on volume to volume basis.

**Infants and Older Children**

**Symptomatic Children with Hb < 7 g/dL**

Causes of severe anemia could be secondary to diminished erythropoiesis in conditions such as leukemia, aplastic anemia, following chemotherapy, infiltration by tumor cells, myelofibrosis or due to ineffective erythropoiesis secondary to various hemolytic anemia, congenital dyserythropoietic anemia, hemoglobinopathies etc. The usual practice is to raise Hb above 10 gm/dL. Red cells transfusions may be required in asymptomatic infants with anemias, e.g. radiotherapy, which requires adequate Hb for optimal effectiveness and for children undergoing major surgery.

**Blood Loss due to Hemorrhage**

Blood loss usually occurs during surgical procedures and more in presence of thrombocytopenia or following accidents. The aim of transfusion is to replace the red cell mass and to maintain the oxygen carrying capacity with adequate tissue perfusion. In massive transfusion (> 1 blood volume replacement in 24 hours) whole blood may be given as it also provides plasma for maintaining oncotic pressure.

**Transfusion of the RBC Product**

Packed red cells (hematocrit 70-80%) in a dose of 10-15 ml/kg body weight is the product of choice for neonates. Clinical and laboratory evidence suggest that RBCs preserved in extended storage media (AS-1 or AS-3) are safe for neonatal transfusions until the units have been preserved for over 42 days.

Donor exposure should be limited by collecting RBCs in a multiple bags (e.g. triple bag or pentapack) and splitting the bag into individual small volume units, which retain the expiry date of the original red cell unit. Alternatively the required amount of red cells can be transferred to a transfer bag using a sterile connecting device under all aseptic measures to ensure sterility.

The age of blood does not matter for small volume top-up transfusions. Hyperkalemia is not a common complication because of higher amounts of plasma potassium in stored RBCs except when large volume transfusions are given. Storage of blood often results in depletion of 2,3-DPG (2,3-diphosphoglycerate) and the resultant high oxygen affinity is a theoretical disadvantage of aged blood, but does not constitute any significant problem in clinical practice. The 2,3-DPG rapidly regenerates following transfusion. 2,3-DPG is greater than 70% during the first 5 days of storage, therefore it is preferable that blood collected within 5 days should be used for exchange and other massive transfusions.

For other infants and older children the dose for transfusion is 15 ml/kg body weight, irrespective of the age. It results in rise of Hb by 2 to 2.5 g/dL. Smaller repeat doses (5 ml/kg) spread over 24 hours may be given in children with severe anemia. Children may be given 15 ml/kg of body weight. Very slow transfusion with constant monitoring and use of
frusemide may be undertaken in infants with severe anemia. Otherwise a partial exchange should be done to avoid volume overload.

**Platelet Transfusion**

Platelet concentrates may be either random donor platelet (RDP) units or single donor platelet (SDP) units. RDP units are prepared from one unit of whole blood and contain \(5.5 \times 10^{10}\) platelets in 40-60 ml of plasma. SDP units are harvested from a donor connected to the cell separator (apheresis) and contain \(3 \times 10^{11}\) platelets. Both are stored at +22°C on a platelet agitator and have a short shelf-life for 3-5 days depending on the type of the bag.

The normal platelet count in infants and children is similar to adults with a range of 150-450 \(\times 10^9\)/L. General guidelines for platelet therapy are given in Table 7.3. The primary indication for platelet transfusion is thrombocytopenia with active bleeding. Thrombocytopenia may result from decreased platelet production, increased platelet destruction or following massive blood transfusion. There is no absolute threshold or critical value below which bleeding always occurs. However, the risk of bleeding is high when platelet count is below \(10 \times 10^9\)/L and very high when platelet count is below \(5 \times 10^9\)/L. In actively bleeding patients or those undergoing major surgical procedures the platelets should be transfused if the platelet counts is below \(50 \times 10^9\)/L. Platelet counts should be maintained above \(20 \times 10^9\)/L in those who have thrombocytopenia following bone marrow failure or undergoing minor surgical procedures. Consensus Conference Statement (1998) recommended that platelet count should be maintained above \(10 \times 10^9\)/L for stable thrombocytopenic patients and \(20 \times 10^9\)/L for those with fever infection and related conditions with prophylactic platelet support. In neonates, the Consensus suggests a higher threshold should be maintained as there is considerable danger of hemorrhage. However, in developing countries, it is more practical to treat clinical bleeding rather than platelet count in view of poor availability of platelet concentrates, high cost and limited facilities.

Platelet transfusions may also be required in the neonatal immune thrombocytopenia (secondary to maternal idiopathic thrombocytopenic purpura (TIP) or neonatal alloimmune thrombocytopenia).

In thrombocytopenia secondary to maternal ITP the platelet antibodies have broad reactivity against all platelets. Transfusion of platelets from all donors including the mother and family members have uniformly short survival. It should be given only in life threatening situations. Intravenous immunoglobulin is effective therapy for both the categories of immune thrombocytopenia. In neonatal alloimmune thrombocytopenia, maternal platelets can be used as they are the most readily available source of compatible platelets. Platelet can be washed to remove incompatible plasma and irradiated to avoid graft-versus-host disease (GVHD). If PLA–1 negative platelets are necessary SDP should be preferred.

Platelets should be rapidly infused over 30-40 minutes. One unit of RDP unit/5 kg body weight is sufficient to stop hemorrhage. Platelets have a lifespan of 7 days but are probably hemostatically effective for only the first 4 or 5 days. About two-third remain in the circulation while the rest comprise a freely exchangeable splenic pool. Determination of a 1 hour post-transfusion corrected count increment (CCI) has been suggested to assess the response to platelet therapy. However, the cessation of hemorrhage is the way to determine the effectiveness of platelet therapy. If the adequate platelet therapy does not arrest the bleeding in the absence of infection and other causes such as disseminated intravascular coagulopathy, platelet refractoryness should considered. In these cases one should investigate for platelet antibodies. Special platelet products like HLA-matched platelets, should be considered to control the bleeding episodes in presence of platelet alloantibodies.

Random donor platelet (RDP units) are usually given irrespective of ABO and Rh blood group if the RDP is not visibly contaminated with red cells. It has been observed that platelet survival is better when ABO compatible platelets are transfused. Heal et al found a higher median CCI with ABO identical transfusions and the lowest with platelet incompatible transfusion, i.e. when recipient has antibodies to donor ABO antigens.9,10

Transfusion of ABO incompatible plasma is more dangerous in the pediatric recipients, especially in the neonates, than in adults due to their smaller blood volume. If necessary the plasma volume of platelets (RDP) can be reduced. Volume reduction is also necessary to prevent volume overload.

There is a possibility of recipient sensitization to Rh-(D) antigen in Rh-(D) negative patients as small numbers of donor erythrocytes are always present in platelet products. Although the ability of the host to respond to immunogenic stimuli may be compromised by disease or by therapy, it is essential to administer the anti D immunization to Rh negative individuals.

**Granulocyte Transfusions**

The quantitative and qualitative abnormalities in myelopoiesis and circulating neutrophils present in the newborn have suggested a possible role for granulocyte transfusions in addition to microbial therapy for treatment of overwhelming sepsis. Neonates are more susceptible to severe bacterial infections than older individuals.

Optimal use of granulocyte transfusion for neonatal recipients is under investigation and is yet to be established beyond doubt. The only granulocyte preparations whose efficiency is documented in the clinical trials are those harvested by leukopheresis. The average cells per leukopheresis unit is $2 \times 10^{10}$, nearly two times of daily production in neonates and about 10% of the daily granulocyte production in adults. It should be borne in mind that septic neonates need granulocyte transfusion urgently.

Stauss has analyzed the data from seven reports of granulocyte transfusions.11 He has concluded that the precise role of granulocyte transfusion for neonatal sepsis is unclear. Some patients of neonatal sepsis respond to antibiotics alone but have high mortality.

The dose of granulocytes transfused should be at least $1-2 \times 10^9$/kg body weight given once in 24 hours or more frequently as required. The volume of infusion is usually 10-15 ml/kg. The granulocyte product should be red cell compatible and preferably irradiated if the infant is premature or immunodeficient. Since granulocyte function deteriorates with storage, they should be transfused within a few hours of collection.

**Fresh Frozen Plasma (FFP)**

FFP is the fluid portion of the blood which is separated and frozen at lower than −30°C within 6-8 hours of collection. In general FFP is used to replace coagulation factors in infants with acquired or congenital deficiencies (Table 7.4).

Since maternal clotting factors do not cross the placenta, hereditary deficiencies of clotting factors may be apparent at birth. Hemorrhagic disease of the newborn, caused by deficiency of vitamin K dependent coagulation factors (factor II, VII, and IX and X) may result in significant cutaneous, gastrointestinal or CNS hemorrhage at 2-4 days of age. Now this disease is rare as intramuscular vitamin K is routinely given at birth. Vitamin K deficiency may also occur in pediatric patients in the setting of malnutrition and/or alteration of the gut microflora following broad spectrum antibiotics therapy or interference of vitamin K metabolism by certain newer cephalosporins.

Coagulopathy is also a feature of disseminated intravascular coagulation (DIC) or impaired hepatocellular function. Management of DIC includes of treatment of the underlying cause and transfusion of FFP and platelets till the process of DIC is

controlled. Hemorrhage prior to invasive procedures in patients with impaired hepatocellular function (e.g. hepatitis or hepatotoxicity due to chemotherapy) is also managed with FFP. In thrombotic thrombocytopenic purpura (TTP), the first line therapy is plasma exchange with large volume FFP infusion, or cryo-poor plasma. FFP is more effective as it is able to provide a labile platelet aggregation inhibitor. FFP also reduces the incidence of coagulopathy associated with L-asparaginase therapy in acute lymphoblastic leukemia (ALL).

Each unit of FFP contains 1 unit of activity/ml of therapeutically useful clotting factors, FFP is administered usually in the dose of 10 ml/kg body weight over 1-2 hours and repeated every 30 minutes as necessary to control the hemorrhage. The dose can be repeated every 12 or 24 hours depending on the clinical situation.

FFP should not be used for the sole purpose of treating hypovolemia as the FFP carries the risk of transfusion transmitted infections. FFP would definitely be preferred for infants who require both plasma volume expansion and clotting factor replacement, as occurs in septic shock or necrotizing enterocolitis.

**Cryoprecipitate**

It is prepared by thawing FFP at 4°C. The cryoprecipitate provides a concentrated form of fibrinogen, F VIII, vWF and F VIII as compared to FFP (approximately a five fold increase in factor VIII concentration). A commonly used dose is 20 ml/kg.

Cryoprecipitate is a useful for acquired hypofibrinogenemic states besides for management of bleeding episodes in factor VIII deficiency, von Willebrand’s disease (Table 7.5).14

**Modified Components**

**Gamma-irradiated Blood Products**

Transfusion associated graft-versus-host disease (TA-GVHD) is due to the immune response mounted by the donor T-lymphocytes against host tissues. Gamma-irradiation in doses of 25-30 Gy prevents the GVHD by inactivating these T cells. Irradiated blood products are also indicated in severely immunodeficient patient fetus requiring intrauterine transfusions and children getting transfusion from first degree relatives. Though occasional instances of TA-GVHD have been reported in the neonates. There is no definitive data to suggest the need for irradiated blood to be given to healthy term infants. Deleterious effects of irradiation have been noted on recovery of red cells and on extracellular potassium which increases with the storage. Therefore, it is preferable to irradiate blood products prior to dispensing.

Besides whole blood, the blood components can cause TA-GVHD. It is usual practice is to irradiate (with a minimum of 25 Gy) these blood components used for intrauterine transfusions or for neonatal patients with birth weight < 1200 grams or whenever the donor and recipient are first-degree relatives. Components that have been frozen (deglycerolized RBCs, fresh frozen plasma, and cryoprecipitate) or blood products such as albumin, plasma protein fraction, and gammaglobulin need not be irradiated.

**Use of Special Filters and Leucocyte Depleted Blood**

Currently available third generation leucodepletion filters achieve a 3 log depletion, i.e. they remove 99.9% of the leucocytes. Leucocyte depletion diminishes the chance of alloimmunization to WBC antigens, decreases the risk of CMV transmission, and possibly also reduces the effects of immunomodulation. Several studies have failed to confirm the postulated high risk of transfusion-transmitted CMV in the neonates as the recipients of CMV seropositive blood and blood products do not have an increased mortality or morbidity. The genuine benefits of WBC reduction are limited. In view of the technical difficulties and high costs of filters the routine use of leucocyte depletion for all transfusions is not justified.

**Saline-washed Red Blood Cells and Platelets**

Washing of RBCs removes about 90% of the leucocytes and 99% of plasma proteins and electrolytes. Saline-

washed red cells are recommended in patients who are hypersensitive to plasma to prevent urticarial reactions in IgA deficient patients to avoid anaphylaxis, in multitransfused patients, e.g. thalassemia, to prevent nonhemolytic febrile transfusion reactions and in babies with paroxysmal nocturnal hemoglobinuria to remove the complement.

Saline-washed platelets reduces the plasma content by 95% without any significant platelet loss. Saline washed platelets are of great benefit in patients with severe allergic reactions. Similarly, washed platelets of the mother are recommended in neonates with alloimmune thrombocytopenia.

**TRANSFUSION IN DISEASE STATES REQUIRING MULTIPLE TRANSFUSIONS**

**Thalassemia**

The aim of management in thalassemia is to maintain the Hb level above 10 gm/dL. Packed red cell transfusions may be required initially at short intervals to achieve the required hemoglobin levels. Subsequently packed red cell transfusions are given at 2-3 weekly intervals.18,19

Generally, RBC units that have been stored for fewer than 7-10 days are advocated for two reasons: (a) Higher 2, 3 DPG levels and (b) better transfusion survival in these units compared to units stored for 35-42 days. However, both these reasons are not valid as red cell stored for relatively short periods do not increase TLC post-transfusion survival or decrease the transfusion requirements.

Thalassemics may develop allergic and/or febrile non-hemolytic transfusion reactions following multiple transfusions. Leucocyte filters are used are recommended with the first RBC transfusion to prevent the development of these side effects. Since the cost of filters is high and the fact that all patients do not develop these reactions. Therefore, practical strategy for a developing country is to use the filters when children develop these reactions. Alternatively saline washed red cells, which have negligible plasma proteins and less than 10% of the leukocytes has been recommended.

**Sickle Cell Disease (SCD)**

Red cell transfusions are given to patients with SCD with the objectives to (a) to correct anemia which increases the oxygen carrying capacity in the anemic patients and (b) To replace the abnormal HbS by normal HbA to reduce the viscosity of blood which in turn reduces the incidence of blood sequestration. Reduction of sickle cells to 40\% in the blood alleviates the pain, prevents local hypoxia and prevents pooling of blood in the spleen and at other sites.

The red cells can be given as a simple transfusion or exchange transfusion depending upon the severity of disease. In a simple transfusion, red cells (10 ml/kg) are given at 12 hourly intervals till hemoglobin level attains normal range. Subsequently blood may be given at 3-4 weekly interval to ensure that the proportion of sickle cells in the blood are kept below 40\%. Exchange transfusion may be undertaken in infants during acute crisis.

**Hemolytic Disease of the Newborn (HDN)**

In HDN, the red cells of the fetus are coated with IgG alloantibodies of maternal origin resulting in accelerated destruction fetal red cell at birth. Exchange transfusion is performed in severe hemolytic disease of the newborn (HDN) with the objectives of:

1. Reducing the load of accumulated bilirubin and of antibody molecules by removal of the plasma from the newborn.
2. Reducing the antibody/coated cells prevents the hemolysis of red cells. There by reduces the bilirubin production;
3. Provides additional albumin to bind residual bilirubin; and
4. Restoring the hemoglobin level.

In severe HDN, in spite of a successful exchange, bilirubin may reaccumulate in the intravascular space due to continued hemolysis or redistribution of bilirubin from other compartments. Exchange transfusion can be repeated if required.

**Hemophilia**

The availability of factor concentrates has drastically reduced the use of cryoprecipitae as the source of coagulation factors.14 The factor concentrate are much safer as they are virally inactivated. Recombinant factor concentrates are now available. However, in developing countries, due to limited availability of factor concentrates and its high cost, fresh frozen plasma (FFP) is being used in majority of cases.
The dose of Factor VIII for hemophilia A is calculated as follows: 0.5 units of factor VIII/kg body weight raises the plasma levels by 1%. Factor VIII has a short half-life of 8-12 hours. Therefore, factor VIII is administered at 12 hourly. The indication of factor replacements for various situations has been reviewed recently. Currently few centers are using factor replacement prophylactically to ensure near normal life and to prevent development of arthropathy.

In hemophilia B, the dose of Factor IX is 1 unit/kg body weight to raise the Factor IX level by 1%.

**Oncology Patients**

Patients especially with leukemia and other malignancies present with anemia. Chemotherapy may also lead to anemia and thrombocytopenia. These children need repeated red cell and platelet transfusions for several weeks or months during and after chemotherapy. These cases need to be monitored periodically. Leucodepleted blood products are advisable if the bone marrow transplant is being considered for treatment of cancer to reduce the risk of alloimmunization and CMV disease. Irradiated blood products are recommended to prevent TA-GVHD.

**REFERENCES**

Ventilatory support in Children

Ventilatory support may be defined as supporting the ventilation of the patient partially or completely to maintain blood gas tension homeostasis within acceptable physiological limits. It may be achieved by moving the air and oxygen into and out of the lungs, by an external device such as a resuscitation bag or a mechanical ventilator through ET tube, tracheostomy or a facemask.

Ventilatory support is not curative. It is a supportive technique. It’s purpose is to provide adequate alveolar ventilation, optimal systemic oxygenation and decreased work of breathing till such time the primary cause of respiratory failure such as, atelectasis, pulmonary edema, respiratory muscle paralysis, etc. resolves.

Vasaline in 1955 was one of the first to suggest that artificial respiration in humans was possible by blowing air through a tube of Reed or cane positioned in the trachea. Though Crafoord, a Swedish surgeon first used positive pressure ventilation during thoracic surgery in 1930s, the polio epidemic of 1950s established the role of intermittent positive pressure ventilation (IPPV) to support ventilation and save life. Subsequently a variety of mechanical devices for ventilating the lungs by IPPV were designed. In recent years, tremendous technological advances have been made in design and sophistication of mechanical ventilators.

By and large the practice of mechanical ventilation in children is an extrapolation of adult techniques. There are no well-designed prospective, randomized studies in pediatric patients, which validate any mode of conventional ventilation as safe and efficacious.

In this article, relevant applied respiratory physiology will be reviewed the basic principles of ventilators will be explained, and patients who might benefit from the support device identified and care of the children on ventilator and the ventilator will be described.

APPLIED RESPIRATORY PHYSIOLOGY

During spontaneous respiration, a pressure gradient is created between the proximal airway and the pleural space due to diaphragmatic and inspiratory muscle contraction, resulting in gas flow in to the lungs. The volume of gas that is moved in and out of the lungs per breath is called a tidal volume (6-8 ml/kg). The airways act to conduct gas, which passes in aliquots to the alveolar space and back. The volume of gas that remains in the lungs at the end of quiet expiration is called the functional residual capacity (FRC). The normal FRC is about 30 ml/kg. This volume of gas primarily takes part in gaseous exchange. The smaller conducting airways have a tendency to collapse at lower volumes on expiration. The volume of gas present in the lungs when airways begin to collapse is called the closing capacity (CC). In children over the age of 6 years FRC exceeds CC, which allows the small airways and alveoli to remain open throughout the respiratory cycle. In children less than 6 years CC generally exceeds FRC, which leads to an increased incidence of atelectasis in infants and young children. That’s why these children benefit from CPAP. Gas exchange from the alveoli to pulmonary circulation occurs entirely by diffusion of gases across the alveolar capillary barrier.
FRC is decreased in respiratory failure from alveolar or interstitial disease. A major goal of ventilatory support is to return the FRC to normal value and thereby improve systemic arterial oxygenation.

Pulmonary Compliance

Compliance of the lungs is defined as the change in volume per unit change in distending airway pressure and is determined by elastic forces within the lungs.\(^3\) Lung compliance is therefore a measure of ‘stiffness’ of lungs. Chest compliance is the change in thoracic cage volume produced by a unit change in transthoracic pressure. Respiratory system compliance is defined as total of lung and chest wall compliance.

Airway Resistance

Airway resistance is the pressure difference between mouth and alveoli or the driving pressure needed to move respiratory gases through the airways at a constant flow rate.\(^3\) The most important determinant of airway resistance is the airway radius. The resistance is inversely related to the 4th power of the radius as defined by Poiseuelle’s Law, which means a 50% decrease in the radius would increase the resistance by 16 times. Even minor decrease in airway lumen size due to edema, mucous plug or broncho-spasm can lead to significant increase in airway resistance.

Time Constants

The time constant of the respiratory system is a measure of how quickly the lungs fill or how long it takes for the alveolar and proximal airway pressure to equilibrate. The product of airway resistance and pulmonary compliance defines the time constant. Knowledge of time constants aids greatly in choosing the safest, most effective ventilator respiratory time and inspiratory time for a particular patient.\(^4\) In a healthy lung 3-5 time constants are necessary to allow complete filling or emptying of alveoli. In a healthy infant one-time constant equals 0.15 sec. Three time constants (0.45 sec) allow approximately 80% filling of all alveolar units. Increasing the inspiratory time beyond 5 time constants does not yield more than 95% alveolar filling.

A patient with increased airway resistance is at risk of gas trapping the end of expiration. Appropriate ventilator setting must be selected to prolong the expiratory phase as much as possible for the child’s tidal volume to be expelled completely.

Work of Breathing

The work of breathing is entirely performed by muscles of inspiration during normal tidal breathing. Normally <5% of total oxygen delivery is consumed to meet the work of breathing by the respiratory muscles. In lung disease the work of breathing is markedly increased. The oxygen demand to meet the increased work of breathing may increase to 25-50% of total oxygen delivery. The increase in oxygen demand causes a redistribution of oxygen delivery. In such circumstances mechanical ventilation may decrease the work of breathing, reroute the oxygen delivery to other vital organs and reverse the respiratory muscle fatigue.\(^5\)

UNDERSTANDING THE VENTILATOR

The ventilator is a device to provide artificial respiration that is to move gases in and out of the lungs. Understanding the ventilator is important in order to choose the right one for a hospital set up or to use it correctly in a particular patient.

Anatomy

The ventilator has basically three parts: (a) face, (b) brain and (c) limbs.

Face

This is the control panel, which is what is seen on the front of the ventilator with the control knobs and keys, manometers and dials. The respiratory parameters are set by using these knobs. In new generation ventilators, the control panel is divided in to three areas, which are separately color coded and displayed. One area shows the set parameters for a patient, the second area shows the actually delivered parameters, e.g. pressures and gas flow, rates which are measured by a pressure transducer at the patient end and a flow transducer. The third area shows the alarm system. It provides audiovisual alarms when set parameters are not achieved. Some of the ventilators have the facility for numeric as well as graphic display.
Brain

Brain of the ventilator is not seen from outside. It’s within the box. It consists of the mechanical component of the early ventilators or the electronic logic of the new ventilators, which control all the functions. With the advent of microprocessor technology, the control of all the respiratory parameters can be performed more precisely. For example, the opening of valves used to take seconds in mechanical ventilators where it now can be done in microseconds with the help of microprocessors. The sensing of pressure generated by the older mechanical ventilators was crude thereby a patient triggering an inspiratory breath use to increased work of breathing.

Limbs

This is the external components, which protrude out of the ventilator box, are called limbs. They have four basic components:

i. Filters: These are incorporated into the pneumatic component of the ventilator for prevention of contamination of the patient from ventilated gas (inspiratory limb filter) and atmosphere air from the patient (expiratory limb filters). The expiratory limb filter needs to be changed after every patient use where as inspiratory one can be used for many patients.

ii. Valves: These are present at either end of the breathing system. When the inspiratory valve opens and expiratory one closes inspiratory takes place. During expiration, the inspiration valve closes and expiratory one opens.

iii. Humidifiers: These are provided for humidification of inspired gases. The nose that normally humidifies inspired gases is bypassed with endotracheal intubation or a tracheostomy. It is important to maintain humidification for optimal mucociliary activity and softening and elimination of the normal secretions of the tracheobronchial tree. The servocontrolled heated humidifier is the common one used in most ventilators. Heating vaporizes water and it delivers 40-80% humidified gas. The size of the water vapor has to be smaller than 1 micron to reach the respiratory bronchioles.

iv. The corrugated tubing: These are small bore (15 mm) non-kinkable low compliant tubings to conduct gases from the ventilator to the patient and from the patient to the atmosphere. In babies and small children where the tidal volume is low, there might be considerable volume loss if the tubing is too compliant.

Physiology

As the ventilator provides artificial inspiration, it has to mimic normal phases of respiration in it’s optimal functioning. Like in normal respiration the ventilator should have the following features:

i. Energy to breathe (driving energy)

ii. Inspiration has to be initiated (inspiration phase)

iii. After desired volume is delivered, inspiration has to stop (cycling inspiratory phase to expiratory phase)

iv. Expiration phase

v. Means of cycling expiratory phase to inspiratory phase.

i. Drive: The ventilator derives its energy or power either from a gas source (“pneumatically” driven, e.g. Bird) or electricity (as in most of the new ventilators).

ii. Inspiration: Inspiration is initiated by ventilators by basically two mechanisms:

a. Pressure generators (Fig. 8.1): Ventilators using this mode have a small driving pressure. The pressure difference between the alveolar pressure and driving pressure determines flow and volume of ventilation. With change in lung characteristics such as low compliance or high airway resistance the pressure difference is low and consequently the flow is reduced and the volume delivered would be less.

b. Flow generators (Fig. 8.2): In this mechanism of inspiration, the driving pressure is much greater and the pressure difference between the alveolar pressure and driving pressure is so large that change in lung and airway characteristics have negligible effect on the flow pattern and therefore by the volume delivered is unaltered.

Most of the new generation ventilators utilize this mechanism for initiation of inspiration.
The effect of the flow and pressure generator ventilators with the various mechanism of cycling on the delivery of tidal volume is shown in Figure 8.3.

iii. **Cycling inspiration to expiration:** During inspiration, a flow is delivered over a time to a preset volume. As a result a pressure is generated in the airway and lungs. All these parameters, i.e. time, volume, pressure and flow have been utilized to terminate inspiration and cycle to expiration.

   a. **Pressure cycled:** Inspiration ends when the preset pressure is reached in the lungs and the breathing system. This mechanism does not take into account the inspiratory time, flow and volume delivered.

   b. **Volume cycled:** Inspiration ends when a particular preset volume are delivered. The duration of inspiration and airway pressure depends on the airway and lung characteristics.

   c. **Time cycled:** Inspiration ends after a particular preset time elapses. The volume delivered and pressure generated again depends on the characteristics of the lung of airways.

   d. **Flow cycled:** The inspiration ends whenever a particular flow rate is achieved. Normally this is 25% of the peak inspiratory or initial inspiration flow.

   e. **Time cycled volume preset:** Certain ventilators though essentially time cycled can deliver a preset volume during a particular inspiratory period because of the power of the machine. They are called time cycled volume preset ventilators. Most of the new generation ventilators offer this mechanism. Flow generator and time cycled volume preset ventilators best achieve maintenance of a steady level of alveolar ventilation in the face of changes in lung compliance or airway resistance.

   iv. **Expiration:**Expiration usually takes place passively to atmosphere. Sometimes the passage of expired gas is modified to provide CPAP, PEEP or NEEP (negative end-expiratory pressure).

   v. **Cycling expiration to inspiration:** In most of the ventilators, this is achieved by a time cycling mechanism.
These simple explanations of the basic principle of functioning of ventilator are for the sake of understanding. The new generation ventilators adopt a variety of complex mechanisms.

**MODES OF VENTILATION**

The versatility of a ventilator in patient care depends on the availability of different modes of ventilation.

The initial development of ventilation was in the field of negative pressure ventilators like Tank, Jacket and Cuirass ventilators. They generated negative pressure around the chest. The function is normal physiologically but it impedes access to the patient. If a tight seal is not achieved especially in infants and children, it cannot deliver an adequate tidal volume. These types of ventilators are not common. Most of the present day ventilators use intermittent positive pressure ventilation (IPPV) to provide alveolar ventilation. In 1950s and 60s it was believed that IPPV is a God sent blessing to save patients lives. With more use in a variety of patient conditions, it was realised that it was not enough; other ventilatory strategies have to be adopted to manage oxygenation and prevent complications. A plethora of ventilatory modes have been designed from very simple to complex. Not many of them have been subjected to critical analysis by controlled trials. So claims of protagonists for a particular mode have to be seen from that point of view. Few representative modes will be discussed here.

They can be classified as:

a. Basic modes: IPPV controlled, Assist, spontaneous
b. Modes to increase FRC and improve oxygenation: CPAP, PEEP, APRV.

c. Modes that allow interaction with patient: IMV, SIMV, auto, proportional assist.
d. Modes, which help in weaning by decreasing the work of breathing: Pressure support, BIPAP.
e. Modes especially useful in children: Pressure limiting, PRVC, HFV, volume support.

**Basic Modes**

**Intermittent Positive Pressure Ventilation (IPPV)**

In this mode, positive pressure generated in the ventilator is utilized to deliver a flow and volume over a period of time. In a healthy lung the pressure needed to deliver an adequate volume is around 20 cm H2O. This mode alters the normal respiratory physiology from negative to positive (Figs 8.4A and B). It leads to impedance in venous return. As the primary goal of ventilation is to maintain oxygenation, ventilatory parameters are often aggressively adjusted to high setting (if necessary) to achieve normal PaO2 (tidal volume, inspiratory pressures, inspired oxygen concentration).

**Assist Controlled**

Mechanical breaths are activated by patients’ spontaneous inspiratory efforts. In this mode the haemodynamic effect is less marked. However, if the patient effort is insufficient or there is apnoea for more than 12 seconds, the preset mechanical rate is maintained automatically.

**Modes to Increase FRC**

**CPAP/PEEP**

When oxygenation is not maintained despite the use of high concentration of oxygen supplementation,
these modes are applied to increase the FRC. CPAP and PEEP are usually defined as airway pressure above atmosphere maintained throughout the respiratory cycle during spontaneous (CPAP) and controlled respiration (PEEP) respectively, so the airway pressure is always positive. (Figs 8.5A and B) These modes are achieved by application of a continuous gas flow source or a valve, a reservoir or a restriction to the outflow of gases at expiration to produce above atmospheric expiratory pressures. CPAP is most commonly applied through an ET tube, however it can be applied through a mask or nasal prongs. Excessive CPAP/PEEP has been shown to reduce venous return and decrease cardiac output, increase right ventricular after load and shift the interventricular septum into the left ventricular. The use of CPAP/PEEP may result in increase in intracranial hypertension or cerebral ischaemia. The increased intrathoracic pressure obstructs venous return to the thorax and mean venous pressure in the central veins increase. These changes are directly correlated with the level of end expiratory pressure applied.

CPAP/PEEP may produce injury to the lungs by over distending the more compliant alveoli.

**Airway Pressure Release Ventilation (APRV)**

This mode utilizes two levels of pressure during spontaneous breathing. CPAP is maintained at a predetermined level and periodically decreased to a lower pressure. The periodic decrease in intrathoracic pressure theoretically minimizes the haemodynamic compromise (Fig. 8.6).

**Modes that allows Patient — Machine Interaction**

**Intermittent Mandatory Ventilation (IMV)**

This mode delivers a preset mechanically generated breath regardless of patients’ inspiratory efforts. This mode was designed to support inadequate ventilation of spontaneously breathing patients. As this mode does not recognize the patient’s effort or the breathing pattern, it leads to asynchronous breathing between the patient and ventilator. In order to avoid this complication SIMV mode was designed (Fig. 8.7).

**Synchronized Intermittent Mandatory Ventilation (SIMV)**

In this mode the ventilator presets the mechanical breaths but patients’ own inspiratory efforts are used to synchronise the intermittent mandatory breath (Fig. 8.8).

**Proportional Assisted Ventilation**

In this method, the ventilator output is modified to meet the patient’s respiratory demands. It functions only in spontaneously breathing patients. The ventilator senses and monitors patients’ respiratory efforts and provides the pressure support needed. If a
patient generates more negative pressure on inspiration, at respiration, the ventilator provides higher-pressure support compared to SIMV. This mode decreases the Peak Inspiratory Pressure. Though this mode is very promising it is still in experimental stage (Fig. 8.9).

**Automode**

This mode serves the patients respiratory pattern and changes from support ventilation (controlled SIMV) to non-support ventilation (spontaneous). This mode has recently been introduced by Siemens (300 A) and has undergone a few favorable trials.

**Modes Useful in Weaning**

**Pressure Support (PS, ASV)**

This mode provides a predetermined pressure assist from the ventilator once the patient triggers an inspiration. The patient determines the respiratory rate, I: E ratio and part of the resultant tidal volume. When upper pressure is reached, the pressure assist is maintained at the preset level until the inspiratory flow rate decreases to 25% of maximum inspiratory flow, when the inspiration ceases and passive exhalation takes place (Fig. 8.10).\(^{15,16}\)

This mode is useful at the weaning phase after prolonged ventilation. In patients with respiratory muscle weakness or fatigue, this mode is used along with SIMV. As the weakness decreases, the SIMV rate needs to be reduced and patients can be successfully weaned.\(^{17}\)

**BIPAP**

This mode delivers bilevel positive pressure and ventilatory assistance to a spontaneously breathing patient. When the patient initiates a breath, the device delivers a small assistance to the ventilation along a positive pressure gradient. Unlike CPAP system it can deliver different pressure at inspiration and expiration. This mode has not been studied in children.
Modes Useful for Children

Pressure Limiting

In this mode, the peak inspiration pressure is limited to a preset level.\(^{18,19}\) Once the pressure is reached, inspiration is terminated irrespective of the volume of gases delivered. It leads to hypoventilation unless the pressure limit is raised. In children there is a variable leak around the endotracheal tube and with increased airway resistance or decreased compliance when the PIP increases, this leak around the tube increases with resultant reduced tidal volume.

Pressure Control Ventilation

In this mode in case of the pressure reaching the preset level, the flow would be diverted from inspiration to produce an inspiratory plateau at that level of pressure.\(^{20}\) This mode was designed to deliver adequate tidal volume without producing excessive peak inspiratory pressures (PIP), which are considered to be responsible for producing barotrauma (Fig. 8.11).

Pressure Regulated Volume Controlled (PRVC) Ventilation

This is a relatively new mode of controlled ventilation (Siemens 300) in which the ventilator analyses tidal volume on a breath-to-breath basis and resets the peak inspiration pressure (PIP) level needed to assure the target tidal volume (Fig. 8.12). The ventilator accomplishes this by regulating inspiratory pressure to a value based on the volume pressure relationship derived from the previous breath and compared with the target tidal volume.

The advantage of this mode is that the tidal volume is guaranteed at the lowest PIP necessary to achieve it.\(^{21}\) It thereby minimizes the possibility of barotrauma and variation in tidal volume delivery due to change in compliance and airway resistance. This mode has a special advantage in children as there is a leak around the tube and there is loss of volume due to compression of gases and compliance of the tubing. This mode guarantees the delivery of a preset tidal volume.

High Frequency Ventilation (HFV)

There are three types of high frequency ventilation (HFV) (frequency 60-400/mt): High frequency oscillation (HFO); high frequency positive pressure ventilation (HFPPV) and high frequency jet ventilation (HFJV). HFO has been extensively studied by physiologists but it remains and experimental method of mechanical ventilation. Till recently only HFPPV and HFJV have defined clinical applications. Compared to conventional techniques, the advantage is that they enable adequate gas exchange to occur using small tidal volumes, approximating dead-space volume.\(^{22,23}\) In ICU patients they reduces peak inspiratory pressure (PIP). So long as adequate humidification and warming of the gas mixture is delivered it offers attractive alternatives to conventional ventilation in a limited number of indications such as:

1. Bronchopleura fistula with large air leak
2. Tracheal lesions secondary to trauma
3. Respiratory failure with elevated peak airway pressure (> 50 cm H\(_2\)O) and reduced respiratory compliance.
HFV is contraindicated in obstructive diseases like Bronchial asthma or in the presence of bronchospasm.²⁴

**Volume Support Ventilation**

In this mode the patient spontaneously triggers the ventilator to provide a pressure limited, flow cycled breath with a condition to provide a tidal volume (as in Bird) or minute ventilation (as in Siemens). These modes have the theoretical benefits of pressure support along with guaranteed minute ventilation. The clinical experience with this attractive mode has not however been published.

**INDICATIONS**

The vast majority of surgical patients do not require pre or post operative ventilation. The indication is primarily the inability to maintain oxygenation.

**Preoperative**

i. Children with respiratory failure either due to previous lung pathology, chest infection or trauma. Ventilation is needed to stabilize the patient prior to surgery and CDH, HMD.

ii. Following cardiopulmonary resuscitation specially in trauma victims.

**Postoperative**

It should be understood that a large number of patients might unexpectedly need postoperative ventilation. Postoperative ventilation improves left ventricular function and decreases the work of breathing thereby allows redistribution of oxygen to vital organs.

A. **Elective preplanned ventilation is carried out in**

   i. Patients already on ventilator preoperatively. (e.g. TOF with chest infection or trauma patients).

   ii. Neonates following major surgery (e.g. diaphragmatic hernia, omphalocele or gastro-schisis

   iii. Following surgery after head injury with the possibility of raised intracranial pressure.

   iv. Following major cranial surgery, e.g. cranio-synostosis.

B. **Residual effect of anesthetics**

   i. Inadequate reversal of muscle relaxants. This is seen in patients with electrolyte disturbances, metabolic acidosis and hypothermia.

   ii. Narcotics.

C. **Preoperative conditions may require ventilation:**

   i. Sleep apnea-often come for removal of adenoid and tonsillectomy.

   ii. Neurological disease like myasthenia and muscle dystrophy after major surgery.

D. **Intraoperative complication**

   i. **Aspiration of gastric contents:** These patients are electively ventilated even if the lesion is minor in the intraoperative or immediate postoperative period, as the area of damage is only radiologically evident after some hours.

   ii. **Massive blood loss:** When blood volume loss is more than two blood volumes and in any situation where adequate replacement has not been provided.

   iii. **Cardiovascular instability:** It occurs primarily in children with preoperative cardiac lesions. The commonest cause in previously healthy children is untreated hypovolemia.

   iv. **Hypothermia:** It is a common everyday occurrence in surgery lasting for more than two hours, because of dry gases, cold fluids and cold environments and non-availability of warming devices. If the temperature goes below 34 °C there is possibility of severe metabolic acidosis and inadequate reversal of muscle relaxants.

   v. **Phrenic nerve injury:** It is a complication following cardiac surgery often only recognized in the postoperative period due to failure to wean the child off the ventilator.

   vi. **Postcardiac arrest:** Until such time that the child is stabilized and raised intracranial pressure reduced.

**ICU Indication**

i. Neonates lung resuscitation.

ii. Preterm HMD.

iii. CDH.

**VENTILATORY STRATEGY**

**Choosing the Right Ventilator and the Mode of Ventilation**

For most postoperative patients any type of ventilator and mode used are good enough because of healthy lung conditions. The only consideration should be prevention of the complication of ventilation namely barotrauma.
However, in children with lung disease with altered compliance and airway resistance the ventilator and mode, which guarantees adequate ventilation with minimal PIP should be selected. A time-cycled volume preset ventilator with a pressure-limiting device is the one most desirable. The new supportive modes like PRVC, volume support, and proportional assist ventilation theoretically hold promise. However, more clinical experience is needed to assess their efficacy.

**ENDOTRACHEAL TUBE OR TRACHEOSTOMY**

If the patient is likely to require long term ventilation for over two weeks and the airway is maintained by ET tube, injury to the larynx and cords might occur.

A nasal ET tube provides more comfort to the patient and is more acceptable. It can also be better secured to the face. It is the preferred route in neonates. However, the tube obstructs the opening of the sinuses in the nose and produces sinusitis in older children. An oral tube is preferred in these age groups.

The tube size (below size 6 mm ID) should be such that, there is an audible leak around the tube. This recommendation was made following the observation that fitting tubes can lead to postoperative stridor due to oedema of the larynx and trachea. Use of cuffed tubes in children in recent reports has not shown such injury. Cuffed tubes might avoid loss of volume, which usually accompanies a leak.

However, child specific ET tube have only recently being designed (kimberly) and not freely available.

**ROLE OF MUSCLE RELAXANT ANALGESIA AND SEDATION**

Children need to be sedated or paralysed to accept a tube and ventilation. Recent reports implicate the use of muscle relaxants with development of postoperative myopathy. It has not been reported with use for less than 48 hours. So use of muscle relaxant should be avoided and if it cannot be avoided it should be limited to 48 hours. As all the surgical patients have some degree of pain, morphine infusion at the rate of 10-20 ug/kg/hr provides good analgesia, sedation and ventilator acceptance. In some patients a midazolam infusion might be used to supplement. Sedative and analgesics have to be used when children are paralyzed with muscle relaxants.

**PERMISSIVE HYPERCAPNIA**

The goal of ventilation is to provide adequate oxygenation and reverse respiratory acidosis.

For many years conventional strategy was to achieve these goals by using a volume oriented approach to normalize blood gases. Now we understand that in patients with reduced compliance, (because of atelectasis or collapse of lungs), adequate lung volume is not available for ventilation. The tidal volume is delivered to a small amount of aerated lung. This may lead to over-distension of alveoli and progressive lung injury. There is enough evidence in animal studies to show that mechanical ventilation can result in acute paranchymal lung injury, which is histologically similar to ARDS (in addition to conventional barotrauma). This ventilator induced lung injury occurs by a number of mechanisms: (i) inspiratory over distension due to high volume (volutrauma) (ii) high pressure may result in very high shear forces at the interface between collapsed and aerated lung areas during reinflation. To prevent lungs injury for both these reasons, it is necessary to use low tidal volume (often 6 ml/kg) with optimal PEEP. This may lead to hypercarbia. Hypercarbia does not produce any gross physiological changes and can be tolerated up to a level of 80-90 mm Hg. This ventilatory strategy is called permissive hypercapnia. This may not be applicable in children with head injury and raised intracranial pressure.

**COMPLICATIONS OF VENTILATION**

i. Repeated extubation: It usually occurs inadvertently due to inadequate sedation or improper fixation. It may lead to episodes of hypoxia with resultant morbidity and mortality. Repeated intubation may lead to trauma of larynx and cords.

ii. Barotrauma (rupture of lung parenchyma): It is believed to be due to excessive positive pressure. The strategy adopted to prevent barotrauma is to maintain a low PIP, with a Pressure Limiting mode. However, barotrauma is seen more commonly at the interface of a healthy and an adjacent collapsed lung. This leads to asymmetric ventilation and higher shear force at the interface.

iii. Volutrauma: is because of over distension of the alveoli at end of inspiration, which leads to injury of the lung. Probably most of the lung injury is due to volutrauma though higher pressures were earlier blamed for it.
iv. **Infection:** The retention of secretions often leads to infection if proper airway toilet in an aseptic manner is not performed. Immuno-compromised patients are more prone to develop infection.

**CARE OF THE VENTILATOR**

Certain components of the ventilator need to be taken care of on a regular basis by the nursing personnel, respiratory therapists or technical staff. These activities are often supervised or even performed by doctors.

**Breathing System**

i. The filters need to be changed as per the recommendations of the manufacturer. It could be every 24-48 hours or more depending on the presence of infection.

ii. The humidifier water level has to be maintained by regular refilling with distilled water. The temperature setting has to be adjusted. After every patient it should be cleaned and autoclaved.

iii. Corrugated tubing needs to be changed every 48 hours. In some tubing there are moisture traps, which need to be emptied at regular intervals.

   The ventilator tubing should be positioned in such a way that there is no drag and no pressure on the patient’s body. Whenever some procedures are carried out, (like physiotherapy or X-ray of the patient), there is the possibility of drag on the tubing and ET tube dislodgment.

iv. Cleaning and sterilization of the reusable components.

**CARE OF THE PATIENT ON VENTILATOR**

The patients who are put on ventilator are usually sick and cannot breathe. They are either unconscious or paralysed and/or sedated. So they cannot look after themselves and need to be taken care of. Patient care is basically two types:

i. **Care of the unconscious patient:** This involves care of skin, eye, bladder and bowels. Prevention of contracture (by providing regular physiotherapy) and bed sores (by regular turning of patients) is important

ii. **Care of the “ventilator” aspects of the patient:**
   
   a. **Care of the ET tube:** When an endotracheal tube or tracheostomy is used, the nose is bypassed. The nose normally provides humidification to the tracheobronchial tree and is essential to maintain the normal defense mechanism of the lungs. So provision of adequate humidification is essential. A conscious person coughs out secretions, which unconscious patients cannot. Repeated endotracheal suctions need to be performed preferably associated with chest physiotherapy. It should be performed aseptically with sterile gloves and sterile catheters. The catheter size should be less than 1/2 the internal diameter of endotracheal tube with a non-traumatic tip and multiple holes, preferably transparent. A tightly fitting suction catheter might generate excessive negative pressure and cause atelectasis. The catheter should be inserted without connecting to suction. After insertion, suction is applied for not more than 10 seconds at a time. Along with the secretions, it sucks out oxygen, which might cause hypoxia. The negative pressure generated may collapse the alveoli causing further hypoxia. Patients should be ventilated with 100% oxygen prior to ET suction, Humidifier, a servo controlled heated humidifier should be incorporated in the inspiratory limb.

   Inadequate humidification leads to reduced or thick secretions. Both doctors and nurses should be able to provide chest physiotherapy such as percussion and vibration.

   b. **Care of the lines (IA, CVP, IV):** Each of these is a potential route of infection. The intravenous, intra arterial, central venous lines should be properly sealed and non-communicating to atmosphere. (All ports should be closed by sterile blockers) and only handled if necessary. The urinary catheters, chest and tube drains should be sealed completely. All the tubing should be changed 24-48 hrs. to prevent any ascending infection.

   The care of the nasogastric tube is very important especially when enteral feeding is provided.

   c. **Nutrition:** To prevent muscle weakness, better wound healing and control of infection a good nutritional status needs to be maintained.

   In the last decade parenteral nutrition in the form of intravenous fat emulsions, proteins and aminoacids and carbohydrates was widely used. This may lead to many complications such as infection, acidosis, electrolyte disturbances,
embolisation etc. It is also very expensive. Now most of the patients receive enteral feeding either prepacked one or prepared. These feeds need to be given through nasogastric tube continuously or feeding at regular intervals.

d. Monitoring: Patients on ventilator are extensively monitored and it’s the responsibility of the ICU personal to observe continuously and maintain a record of it. Common monitoring is:
   i. CVS: Heart rate, blood pressure, central venous pressure, (Cardiac output).
   ii. Respiratory system: Respiratory rate, tidal volume and minute volume, oxygen saturation.
   iii. Temperature and urinary output.
   iv. Ventilator monitors tell us about airway pressure, minute volume, inspired oxygen concentration, compliance and resistance of the lungs and airways. Pressure, flow and volume are important parameters monitored usually at the expiratory limb of the breathing system at the patient end.
   v. Laboratory: Blood gas analysis and electrolytes, kidney function test, culture and sensitivity.

e. Fluid balance and transfusion: Maintaining the fluid infusion or blood transfusion record is the nursing responsibility. Besides the record keeping the nurse should assess the adequacy of the fluid therapy and provide proper feedback to the treating surgeons.

f. Prevention of infection: Besides providing aseptic care in all the techniques and procedures performed in these patients, some simple but important measures are important in preventing the infection.
   - Barrier nursing, only one nurse should be touching and handling one patient at a time.
   - Before and after touching the patient every one should wash their hands with soap and water followed by use of 70% ethyl alcohol or any similar disinfectant solution.

WEANING

An attempt to wean a child from the ventilator should be made after the cause of ventilation shows improvement, the patient is in minimal oxygen (< 40%) and inotrope support is < 5 ug/kg of dopamine or dobutamine and a PEEP. There should not be any sternal recession, intercostal indrawing or diaphragmatic breathing. Surgical patients after short-term ventilation normally do not need a prolonged process of weaning process unlike long-term ventilated patients.

i. ‘T’ piece weaning is the conventional method of weaning.29 Once the patient meets all the criteria for weaning the ventilator is disconnected and the patient connected to a ‘T’ piece with oxygen. If patient respiratory status does not deteriorate for a period of 2-4 hours ventilation delivery is no more needed.

ii. Gradual weaning is necessary in patients who have been on a ventilator for a long-time, or who have muscle weakness or fatigue.30,31 In this technique, once spontaneous effort comes back the ventilator is set to SIMV mode with pressure support from IPPV mode. The support from the SIMV breaths is gradually decreased as the patient’s respiratory effort improves. Once it is decreased to a rate of 4/mt no support is needed and only pressure support upto 20 cm H₂O is provided. Pressure support gradually decreased and when it reaches 10 cm H₂O the patient can manage on his own.

The weaning process basically consists of three steps:

i. Weaning from the ventilator (described above).
   ii. Weaning from the ET tube. Once the ventilator is disconnected the ET tube should be left in situ for at least 2-4 hours and proper humidification maintained. The ventilator should be kept ready should there be a need. If the respiratory parameters, (clinical and oxygen saturation) are maintained, the patient is extubated.

iii. Weaning from the oxygen: Normally weaning attempts start when the patient maintains oxygenation at a FiO₂ of 0.4. Hence after extubation, all children should be administered humidified oxygen (40%) either through hood, mask or nasal prongs. Gradually the oxygen percentage is decreased.
   The criteria of weaning in children are more clinical oriented than adults.

CONCLUSION

The basic principles in mechanical ventilator are:
1. To protect the ventilated lung (healthy or diseased) using adequate ventilatory support as soon as
possible and for as short a time as necessary.

2. To prevent oxygen toxicity using the lowest FiO2, applying complimentary means of support, which can lead to an improvement PaO2. For example, PEEP/CPAP.

3. To recruit the infiltrated, atelectatic and consolidated lung using adequate PEEP level.

4. To maintain gas exchange, accepting a PaO2 level between 50-70 mm Hg and moderate hypercapnoea (PaCO2 45-55 mm Hg).

Pediatric Anesthesia—
General Considerations

Pediatric anesthesia has progressed rapidly throughout the years. The first recorded case of pediatric anesthesia occurred in 1842 when Crawford W Long, MD, of Jefferson, Georgia, administered ether to an 8-year-old boy for the amputation of a toe.¹ With this introduction, surgical procedures that would previously have been impossible for children could now be performed. Ether seemed to be the anesthetic of choice for use on infants and children. The success of ether can largely be attributed to its wide margin of safety between ventilatory and cardiovascular depression and its lack of dangerous toxic effects.

Beginning in the 1930s and through the 1950s, several new anesthetic agents and new methods for their administration were introduced. Also introduced in the 1930s was thiopental, which caused a rapid induction of anesthesia by intravenous injection. After halothane debuted in the 1950s, there was rapid change in pediatric anesthesia.² Pediatric Anesthesia has progressed rapidly throughout the years. This has allowed us to do the difficult and complicated surgery. Today, pediatric anesthesia has grown to include new anesthetic agents, more advanced technology and sophisticated equipment, and special training that provides education in all aspects of pediatric anesthesia. Teaching and communication came to forefront augmenting the growing base of clinical research.

Ways to control children’s (and parent’s) fears were explored, and more predictable medications were developed. Safety was enhanced, initially by use of the pre-cordial stethoscope, BP cuff (or arterial lines), ECG, continuous temperature monitoring and better fluid management. Greater control of blood volume and pain management allowed for even more complex and life saving surgery. Though introduced in the 1970s, pulse oximetry became the national standard of care, enhancing patient monitoring, and greatly reducing the morbidity and mortality in children. Out patient surgery and patient/child controlled analgesia are now common place. Organ transplantation and surgery of the neonates (and more recently the fetus) are the cutting edge.

Anesthesia for children requires consideration of how development affects patients psychology, anatomy, physiology and response to drugs. Infants always prove a challenge to the anesthetist because of their special needs, size or congenital abnormalities.

ANESTHETIC CONSIDERATIONS

Unlike popular belief, children are not mini-adults. They have a different anatomical and physiological make up. This means a great difference in anesthetic options and a lesser margin of error.

The respiratory system is capable of supporting life from 26 weeks. However, alveolar growth continues till 8 years of age.³ Smaller airway diameter means high airflow resistance. Oxygen consumption is as high as 7 ml/kg/m in neonates. Due to the highly compliant chest wall, functional residual capacity is low, and airway closure can occur at end expiration. Immature respiratory centers are prone to fatigue. This means the rapid development of hypoxia. Also, the smaller functional residual capacity and high respiratory rate speeds up induction with inhalational agents. The large tongue, “higher” glottis, angulated vocal cords and long U shaped epiglottis can make tracheal intubation difficult in infants.⁴
Higher resting cardiac outputs in children speed up anesthetic induction. Predominance of parasympathetic control at birth explains the onset of bradycardia with noxious responses.

Maturation of renal function takes 2 years. The ability to handle solute loads and excretion of anesthetic agents is impaired until such time hepatic metabolism, notably conjugation, takes 3 months to develop, while oxidation reduction appears earlier. Following 3-4 months, hepatic metabolism is increased and is comparable to adults at 3 years of age.

**PREOPERATIVE ASSESSMENT**

Most centers offer opportunities for preanesthetic assessment of children through preanesthesia clinics prior to surgery. The time constraints of these clinics may preclude confidence building measures, but wherever possible, the first interview between the anesthetist and the child and his parents can help to build a rapport with the former and allay anxiety of the latter. The anxiety is specially marked in parents of infants going in for their first surgery. Arrangement of organized trips to the hospital with film or puppet shows for patients and their attendants may help inform them about the procedure planned, though in children with past anesthetic exposure, anxiety is not decreased by such efforts.

A detailed history, with examination of past medical records is essential. Physical examination in children is successful in degrees depending on the cooperation and age of the child. Standard examination of the airway may be difficult in small children except when they are crying with a wide open mouth. History of loose deciduous teeth, needless to say, must not be omitted.

Most children appearing for surgery fall into ASA I-II groups. Earlier routine requirements of a hemoglobin and urine analysis are being questioned, because the return of medical information is significantly less compared to the costs, and the trauma of needles adds another anxiety to a frightened child.6 However, exceptions to the rule occur where a baseline hemoglobin would serve for postoperative comparison. Examples include surgery with anticipated blood losses (vascular lesions), or clinical anemia. Included are also infants of less than 6 months of age with physiological anemia, specially preterm babies.6 Laboratory testing would depend on the preoperative disease process, and surgery contemplated, with an emphasis being laid on avoidance of blanket testing.

Children with upper respiratory tract infections (URTI) form a controversial subgroup. Airway hyper-reactivity present for 2 weeks after an episode of URTI, may manifest as intraoperative desaturation, laryngospasm and bronchospasm are other adverse events.7 Complications are higher among younger children.7,8 The irritability of the respiratory mucosa takes 6-8 weeks to diminish. Interestingly, most complications, were associated with endotracheal intubation.7 However, mortality from the intra operative complications is low, as most are readily treatable.9,10 Since children develop URTI at the rate of 5-10 episodes per year, postponing for 4-6 weeks till the end of airway reactivity may not be totally feasible. Also, allergic rhinitis may mimic viral rhinitis.

Faced with such a situation, it is prudent to consider a risk benefit ratio for the child. A child with frank purulent secretions, running fever should probably be postponed, as also children with bronchospasm at the time of surgery. Children with improving symptoms could probably undergo surgery without a major event. Also, discharge times in daycare surgery for children with URTI can be increased to allow for a greater period of postoperative monitoring.

**FASTING**

In recent years the whole approach to preoperative fasting has undergone extensive evaluation (Table 9.1). As infants have a higher BMR and a larger body surface area/weight ratio than adults, they tend to dehydrate more easily. A number of studies have found no difference in gastric residual volume/pH when children are allowed to ingest clear fluids up to 2-3 hours prior to induction.

The finding that clear liquids are rapidly emptied from the stomach have questioned earlier fasting guidelines. Fear of hypoglycemia, specially in infants also led to a revision of previous guidelines advocating prolonged fasting preoperatively. This has increased patient and parental comfort. The guidelines apply to healthy patients of all ages, undergoing elective procedures. Clear liquids include water, fruit juices without pulp, carbonated beverages, black coffee and clear tea. Light meals consist of toast and clear liquid. The amount of light meal or nonhuman milk ingested is important prior to recommending fasting periods.

**PREMEDICATION**

Children in the age group of 6 months to 6 years are in need of effective premedication as they are traumatized by parental separation and are difficult to reassure by strangers. An entire gamut of drugs are available though the oral, intranasal, rectal routes, have gained popularity (oral ketamine, midazolam, diazepam, phenergan, chloral hydrate, fentanyl lollypops, midazolam and diazepam suppository). Injectable narcotics and sedatives can be administered in older children.

Pharmacological alleviation of preoperative distress and anxiety is challenging in a pediatric patient, who are non-co-operative due to anxiety and fear of needles driving children away from the health care provider deeper into the arms of the accompanying parent.

Traditional intramuscular premedication combines an opioid with an antisialogogue. Intramuscular ketamine 3-4 mg/kg with anticholinergic and benzodiazepine produces a dissociative state within 5 minutes of injection lasting 15-20 min. Intramuscular midazolam (0.05 - 0.15 mg/kg) achieves an onset of action in 1-2 min. However, intra-muscular injections are painful and best reserved for uncontrollable children.

Oral premedication is popular with both physician and patients alike. It is non-invasive, usually cheaper, easy to administer and causes less anxiety. Diazepam, at 0.13 mg/kg as either tablets or syrup achieves the desired effect after 60 minutes. Oral midazolam 0.3 – 0.7 mg/kg is rapidly gaining popularity as a premedicant, acting in 30-45 min. However, commercial preparations are few, and disguising the bitter taste of the drug is a challenge. Honey, fruit juice and 25% dextrose have all been tried to suppress the taste. Ketamine though not specifically marketed in an oral form, has nevertheless been used in doses from 4-6 mk/kg, either alone or with midazolam, with better results in the combination. Ketamine orally has a rapid onset within 10-15 min, and should be combined with an antisialogogue (atropine 0.02 mg/kg) to reduce secretions.

Rectal short acting barbiturates achieve a sedated patient with a risk of airway obstruction. Diazepam, midazolam and ketamine, alone or in combination have also been attempted. However, the route may be uncomfortable for older children and the erratic absorption due to fecal contents may blunt the effect.

For children with a functional intravenous access, midazolam 0.05-0.07 mg/kg, morphine 0.1 mg/kg, fentanyl 0.25-0.5 ug/kg or ketamine 0.5-2 mg/kg produce rapid onset within 5-10 min. Nasal sufentanil, midazolam and ketamine have been attempted, though the route is uncomfortable and may be associated with increased injury.

**INHALATIONAL AGENTS**

**Halothane**

Revolutionizing volatile agent usage, halothane was the first in a series of fluorinated hydrocarbons providing a rapid onset of action and clear headed recovery. Metabolism of halothane lead to the formation of Trifluro Acetyl radicals, implicated in the development of halothane hepatitis. This condition , postulated to be immune mediated, is a diagnosis of exclusion. Avoiding re exposure to individuals with prior histories of adverse reactions like pyrexia and jaundice or those with a positive family history limits this complication.

**Isoflurane**

Isoflurane has a lower blood gas solubility than halothane accounting for a faster onset and recovery. This makes it a useful agent in the outpatient setting, but not good for induction of anesthesia.

Dose dependent ventilatory depression exists, and bronchoconstriction is attenuated. Increased sympathetic activity leads to a lesser depression of myocardial contractility, tachycardia and vasodilatation. Cerebral autoregulation is maintained at higher concentrations than halothane.
It does not sensitise the myocardial to catecholamines, so the arrhythmogenic potential is low.\textsuperscript{22} Hepatic perfusion is better maintained than halothane.

\textbf{Sevoflurane}

Sevoflurane is a potent, non-pungent liquid. No trifluoroacetic radicals are formed with its metabolism. Low blood gas solubility leads to a fast induction and recovery. Alone, it produces conditions for intubation at lower inhaled concentrations than halothane and has been suggested as an alternative to muscle relaxants in cases where rapid recovery is needed.\textsuperscript{23,24}

Lesser tachycardia than isoflurane and lesser cardiac depression than halothane, without coronary steal is an attractive feature.\textsuperscript{25-27} Arrhythmias are uncommon. Dose dependent respiratory depression is as common as with other fluorocarbons.

\textbf{Desflurane}

A minimally metabolized, cardiostable agent, Desflurane has the lowest blood gas partition coefficient among volatile agents, accounting for a speedy onset and recovery.\textsuperscript{28} However, it is irritant to the airways, causing laryngospasm, breath holding and coughing, hence not recommended for inhalational induction.\textsuperscript{29} It exists as a gas at room temperature in most tropical countries and has to be dispensed through specialized delivery systems.

Dose dependent respiratory depression is observed so is a lesser negative inotropic effect than other fluorocarbons. There is no arrhythmogenic potential. The awakening is rapid and smooth, unassociated with apneic spells in infants.\textsuperscript{30}

\textbf{Nitrous Oxide}

The only inorganic compound in wide usage used for general anesthesia, Nitrous oxide is a gas (boiling point –88.5°C) with low solubility. Since, nitrous oxide alone is insufficient to produce unconsciousness, it is combined with more, potent volatile agents as an adjunct, and helps reduce their dosage. Nitrous oxide is a potent analgesic. It produces cardiovascular and respiratory depression that is clinically unimportant in healthy subjects.

Diffusion of nitrous oxide into closed spaces during administration may increase the volume of pneumothorax, in bowel and endotracheal cuffs. Similar effects in the middle ear cavity may be the reason for postoperative nausea and vomiting seen with the agent. Also, prolonged exposure can lead to bone marrow suppression and vitamin B\textsubscript{12} deficiency.

\textbf{INTRAVENOUS AGENTS}

\textbf{Thiopentone}

This derivative of barbituric acid, since its introduction by Ralph Waters and John Lundy, has revolutionized anesthetic technique. It replaced the slow, unsteady induction of ether with a smooth rapid onset. It is commonly used in a concentration of 2.5\% as higher concentrations are progressively irritating to veins.\textsuperscript{31}

However, hypovolemic subjects may experience a severe drop in blood pressure that may not be compensated. Common with most anesthetics, thiopentone causes a dose dependant depression of respiration and myocardial contractility. Accidental intra-arterial injection causes vasospasm and severe pain, leading to gangrene in the absence of timely therapy, which includes dilution of the drug, pharmacological vasodilation or surgery.

Thiopentone induces a reduction in cerebral metabolism, reducing oxygen requirements. It has been mooted as a brain preservative following hypoxic insults, but studies are inconclusive.\textsuperscript{32}

\textbf{Propofol}

Propofol a substituted isopropylphenol, is marketed as 1\% emulsion in lipid with long chain triglycerides. It has a fast redistribution from blood to tissues and a faster elimination than thiopentone, accounting for a clear headed, rapid recovery.

Pain on injection is a distressing feature of an otherwise rapid and smooth induction. Propofol causes myocardial and respiratory depression to a greater degree than thiopentone.\textsuperscript{32} Bradycardia, associated with the drug is probably due to a resetting of the baroreceptor reflex arc. It suppresses pharyngeal and laryngeal reflexes effectively, so it is the preferred agent for LMA insertion.

The high systemic clearance of propofol enables it to be used in infusions, promoting faster recovery
at the end of surgery. Nausea and vomiting are reduced.33

**Ketamine**

First used in 1965, ketamine holds a unique place among the plethora of induction agents. It is a powerful analgesic and induces a phenomenon of dissociation characterized by apparent wakefulness while withdrawal from surroundings. This is brought about by a dissociation of the thalamocortical and limbic systems.31

Used in a variety of routes (intravenous, intramuscular, oral, nasal), ketamine has a rapid onset of action with a rapid clearance. Oropharyngeal reflexes are preserved though silent aspiration has been reported. Central sympathetic stimulation causes tachycardia and hypertension. Respiration is depressed though to a lesser degree than other anesthetics. Bronchodilation and increased secretions are seen.34 An increase in intracranial pressure with the drug makes it an unlikely selection for patients with intracranial disease.

Emergence delirium during discontinuation has been reported in adults, though not in children.35 However, absence in the latter has been postulated to be due to their failure to communicate.

**Neuromuscular Blocking Agents**

Neuromuscular blocking agents allow muscle relaxation in surgery, allowing for greater ease of operation. They facilitate tracheal intubation and are used in intensive care units to effectively control a patient’s respiration when on a ventilator.

Neuromuscular transmission is carried out by acetylcholine released by prejunctional neurons in the synaptic cleft, where it binds to acetylcholine receptors in the motor end plate, triggering a chain of events leading to muscle contraction. Acetylcholinesterase present in the synaptic cleft rapidly clears acetylcholine, terminating its actions. Acetylcholine receptors differ in morphology between newborns and adults, and mature to adult levels in 2 years. Also, prejunctional acetylcholine reserves are small in neonates, making them highly sensitive to neuromuscular blockade. However, a high volume of distribution leads to a lower plasma concentration so the net dose of the relaxant, according to body weight is unchanged.

Depolarizing agents, commonest of which is succinylcholine, causes an initial weak stimulation, manifests as fasciculation, followed by paralysis. Succinylcholine has a rapid onset (45–60s) and fast, spontaneous recovery, making it the drug of choice in situations where rapid intubation is required as well as it is essential for the treatment of laryngospasm. However, it increases serum potassium, a greater rise encountered in paraplegia, burns, muscle dystrophies. It can lead to bradycardia due to enhanced vagal tone, specially with a second dose in the same patient and is known to trigger malignant hyperthermia. These factors dampened enthusiasm for its use.

Non-depolarizing agents are free of such side effects. The relaxant molecule directly occupies the acetylcholine receptor and inhibits acetylcholine binding, producing muscle relaxation not preceded by fasciculations. However, compared to succinylcholine, most non-depolarizing agents have a longer onset and duration of action. Depending on their clearance, they have variously been divided into the longer acting (e.g. pancuroneum), intermediate acting (e.g. vecuroneum) or short acting (mivacurium).

While depolarizing blockade wears off by itself, non depolarizing blockade has to be reversed with anticholinesterases. These drugs inhibit the acetylcholinesterase enabling high concentration of acetylcholine to accumulate at the neuromuscular junction and over come blockade. Danger of stimulation of muscarinic along with nicotinic receptors means that muscarinic receptor inhibitors like atropine or glycopyrrolate are given concomittantly.

**Opioids**

Synthetic or natural derivatives, opioids act on receptors throughout the body to produce a variety of effects. Their chief role in anesthetic practice involves their analgesic properties, and their ability to attenuate stress responses to noxious surgical stimuli. The latter attribute is only partly achieved, though to a greater degree than other anesthetic agents.

Morphine, isolated commonly from the opium poppy is used through intramuscular, intravenous, subarachnoid, epidural and oral routes. The effect of opioids on different receptors is shown in Table 9.2. Both intermittent boluses and continuous infusions are described.36 Pethidine with an inherent Atropine – like
structure is associated with tachycardia. However, later developments like fentanyl, alfentanil, and sufentanil and remifentanil are highly lipid soluble. Hence, they have a rapid onset and shorter duration of action, making them attractive choices in neonates, who have an increased depression of respiration with opioids.37

Beyond 1 month to 2 years, the increase in the volume of distribution and rapid elimination of opioids calls for an increase in drug doses by almost 1.5 times if based on weight (but the same if on body surface area).38

Most opioids are cardiovascular stable in the well hydrated, normal patient. Fentanyl and its congeners can provoke bradycardia, specially when used with propofol and vecuronium. However, in shock, opioids can cause an additional myocardial depression. Respiratory depression is usually gradual with a rise in apneic threshold and accumulation of CO2. Constipation and histamine release leading to bronchospasm and anaphylaxis may be seen in those susceptible with morphine. Antagonism is best achieved with naloxone at 2-4 μg/kg. Since duration of action is short, an infusion of 1–10 μg/kg/hr is recommended.36

LOCAL ANESTHETICS

These group of drugs achieve an inhibition of nerve conduction. Commonly classified as ester or amide, based on structural features, local anesthetics can achieve sensory, motor and autonomic blockade, depending in the area chosen.

Lignocaine, bupivacaine and the recently introduced ropivacaine are the prime agents in current usage. Maximum doses for lignocaine with or without adrenaline are 7 and 4 mg/kg while the same for Bupivacaine are 3 and 2 mg/kg. The addition of adrenaline causes localized vasoconstriction and delays the clearance, prolonging action. The more rapid onset of block attributed to adrenaline is unsubstantiated.

Inadvertent intravascular injections, or over doses can lead to convulsions, coma and death. Bupivacaine is singularly cardiotoxic and can cause resistant ventricular arrhythmias. Ropivacaine, a congener of bupivacaine apparently lacks the cardiotoxicity while retaining the increased duration of action. Hence, all local anesthetic administrations should occur in the presence of equipment for cardiopulmonary resuscitation.

MONITORING

With the advent of extensive monitoring equipment, the safety standards during the perioperative period have reached a new high. But, one should not forget the value of the precordial stethoscope, tactile palpation of fontanelle and skin for fluid status and most importantly constant observation of the pattern of respiration and skin color.

The measurement of O2 saturation is an invaluable perioperative tool. The probe is available in different sizes for neonates and older children (wrap around or clip on). Measurement of end tidal CO2, continuous temperature monitoring, invasive pressures (CVP and arterial) should be done where indicated. Continuous temperature monitoring especially in neonates, very sick children or in those undergoing major surgical procedures is must. Operating Room temperature should be maintained appropriate to age of the children as their capacity for thermoregulation is poor.

MANAGEMENT OF ANESTHESIA

Given the variation in children, anesthetic management differs from adult practice in certain areas, though the basic techniques remain the same.

Compared with adults, intravenous induction in children is reserved for those cooperative enough to allow a needle, or with pre-existing intravenous access prior to their entry into the theatre. The use of EMLA
(eutectic mixture of local anesthetic) with Lignocaine and Prilocaine or Amethocaine cream applied on the intended puncture site reduces the pain of needle entry. However, some children may be frightened by the very sight of the needle.

For this subgroup of patients an inhalation induction appears to be non-invasive and pain free. The concentration of anesthetic agent is either gradually stepped up or is increased to a maximum and a co-operative child asked to inhale to vital capacity and hold his breath (the single breath technique). Intubation if required is performed under deep inhalational anesthetic agent or after a muscle relaxant is administered, after confirmed ease of mask ventilation. Muscle relaxants are usually avoided in children with obvious or potential difficult intubation in whom intubation can be attempted while spontaneously breathing using deeper planes of anesthesia. Newer inhalation agents like sevoflurane are rapidly acting and less irritant.

Recently, parental participation at the time of induction has made anesthesia more smooth and less traumatic for the children. In Europe this practice is preferred than in US.

Large occiput, small head size and large tongue make pediatric mask ventilations challenges for the uninitiated. Part of the solution lie in pillows or rolls under the neck to provide appropriate extension. Laryngoscopy can be hampered by the large tongue size and the overhanging , omega shaped epiglottis, making visualization of the larynx difficult.

Appropriate size of face mask, airway, laryngoscope blade, tube is now available for neonates and children. However, the 15-22 mm connections on masks, tracheal tubes and anesthesia circuit remain standardized to avoid confusions. Laryngeal mask airway is being used in all age groups starting from the neonates to older children for all types of surgery wherever possible. Fiberoptic bronchoscopes is useful in difficult airways situations as well as in assessing the correct placement of double lumen tubes which are now available in pediatric sizes for thoracic surgery.

The cricoid cartilage is the narrowest point of the airway in children below the age of 5 years. Cuffed tracheal tubes are avoided in this age group to prevent post intubation croup. The correct internal diameter of a tracheal tube for a child older than 2 years is approximately given by the formula.

\[
\frac{\text{Age (years)}}{4} + 4 = \text{Tube internal diameter (mm)}
\]

While the depth of insertion (tube length) till mid trachea from the mouth (more than 2 years) as

\[+ 12 \text{ Tube length (cm)}\]

Circuits for delivery of anesthetic gases to children should be light weight, safe and with a reduced dead space. The Mapleson F, or the Ayre’s T piece is the most popular circuit in use among pediatric anesthetists, fulfilling all the above criteria. Mapleson D and A systems have also been used in children. Circle absorber systems with reduced diameter of tubings are fast emerging in pediatric anesthesia as a reliable method for conservation of heat, humidity and anesthetic agents.

The development of the laryngeal mask airway (LMA) in 1988 has revolutionized anesthetic practice. The LMA when inserted is sited above the larynx and forms a seal around the laryngeal inlet with the tip resting against the upper esophageal sphincter. It requires a lesser depth of anesthesia compared to a tracheal tube for both insertion and toleration during maintenance of anesthesia. Insertion of the LMA is easily learnt and usually does not require a laryngoscope. This, coupled with the non-invasiveness of the device leads to less pharyngeal and laryngeal stimulation, a boon in patients with reactive airways and cardiac disease. With the availability of pediatric sized laryngeal masks (size 1, 11/2, 2, 21/2). For routine surgery and patient’s with difficult airways, pediatric sized laryngeal masks have become very popular.

Maintenance of anesthesia usually involves ventilating the child with an anesthetic gas mixture with muscle relaxation, if required. Newer intravenous agents like propofol have a faster recovery and infusions of these can be used instead of halogenated anesthetics for maintenance of anesthesia. The respiration in majority of children is controlled or assisted , as the immaturity of respiratory centers and lung dynamics makes a spontaneously breathing child more prone to respiratory depression.

Emergence from anesthesia involves reversal of muscle relaxation and ventilation with anesthetic free
oxygen to reverse the concentration gradient and promote clearance. Preterm neonates with high incidences of apnea in the postoperative period require intensive monitoring after surgery.

**Intravenous Fluids**

Perioperative fluid therapy has following purposes:
1. To supply water and thereby to create enough urine volume to excrete solutes.
2. To replace insensible fluid losses.
3. To replace electrolytes lost from the urine, skin and gut.
4. To supply calories to reduce tissue catabolism.

Infants have a total body water of 75% as compared to 60% in adults. Also their extracellular fluid volume is 44% as compared to 15-20% in adults. Therefore, combined with their high metabolic rate they are prone to dehydration. Neonates have poor energy reserves and immature enzyme system and do not withstand starvation well. It is hence imperative to supplement glucose in the perioperative period. Intraoperatively dextrose and balanced salt solutions are used for this purpose. Ringer’s lactate is considered a good replacement fluid in older children.

Various calculations involving body weight surface area, or caloric expenditure have been used to determine fluid therapy in children undergoing surgery. Assessment of fluid and electrolyte imbalance is performed during preoperative evaluation and it should consider the cardiopulmonary status, renal function, and any existing systemic abnormalities that may have an impact on fluid and electrolyte management.

The estimated fluid deficit (EFD) = Hours fasting × Maintenance fluid requirement (MFR) (ml/kg/hr)

First hour fluid = MFR + ½ EFD
Second hour fluid = MFR + ¼ EFD
Third hour fluid = MFR + ¼ EFD

Fasting fluid is taken as 3 ml/kg/hr

Maintenance fluid requirement
For superficial surgery 1-2 ml/kg/hr
For abdominal procedure 6-10 ml/kg/hr
For thoracic surgery 4-5 ml/kg/hr

Infants less than 4 years of age who are kept fasting for more than 6 hours may become hypoglycemic and irritable. Whereas Nilsson et al have failed to demonstrate hypoglycemia in infants less than 2 years of age including those who fasted for 6-8 hours. So it is advisable to do blood glucose in these infants who are fasting for longer periods and if blood glucose < 40 mg/dl, glucose solution should be infused. However, preterm infants who are receiving glucose containing solution should be observed for hyperglycemia. The metabolic need for glucose in the infant is 5 g/kg/day.

Blood transfusion is recommended in neonates with HCT < 30 and in infants or children when HCT < 25.

**POSTOPERATIVE PAIN MANAGEMENT**

Since, prehistoric times, the emotional component of pain and meaning of the sensory experience of the pain has been interpreted in the greater context of the time. This has been true for infant children who are unable to articulate their pain. Pain in the mid - 19 century was considered very real in infant. Today, the concept of neonatal and pediatric pain is well established. The development of rectal analgesia has also helped in reducing the pain in the postoperative period.

Pain is an “unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such a damage”. The development of pain pathways have been elucidated in neonates and older children and infants challenging earlier erroneous beliefs that pain transmission was under developed in children. A multimodal approach using opioid and non-opioid based analgesics, with regional anesthesia works best in the pediatric age group. Included within these are steps to involve both the child and parents in the management along with sympathetic support and child friendly surroundings to cope with the negative emotional falling out commonly associated with pain.

Clinical assessment of pain in children is challenging. Depending on the age, children may not communicate their discomfort due to a various reasons, ranging from a stranger anxiety to fear of needles. Bear in mind that assessments of the degree of pain are incomplete till they are associated with therapeutic measures.

Since pain is a subjective phenomenon, self-reporting by patients remain the gold standard of assessment. By 18 months children develop words for pain, while by 3-4 yr, cognitive development is sufficient to allow the child to quantify the pain. Other modes include observational assessment for
behavioral changes, agitation, reported by either healthcare worker or parents themselves. The limitation here being the inability to differentiate, in certain scenarios, between signs due to pain and these due to anxiety. Another measure is a quantification of physiological responses to monitor the degree of pain. These methods may be expensive and nonspecific, though are effective in those with cognitive disability or immaturity. Instead of a single parameter, most pain scales incorporate a multi-dimensional assessment, based on the age of the child, sensitivity of illness and the surgical procedure carried out.

Clinical Assessment of Pain in Children—Infants and Adolescent in Table 9.3.

PHARMACOLOGICAL INTERVENTIONS

Non-steroidal anti-inflammatory agents (NSAIDs) include inhibitors of prostaglandin synthesis and weaker opioids. Prostaglandin are mediators of inflammation derived from arachidonic acid by cyclooxygenase. These act on free nerve endings to stimulate pain receptors and are patent vasodilators within action, compiled with increased capillary permeability, leads to edema and erythema. They are also responsible for platelet aggregation, pyrexia and increased renal blood flow.

PROSTAGLANDIN SYNTHETASE INHIBITORS (PSI)

PSI form the most commonly used analgesic medication worldwide, with most available over the counter. The agents, inhibit cyclo-oxygenase pathways, reduce the production of prostaglandins and thromboxanes and attenuate the effects of the inflammatory mediators. Compared to opioids, they lead to no depression of consciousness, respiration or hemodynamics, and are free of addictive potential making them attractive choices for outpatient therapy.

Acetaminophen, due to its convenience, effectiveness for mild to moderate pain and safety, is the most commonly used analgesic agent in children.

Acting on the central cyclo-oxygenase, rather than peripheral, its anti-inflammatory activities are limited, so too its adverse effects on renal, platelets and gastrointestinal function.\textsuperscript{54} It is available as oral, rectal, intramuscular preparations, though the later would not be the mode of choice in children. An intravenous prodrugs proparacetamol has also been developed but is not yet licensed for use.\textsuperscript{55}

The analgesic concentrations of acetaminophen in children have not yet been accurately evaluated.\textsuperscript{56}

**Paracetamol Dosing in Children\textsuperscript{56,44}**

**Oral**
Load 20 mg/kg, then 15 mg/kg 4-8 hrly max 90 mg/kg/d (neonates 60 mg/kg/d).

**Rectal**
- Load 30-45 mg/kg (20 mg/kg in neonates). Then 20 mg/kg 6-8 hrly to a maximum 90 mg/kg/day (60 mg/kg/day neonates)
- Taper after 48-72 hrs
- Watch for evidence of hepatotoxicity, specially in dehydrated, malnourished subjects.

Ibuprofen and diclofenac are available in oral suspension and offer effective pain relief for mild to moderate pain. However, administration round the clock and not as and when required maintains a steady state concentration.

The important NSAID doses are summarized in Table 9.4.

**Contraindications to PSI\textsuperscript{44}**
- True allergy
- Peptic ulcer disease
- Renal failure
- Uncorrected hypovolemia
- Bleeding dyscrasia
- Qualitative/Quantitative platelet dysfunction
- Asthma
- Ongoing or risk for surgical bleeding
- Proven influenza or variable infection.

**Weak Opioids**
Combined with PSIs, weak opioids receptor agonists provide superior analgesia compared with either drug alone.

Codeine in doses of 0.5 mg/kg orally 4-6 hourly combined with PSIs is suitable for pediatric outpatients. A high oral bioavailability and partial demethylation to morphine increase analgesic efficacy. Parenteral preparations are associated with allergic reactions, and are not preferred.\textsuperscript{44} Oxycodine and hydrocodone, semi-synthetic variants at 0.1 mg/kg 3-4 hourly are acceptable alternatives.

Tramadol a μ receptor agonist is another option to control mild to moderate pain. Additional mode of action is inhibition of serotonin uptake. Dose ranges include 1-1.5 mg/kg parenterally. Oral preparations, for pediatric use are not marketed by the manufacturer, who limit the drug for pediatric use. Table 9.5 shown Adverse effects of opioids.

**REGIONAL ANESTHESIA IN CHILDREN**

Rapid strides in safer anesthetics, development of better techniques and recognition of pain pathways in children have lent focus on regional anesthesia among children. Usually supplemented with General

mebooksfree.com
anesthesia, it helps provide a smooth emergence and comfortable recovery.

Anatomic variations in the central nervous systems in children compared to adults make regional techniques in children an independent entity, not just a scaling down of adult procedures. Incomplete myelinization of nerves, completing only at the second year of life, reduced diameter of nerves and decreased distances between the nodes of Ranvier alter pharmacodynamics of local anesthetics. The spinal cord occupies the entire spinal canal in the embryo, but is gradually drawn upwards with the rapid growth of the axial skeletons. At birth, the lower end of the spinal cord is situated at L3, reaching L1 in the first year of life. Correspondingly the dural sac is shifted from S3-4 in a newborn to S1-2 by 1 year of age. The distinct vertebral pieces of the sacrum are not fused till 25-30 years. Loose attachments of nerve trunks of fascial planes promotes wider spread of drug.

Regional anesthesia is well tolerated in children, with no major hemodynamic side effects till 8 years of age. However, patient cooperation for seeking paresthesias is often not possible, due to non comprehension by frightened children. Hence, Dalens recommends nerve stimulation or loss of resistance techniques coupled with sedation or general anesthesia.

Contraindications include infections at puncture site, bleeding allergy to the drugs being used and hypovolemia in case of central neuraxial blockade.

Complications commonly arise as a result of inadvertent intravascular injection. Respiratory compromise can occur with overdosage with opioids or excessive spread in central neuraxial blockade. Local trauma, pneumothorax, accidental subarachnoid injections and nerve injuries depend on the particular block used.

### COMPLICATIONS FOLLOWING REGIONAL ANESTHESIA

**Prevent**

Aspirate prior to injection  
Slow injection (10 ml/min)  
Do not inject against resistance  
Monitoring during injection.

**Treat**

**Common**

**Oxygenate:** Face mask or endotracheal intubation if needed.

Hemodynamic support, external cardiac compression, fluid bolus, and inotropes.

**Convulsions**

Thiopentone 4-5 mg/kg IV, Diazepam 3-5 mg, Midazolam 1-2 mg IV and Muscle relaxant and intubate if convulsions persist.

**Arrhythmias**

Treat according to nature of arrhythmia  
Defibrillate first, for ventricular fibrillation/tachycardia at 3J/Kg.

### CAUDAL ANESTHESIA

Caudal epidural analgesia with Bupivacaine 0.25-0.125% as per requirement with volumes ranging from 0.5-1.25 ml/kg depending on surgical site administered at the time of induction provides good intraoperative and post operative analgesia. A variety of adjuncts can be used like morphine, fentanyl or ketamine. Caudal catheters can be used for thoracotomy and extensive laparotomy for pain relief where High Dependency Unit Care is available. Caudal epidural is relatively an easy procedure in children because the landmarks are better defined.

Non-union of the vertebral arches of S4-5 creates a hiatus flanked on either side by two easily identifiable bony crests, the sacral cornu. The sacral hiatus provides an easily palpable access to the caudal epidural space in children. Caudal anesthesia is commonly used for surgery on the urogenital tract, perineum and lower extremities.

The block can be performed with patient prone or commonly lateral. The needle is advanced through the cornu, piercing the sacrococcygeal membrane at right angles, then directed rostrally to a depth of 3 mm in the sacral canal. Proximity of the anus has limited catheter insertions for prolonged anesthesia among practitioners, though proponents of catheter techniques are present.
Like most epidural blockade, caudal anesthesia is volume dependent. A variety of schemes for drug volumes have been devised, among which the most popular is that of Armitage.\textsuperscript{63} 0.5 ml/kg of local anesthetic blocks of sacral, 1 ml/kg high lumbar, and 1.25 ml/kg provides a midthoracic spread. However, if higher volumes are to be used more than 20 ml then the caudal route is best avoided due to the risk of high cephalad spread of anesthetic.\textsuperscript{64}

Misplacement of needle tip can cause intravascular or subarachnoid injections, “failed” blocks and rectal perforations.

Both local anesthetic blocks and infusions, as well as opioids, have been successfully used to provide anesthesia through this route.\textsuperscript{62,65}

**LUMBAR EPIDURAL BLOCKADE**

Special equipment has been designed for children up to 4 years of age (5 cm 19G Touhy needle). For older children the routine 8-9 cm 18G Touhy needle can be used. It should be remembered that the distance from skin to epidural space is short and the ligaments are soft. Loss of resistance using air is more sensitive in children. The epidural fat in young children is very loose. It is therefore, advisable to thread catheters to appropriate thoracic levels from lumbar or caudal space to avoid potential dural punctures or cord damage.

The degree of difficulty experienced in performing an epidural blockade increases proportionately with increasing height progressively from the sacral hiatus up the vertebral column.\textsuperscript{66} Vertebral spinous processes horizontally afford greater working interspace for the negotiating needle in the lumbar region. Introduction of a catheter allows indefinite prolongation of anesthesia. The technique can be used as a safe anesthetic in older, cooperative children and adolescents or as a supplementation with general anesthesia, reducing opioid and volatile agent dosages. The high quality of analgesia provided in the postoperative period promotes faster recovery specially since it enables patient movement and cooperation for procedures like chest physiotherapy.

The patient can be positioned lateral, sitting or prone, with rolls under the iliac crests. Adequate flexion in the sitting and lateral positions is brought about by an assistant if the patient is anesthetized or sedated. The puncture site can be L3,4 or L2, 3 in older children, but Dalens recommends a puncture at the L4, 5 or L5, S1 in children below 10 years to avoid direct trauma to the cord.\textsuperscript{67} The line joining the iliac crests crosses the L5 in neonates and in older children, and corresponding vertebrae are thus located.

The Tuohy needle with a curved hubbard tip is popular among epidural enthusiasts. The curve at the tip prevents dural puncture, while the laterally facing outlet allows easy threading of the catheter. Various sizes are available, 16G or 17G needles threading 18G catheters are commonly used in adults and adolescents. 19G needles with 22G catheters are appropriate in children up to 25 kgs. 22 and 20 G needles and smaller catheters are available. Spinal infusion catheters have been used in the epidural space with smaller needles. However, increased resistance to injection, difficulty in visualizing cerebrospinal fluid or blood in cases of misplacement, and difficulties in placement have dampened enthusiasm for their use.\textsuperscript{66,67}

Localization of the epidural space is done through documentation of loss of resistance through saline, or air, or the detection of negative pressure by indrawing of a hanging drop at the needle hub. Epidural lignocaine, bupivacaine, with or without opiates like morphine and fentanyl have been used either as boluses or infusion.\textsuperscript{62} However, intravenous opioid usage concomitant with neuraxial opioids is not advisable due to synergistic respiratory depression.\textsuperscript{66}

**SPINAL ANESTHESIA**

Spinal anesthesia is commonly used for lower abdominal or lower limb procedures like inguinal hernia repair and orthopedic limb surgery. The advantages it enjoys in children include better hemodynamic stability then adults and decreased incidence of postdural puncture headache. Nevertheless, the duration of the block is significantly reduced. (Bupivacaine 45 min compared from 3 hrs in adults) Spinal anesthesia used without sedation in preterm infants leads to a lesser incidence of postoperative apnea and bradycardia compared to general anesthesia.\textsuperscript{68} Most technical features remain the same as epidural anesthesia. The important difference lying in the use of a thin bore needle to deliberately puncture the dura with the smallest hole possible. Onset is usually faster, within 4-5 minutes, with reversal of block and recovery
of sensations after around three hours. Intrathecal opioids are associated with a significant risk of respiratory depression postoperative and warrant careful monitoring for 24 hours after surgery.

Older children have been shown to suffer postdural puncture headache, specially after large bore needle usage, but the headache is short lasting. Epidural blood patches have been used to produce good results in dural puncture headaches in adolescents.

Subarachnoid block is useful in lower abdominal or perineal surgery in ex-premature babies to avoid risk of post operative apnea. Care should be taken to puncture dura below L3 to avoid damage to the cord. The distance from skin to dura is approximate 0.5 - 1 cm in premature and term neonates respectively. Special 2.5 cm; 25 G, short bevelled needles are to be used for spinal anesthesia.

Bupivacaine alone or with fentanyl or morphine can be used in doses as given in Table 9.6.

NERVE BLOCKS

Ilioinguinal, iliohypogastric, infraorbital, dorsal nerve of penis block, and intercostal nerve block are administered at the beginning of surgery which provide good intraoperative and postoperative analgesia.

Penile Block

Circumcision, urethroplasty, hypospadias repairs can be undertaken with this technique, though the limited range of blockade means that it is totally adequate only for the first of the above mentioned surgery. The penile block anesthetizes the terminal branch of the nerve as it courses under the symphysis pubis. The anesthetic is injected in the subpubic space, between the pubic and perineal membrane on one side and the fibrous envelope covering the crura or corpora cavernosa on the other. The injection is made with the penis stretched downwards to keep scarpà’s fascia intact. The two puncture sites are located below each pubic ramii, on either side of the pubic symphysis, and the needle is introduced perpendicular to the skin and then medially and caudally till the “give way” of scarpà’s fascia is located.

DAY CARE SURGERY

Day care surgery is gaining popularity in pediatric practice surgery today as it cuts costs, avoids nosocomial infection and causes least disruption to family life. Improving standards of postanesthesia care units, better monitoring facilities and newer short acting agents like propofol, midazolam, fentanyl and remifentanil have made day care surgery possible. It is recommended that the surgery should be of short duration, with minimal blood loss. Day care surgery is however, contraindicated in premature infants less than 44 weeks post-conceptual age, extensive/painful surgery and children with poorly controlled and associated comorbid conditions (asthma, diabetes, seizure). Newer, rapid acting anesthetic agents like desflurane, propofol and sevoflurane as well as improved monitoring have made hospital stay times shorter than before.

SPECIFIC CONSIDERATIONS

Congenital Hypertrophic Pyloric Stenosis

The regular “projectile” vomiting in infants within the first week of life heralds the beginning of dehydration and dyslectrolytemia, if not adequately corrected. Hypovolemic children experience episodes of hypotension intraoperatively, and are poorly compensated for intraoperative fluid shifts. Dyslectrolytemia may predisposes to unpredictable, delayed responses to anesthetic agents, prolongs recovery and increases risks of intraoperative cardiac rhythm disturbances.

The large gastric volume preoperatively make these patients ideal candidates for pulmonary aspiration during induction of anesthesia when protective airway reflexes are absent and the endotracheal tube is not in place yet. Decompressions, reduce the risk but do not obliterate it entirely. Nasogastric tubes for gastric lavages and decompressions can be left open to atmosphere at the time of induction. Since the presence

</table>
of the tube hampers lower esophageal integrity, some practitioners remove it preinduction.

Safest among pediatric induction routines is the rapid sequence approach. After adequate preoxygenation an induction agent with short acting muscle relaxant are injected to provide rapid loss of consciousness with relaxation. A backward pressure on the cricoid, the Sellick’s maneuver prevents regurgitation while the patient is anesthetized. It is generally applied by an assistant till the airway is secured.

Uncooperative children, absence of intravenous access, anticipated difficulties in intubation, operator inexperience, deem alternative methods of induction, based on operator preference and patient status. Thus, induction techniques may range from inhalation induction with Sellick’s maneuver applied by an assistant, to awake intubation in a moribund infant with a difficulty airway.

Maintenance is with a combination of O₂, N₂O and volatile agent. Muscle relaxation is usually provided with a non-depolarizing agent. Intraoperative opioid usage mandates vigilant postoperative monitoring of respiratory function. Analgesia for intra and postoperative periods can effectively be provided with local infiltrations of anesthetic agents or caudal epidural blocks.

**Bowel Arteria**

Patients in this group are managed similarly to pyloric stenosis, bearing in mind that optimization of preoperative dyselectrolytemia and fluid deficit is essential to avoid intraoperative hemodynamic instability and postoperative morbidity. Rapid sequence, or similar induction techniques are safe approaches to avoid pulmonary aspiration. Maintenance can be with oxygen air and volatile agent plus opioid supplementation. The propensity for nitrous oxide to enter and expand closed cavities is the basis for the wisdom behind it’s avoidance.

Regional anesthesia, either as wound infiltrate or lumbar and caudal epidural blocks provides satisfactory analgesia. Catheter techniques allow the analgesia to be continued in the postoperative period as well.

**Gastrochisis and Exomphalos**

The hypothermic and dehydrated state that these babies commonly present will necessities rapid securing of intravenous access and fluid resuscitation with crystalloids like Hartman’s solution and colloids. Preoperative investigation are necessary to reveal current physiological status which has to be optimized.

Anesthetic induction techniques remain the same as previously described. The use of nitrous oxide during maintenance of anesthesia is strongly discouraged to avoid distention of the gut. To avoid oxygen toxicity the addition of air in the inspiratory mixture is utilized.

Parenteral opioids, as well as epidural catheters have been described for intra and post operative analgesia. Abdominal wall closure under tension may be associated with increased airway pressures, and in extreme cases, reduced blood pressures. In such condition a delayed secondary closure of the abdominal wall may be decided upon. Tense closures of the abdomen may necessitate elective postoperative ventilation.

**Inguinal Hernia**

Most institutions undertake this procedure as a day care surgery. Premedication is thus avoided. Pain from venipuncture is provided with EMLA cream used carefully.

Induction of anesthesia by intravenous or inhalation routes is dependent on the cooperation of the child and the preference of the anesthetist. Short acting agents like propofol, sevoflurane and desflurane contribute to a clear headed, faster recovery. Intubation can be avoided and a laryngeal mask airway or a face mask used to keep the airway patent. Pain relief is commonly provided by caudal epidural, lumbar spinal or local anesthetic infiltration into the wound.

**Esophageal Atresia and Tracheosophageal Fistula**

Tracheoesophageal fistula repair form a daunting challenge to the anesthetist both during induction and maintenance. The problems of securing an airway in a neonate is compounded by the uncertain ventilatory
path once the endotracheal tube is presumably in place. Endotracheal tube openings facing the fistula can direct ventilation into the stomach, or the blind pouch, if present.

Either inhalational or intravenous induction is practiced on these children, based on operator ease. The tip of the endotracheal tube is carefully positioned beyond the fistula to allow adequate ventilation. Any alterations in this arrangement as caused by jerky positional changes from supine to central or unmonitored head flexion or extension is to be guarded against vigilantly.

General anesthesia with a volatile agent and opioid is most commonly used in our institution. Nitrous oxide is avoided by some to prevent added gastric distention. Ventilation with low tidal volumes and high frequencies till the fistula is ligated prevents excessive gastric insufflation.

Epidural catheters threaded into the thoracic region via lumbar or caudal route provide good quality analgesia, their continuation in the postoperative period speeds recovery and reduces the incidence of pulmonary complication.

The surgery necessitate a close cooperation at all time between the surgeon and the anesthetist. The extrapleural surgical approach requires a constant communication to prevent tearing the pleura. The upper esophageal pouch is identified with a large catheter which has to be securely fixed for appropriate anastomosis. Intermittent release and ventilation of retracted lung is important whenever deoxygenation commences. Tracheal compression during surgery is immediately recognized by the high inflation pressure required to ventilate, it is important to readjust the retractor or check the clamps, prior to proceeding. Tense, distended stomach impeding ventilation may need to be decompressed prior to closure of the fistula.

**Congenital Diaphragmatic Hernia**

Notwithstanding current advances in ventilation like the extracorporeal membrane oxygenation, mortality from this condition can be between 30-50%.

Current outlooks prefer to stabilize the child’s oxygenation and hemodynamics prior to surgery. The best time for which is arrived at on discussion between the surgeon and anesthetist. Sick babies on ECMO, Nitric oxide or high frequency oscillatory ventilation may be operated in the ICU, if the logistical problems of transporting the patient in the OT is insurmountable.

Most neonates taken up for surgery are already intubated, sedated and have intravenous access for surgery. Anesthetic induction for children not intubated yet must avoid the dangers of nitrous oxide and the risks of mask ventilation. Both of these can increase pressures in the herniated gut contents and cause hemodynamic compromise.

Maintenance of anesthesia is with both opioids and muscle relaxants. Children hand ventilated during surgery mandate the availability of an airway pressure gauge to avoid barotrauma.

Epidural anesthesia with catheters have been described but is avoided in children with ECMO who are anticogulated.

**Neurosurgery**

Children with repair of neural tube defects, or cranially (encephalocele) or along the spine (meningomyelocele) may pose challenges in intubation. Large lesions impair supine positioning. Intubation in such cases is either in the lateral position or supine after positioning the child with pillows and towels. Latex precautions are essential.

Anesthesia can be induced either intravenously or by inhalational route if airway difficulty is anticipated. However, inhalational induction may increase intracranial pressures. Nitrous oxide, volatile agent and opioids with a muscle relaxant provide balanced anesthesia for all cases. Extubation is preferred only in an awake patient with satisfactory recovery of airway reflexes.

Increasing depth of anesthesia at times of noxious stimuli (Laryngoscopy, surgical stimulation) prevents sharp rises in intracranial pressures. Most induction agents, barring ketamine when used alone, lower ICP. Among volatile agents, Isoflurane has the most favorable profile in cerebral hemodynamics.

**Bronchoscopy**

Children with recently aspirated foreign bodies namely food, pose the dual risk of aspiration pneumonitis due to full stomach, and the danger of intrapulmonary swelling of the vegetable body. Older bodies are associated with pulmonary consolidations. If an acute respiratory compromise is not present,
regular chest physiotherapy preoperatively reduces intra and postoperative morbidity.

Spontaneously breathing children during bronchoscopy may prevent distal dislodgement of foreign bodies. On the other hand, control of ventilation with muscle relaxants allows a lighter plane of anesthesia to be developed, leading to a faster recovery. The ventilatory side ports of bronchoscopes enable connection to anesthetic circuits, but the large amount of leak often created necessitates high gas flow and pollution. Interrupting ventilation during surgical manipulation can cause sharp falls in oxygenation which has to be constantly monitored and communicated to the surgeon to allow transient cessation of surgery and resumption of ventilation.

Upper airway edema postoperatively is reduced by steam inhalation, nebulized epinephrine and steroids. Chest physiotherapy needs to be continued postoperative in patients with pulmonary complications.

**Trauma**

Basic principles of trauma management in a child remain the same as an adult. A rapid assessment followed by securing the airway and ventilation remains the first essential step. Younger children, with larger occiputs have a greater neck flexion than desired. With polytrauma, usage of shoulder rolls and pillows for optimal head positioning may not always be possible. Nasal intubation, airways and nasogastric tubes are avoided with evidences of basilar skull fractures like otorrhea, CSF rhinorrhea or periorbital ecchymosis.

As in adults all pediatric trauma cases are considered as full stomach, and appropriate anti aspiration precautions are taken. Rapid sequence “crash” induction are essential for commencement of anesthesia. Agents used for anesthesia are chosen carefully and titrated to avoid hemodynamics compromise while maintaining hypnosis and analgesia. Ketamine has been an attractive choice in hypovolemic patients, and carries a low risk of emergence delirium in children.

**Biliary Atresia**

It is characterized by a lack of patency of the extrahepatic bile duct with an incidence is 1:15,000 live births. In 10-15% of patients, it is associated with other abnormalities like absent inferior vena cava, intestinal malrotation, polysplenia and preduodenal portal vein.

Biliary atresia presents in infants from 1-6 weeks of age – these patients comes for Kasai Operation (Hepatic portoenterostomy). Preoperatively, these infants should be assessed for liver function tests. Liver function is fairly well preserved in the first few months of life. Ductal fibrosis begins as the infant grows and liver function deteriorates. The degree of liver dysfunction and the drugs ability to bind to plasma proteins are important variables in determining drug kinetics in patients with liver disease. Prothrombin time should be within normal limits. Fresh Frozen Plasma should be infused if there is any deviation from normal values.

Intravenous induction with thiopentone (4-5 mg/kg as 1%) can be achieved if venous access is present. Otherwise sevoflurane is the inhalational agent of choice for the induction. Before the introduction of sevoflurane, majority of our patients were induced with halothane when venous access was not present.

Anesthesia can be maintained with oxygen-nitrous oxide, isoflurane or sevoflurane and fentanyl. Air can be replaced with nitrous oxide as the bowel distension caused by nitrous oxide may caused technical problems to the surgeon. Atracurium is the muscle relaxant of choice as it is metabolized by Hoffman’s elimination.

Standard monitoring and care provided to the infants undergoing surgery should be provided. CVP and arterial cannulation are not necessary for uncomplicated cases. Intraoperatively care should be taken at the time of retraction of liver. Hypotension due to decrease venous return and bradycardia (vagal stimulation) should be noted and corrected immediately.

Intraoperative fluid should be replaced by Ringer’s lactate 6-10 ml/kg/hr. Repeated Blood Sugar estimations are done and 5% dextrose is added to Ringer’s lactate when the blood sugar is low.

It has been seen that liver blood flow and oxygen supply are better maintained during isoflurane than during halothane anaesthesia.

At the end of surgical procedure, if major fluid shifts have not occurred, blood loss has been minimal and the patient is warm, muscle relaxation is reversed with neostigmine (0.05 mg/kg) and atropine.
(0.02 mg/kg) and the trachea is extubated. Postoperative ventilation may be required in infants with other organ system failures (sepsis, cholangitis, or pneumonia) hypothermia and blood loss of more than one blood volume. These should be recovered in a high dependency unit.

**Liver Tumors**

Children with hepatic tumors usually present with abdominal mass. Infrequently they will have anemia, jaundice, and ascites. Liver function tests are frequently within normal limits. Hepatoblastoma has also been associated with sexual precocity due to liver’s exotrophic gonadotropic production and the Beckwith-Wiede-Mann syndrome.

Other associated disease with hepatocellular carcinoma are Von-Gierke’s disease, type I glycogenesis, cystinosis, extrahepatic biliary atresia, α-1-antitrypsin deficiency, hypoplasia of intrahepatic bile ducts, Wilson’s disease, Giant cell hepatitis, and Soto’s syndrome.

The principles about the anesthetic management of these patient is similar as those with biliary atresia. Cardiovascular evaluation and ECHO should be done to rule out any cardiomyopathy in patients who receive adriamycin before coming for surgery.

Hepatic resection is usually associated with massive blood loss, so invasive monitoring should done to measure arterial and central venous pressure. The blood loss is reduced with the use of ultrasonic aspirator. Two large bore peripheral intravenous cannulae and 2-3 lumen internal jugular vein cannulation should be achieved. Frequently ABG, chemistry and coagulation profile may be required. Urine output should also be monitored. Massive blood loss may require replacement of Fresh frozen plasma, and platelet concentrate in addition to blood transfusion. These patients may require ventilatory support postoperatively.

**Thoracic Surgery**

Alterations in lung ventilation perfusion ratios occur with changes in body posture. In the lateral position as in surgery, perfusion and ventilation is superior in the dependent and non-dependent lung respectively, in spontaneously breathing individuals. Altered chest wall compliance can account for these changes. Airway closure during tidal volumes can occur due to low functional residual capacity. A high metabolic rate and oxygen consumption, with low lung volumes vital capacities and residual capacities make lung separation a difficult proposition.

Preoperative assessment to deduce baseline physiological status is essential. A history and examination with baseline blood biochemistry and hematology is the same as for an adult. However, pulmonary function tests, though having been devised for children, may be hampered by poor cooperation. Pulse oximetry is a reliable non-invasive substitute for arterial blood gas analysis. Optimization and chest physiotherapy needs to continue to reduce postoperative morbidity.

One lung ventilation techniques, while widespread in adults are limited in children due to non-availability of equipment methods. These include:

- Simple surgical retraction – most commonly practiced, but can lead to anatomic damage.
- Double lumen tubes: size 28 or 32 french sizes are available for older children. Muraro tubes, consisting of two separate tubes attached to each other are available in sizes for smaller children.
- Bronchial blockers, either specialized univent tubes, or Fogarty catheters or single lumen tubes guided by fiberoptic bronchoscopic techniques provide alternatives.

Caution is recommended with usage of nitrous oxide, specially in relation to gas filled cysts in lobar emphysema. Positive pressure ventilation may expand an emphysematous lobe causing mediastinal shift.

Good postoperative analgesia is mandatory else the reduced chest wall movement consequent to pain promotes atelectasis. Older children can be motivated for chest physiotherapy once good relief is achieved. Epidural catheters, threaded through the lumbar and caudal route up the thoracic interspaces provide effective postoperative pain control with opioid or local anesthetic combinations. Opioids intravenously by boluses or infusions can depress respiration and consciousness. Intercostal and interpleural local anesthetic can provide temporary relief, but carry the risk of systemic absorption of the drug.

**Craniosynostosis**

It is the premature fusion of one or more cranial sutures and cause an abnormal skull shape. Most often
it involves only the sagittal suture and results in a deformity that is primarily cosmetic. These patients have normal ICP and intelligence. Without treatment, this may result in intracranial hypertension as the brain grows. Multiple suture craniosynostosis is most commonly seen in association with craniofacial anomalies, particularly Apert’s and Crouson’s syndromes which are also associated with hypoplasia of the orbits and midportion of the face.

The anesthetic problems in patients coming for craniectomy and frontal advancements are difficult intubation, fixation of endotracheal tube, blood loss, increased ICP (for this furosemide and mannitol may be required).

Repairs range from multiple craniectomies to removal of a single strip. Blood losses from scalp incisions can be significant necessitating transfusions. Venous air embolism may occur and vigilance is essential.72

**SUMMARY**

With the progress in different aspects of anesthesia, complicated pediatric surgical procedures are possible today. Better understanding of the physiology and pharmacology of the newer drugs has led to the advancement in anesthetic techniques. Rapid acting inhalational agent like sevoflurane has made induction and recovery quick and smooth. Parental participation in the induction procedure has made induction less traumatic. Intravenous induction has been facilitated by EMLA cream. Laryngeal mask airway has revolutionized the airway management in children, whereby tracheal intubation is avoided in majority of patients. It is also listed as a tool in difficult pediatric airway management. The concept of fluid therapy has recently being changed to infusion of balanced salt solution as primary maintenance and replacement fluid.

Postoperative pain relief is provided more by regional blocks and the child/parent/nurse can also control the analgesia demand to suit patient comfort.

Relief of Postoperative Pain in Children

For years acute pediatric pain management has been practiced without a clear rationale of analgesic therapy. Improved understanding of opioid and local anesthetic pharmacology in infants and children has led to the development of formal analgesic regimens for the management of pain particularly postoperative pain.1,2 Despite the advances in analgesic therapy, numerous studies show that postoperative pain is still inadequately treated in children, adolescents and almost ignored in infants due to following reasons (Table 10.1).

Every child, irrespective of age, must get adequate pain relief after as his/her right. A multimodal approach in pain relief has better pain relief with lesser side effect. This can be achieved by using combination of local or regional anesthesia unless contraindicated, opioids, and nonsteroidal antinflammatory drugs (NSAID) or paracetamol. The parents’ emotional involvement and child friendly environment also play an important role in pain management.

DEVELOPMENT OF PAIN IN THE FETUS AND THE NEONATE

Very little is known about the perception of pain by the fetus and the newborn. Early studies of neurological development concluded that the fetus and the newborn were not capable of having organized response to painful stimuli and could not perceive or localize pain.3 They had no memory of pain and therefore did not require analgesia even for very painful procedures. Recent studies however have shown that a fetus reacts to stimuli in utero and that newborn demonstrates hormonal changes in response to surgery that can be decreased by intraoperative use of narcotics and deep anaesthesia.4,5

New evidence suggests that human fetus pain pathways as well as cortical and subcortical center necessary for pain perception are well developed late in gestation and the neurochemical systems now known to be associated with pain transmission and modulation are intact and functional.6

PAIN ASSESSMENT

Pain assessment is necessary before prescribing analgesics. This gives information about efficacy of drugs, individual requirement, time to intervene for analgesia, deciding the route of administration and helps in the studies of analgesics drugs.

The assessment of pain is difficult in neonates and nonverbal age as they can not self-report about pain. The most accurate methods of rating pain are when child can himself report the site and intensity. Emphasis was placed on behavioral indicators (facial expression, cry and body movement), physiological parameters (heart rate, respiratory rate, oxygen saturation and intracranial pressure) and biochemical parameters (ACTH, beta endorphins, cortisol).

The following physiological and behavioral distress measures have been investigated in children as potential pain measures (Tables 10.2 and 10.3).7

Table 10.1: Factors responsible for under treatment of pain in children

- Opioid induced respiratory depression
- Potential for addiction
- Difficulty in assessing pain by physicians
- Inability to communicate pain by older children
- Fear of shot in some children
In neonates, a number of tools have been developed using facial expression, body posture, crying, heart rate, oxygen saturation and state of sleep. Neonatal infant pain scale (NIPS), and CRIES postoperative pain assessment scale is being used for validating neonatal pain. CRIES scale is valid for 32 - 60 weeks of gestation and uses parameters of C-Crying; R-Requires oxygen to maintain saturation greater than 95%; I-Increased vital signs; E-Expression; and S-Sleeplessness. 0-2 points given for each parameter with total score of 10 and score of 4 and above require analgesic supplementation.8

Pain in younger children (< 4 yrs) can be assessed by objective pain score (OPS). In this 0-2 points allotted for each physiological parameters, i.e. systolic blood pressure, crying, movement, agitation (confused excited), complains of pain and 4 or above to be treated for pain (Table 10.3).

The following methods are also used for pain assessments in children above 3 years (Table 10.4).

VAS (visual analogue scale) is used for pain assessment in children above 4 or 5 years depending upon education and understanding of the child. This has 0-100 mm marking on the horizontal scale, 0 is no pain and 100 is worst imagine pain. Child reports their pain on the scale.

### Design Issues

In designing a comprehensive plan for postoperative analgesia the objectives need to be clearly defined for each patient. These are dependent on various considerations as given below.

1. Type and site of surgery
2. Severity of pain expected
3. Predicted recovery course
4. Abilities of the patient
5. Patient and family needs and desires
6. Associated medical and psychological issue
7. Technical aspects of interventions

Decision regarding postoperative pain needs to be made with a complete understanding of the surgical procedures and expected convalescence.

### Type and Site of Surgery Planned

For example, superficial surgical procedure such as excision of small nevi produces significantly less

discomfort and pain compared to more invasive procedure such as excision of abdominal or thoracic masses. Additionally patient undergoing superficial procedures may be discharged hours after the surgery while the patient following more invasive procedure may have prolonged recovery including a period of time in the intensive care unit.

Severity of Pain

Mild analgesics are appropriate for the patient following superficial operations but are inappropriate for patients undergoing major operations like laminectomy or rhizotomy. As a result analgesic plan needs to be tailored specifically to the procedure. The benefit of epidural analgesia may far outweigh the potential disadvantage of urinary retention.

Abilities of Patients

In contrast to most adult patients, the age maturity and development level of pediatric patients vary with each child. Blanket assessments based on the surgical procedure and expected convalescent period ignore the needs of various pediatric patient populations that results from vide spectrum of development and cognitive abilities.

Needs and Desires of the Family

Past experiences of family members resulting from inadequate pain management of their child may require a more efficient management in future. Similarly, beliefs held by the family regarding the utility of analgesic and need for pain control also merit consideration, e.g. some families view opioid analgesics as routinely dangerous and addicting.

Associated Medical and Psychological Issue

For medical conditions such as severe liver or renal disease alter the metabolism and excretion of analgesics and have necessitated modification in standard pain management protocols. In the face of altered pharmacokinetics, doses and dosing intervals of analgesics may need to be varied.

Hospital environment can lead to significant behavioral and psychological changes leading to depression, anxiety and fear. This may be mistaken for pain in the postoperative period. Similarly, the behavioral issues surrounding children with known drug abuse problems further complicate postoperative pain management.

Technical Aspect

The technical issue revolves around procedures and equipments required for various pain control therapies. Regional analgesia continuous infusion using syringe pumps and more recently patient controlled analgesia (PCA) requires special equipment as well as technical skills.

THERAPEUTIC MODALITIES FOR PAIN MANAGEMENT

An effective systemic analgesic as well as route of administration already exists for pediatric pain management. Unfortunately the adequate analgesics and delivery systems are underutilized because of prevalent and persistent misconceptions regarding the propensity for respiratory depression and addiction in children and the actual presence of pain in certain age group. Similarly, potent and safe regional anesthetic/analgesic techniques so often used in adults are sparingly used in children due to lack of adequate skill and nursing facilities.

Nonopioid Analgesics

These agents provide relief of mild to moderate pain when used alone and provide additive analgesic when combined with opioids. Ketorolac, a recently released parenterally administered NSAID has shown analgesic potency similar to opioids. Ketorolac 2 mg is considered equipment to 1 mg of morphine by the IM route. Unlike opioids, ketorolac does not produce respiratory depression, reduction of gastrointestinal motility or addiction (Table 10.5).

Opioids

Opioid analgesics are the mainstay of pain management in the postoperative pediatric patient. No matter what opioid or administration technique is selected, careful titration and adjustment is usually needed.

Oral Route

Presence of nausea, vomiting and delayed gastric emptying due to the effect of surgery and anesthesia
precludes the use of oral analgesic in the immediate postoperative period. Codeine is the most commonly used oral opioid for relief of mild to moderate pain. Morphine can also be used for relief of moderate to severe pain. Parenteral Medication

Intravenous is the best route for analgesic administration wherever available and there is little of any indication for IM route in such children. Drugs can be administered as boluses or as continuous infusions. It is much easier to administer boluses and provide rapid relief of pain. The disadvantage includes short periods of analgesia followed by periods of inadequate analgesia before the next dose is administered. Besides side effects associated with higher blood level are common. Continuous infusion on the other hand provides continuous analgesia with low plasma level even in newborn and infants. Probably the best way to administer drug is to give a loading dose to provide patients comfort followed by an infusion. Morphine and pethidine are the most commonly used narcotics in India.

Use of Opioids in Analgesia

Paediatric anesthesiologists have noted more frequent ventilatory problems in neonates when opioids are used. Possibly this may be due to the fact that the clearance of opioids is decreased in neonates, leading to unexpected high blood levels and a greater risk of respiratory depression. Additionally infants may be more sensitive to opioids as a result of a more rapid transfer of opioids across the blood brain barrier. Yet neonate after major surgery suffers pain and requires opioid administration. As a result of these altered pharmacokinetics and pharmacodynamics slow titration of small incremental doses and careful observation is required to safely provide adequate opioid analgesia to the postoperative neonate.

Patient Controlled Analgesia (PCA)

Intravenous PCA is a novel method where a microprocessor operated infusion pump is programmed to deliver predetermined safe amount of intravenous opioid at specified interval on patient demand. The introduction of PCA in the pediatric population seems promising because it is self limiting when pain free patients go off to sleep, they can no longer medicate themselves. Unfortunately PCA is not applicable to children less than 7 years of age or those with minimal Cognitive skills. Another drawback is that it is an expensive device. PCA has been used in children 11 years and older with varying results but most adolescent use PCA responsible and with satisfaction. Morphine is the drug of choice. Instead of patient controlled, the same technique can be used as nurse controlled analgesia (NCA) is smaller children. The regimes are given Table 10.4.

Side Effects

Respiratory depression is the most feared and potentially serious side effect of opioids. The incidence of respiratory depression with μ-agonists is directly related to the dose of drug used. Minor side effect such as nausea, vomiting, urinary retention, drowsiness, hallucination, nightmare, light headedness and ileus occur no more frequency in children than in adults. Tolerance is an uncommon clinical problem in children when opioids are used in appropriate doses for short period of time.

Regional Anesthesia/Analgesia

Although, opioids are simple to administer, convenient and inexpensive means of managing postoperative pain the judicious use of specific regional anesthetic techniques offer better pain relief for some specific surgical procedures. Nerve block produces reliable and effective analgesia without the risk of sedation and respiratory depression. Such features make most neural blockade techniques suitable for outpatient surgery.

Peridural Administration

Peridural administration of local anesthetics significantly diminishes or abolishes nociceptive impulses from entering the Central Nerve System. Placing local anesthetics at the level of the spinal cord produces profound analgesia without producing the systemic sedation seen with opioid therapy. Caudal and epidural administration of local anesthesia are the chief route of peridural administration.

Local anesthetics can be given either as a single bolus or as a continuous infusion through a catheter. Single caudal injection of bupivcaine with epinephrine provides prolonged analgesia in children undergoing superficial inguinal and penile procedures lasting up to 23 hrs in children under 5 years and 6-10 hrs in older children.

Continuous infusion of local anesthetics through epidural or caudal catheters provides the opportunity to produce pain relief during the period of infusion. Infusion of bupivacaine in concentration from 0.1 - 0.25% at low rate of infusion provides excellent analgesia with bupivacaine level well under the toxic range.17

Peridural Narcotics

Peridural delivery of opioids analgesics produces prolonged and profound analgesia as they occupy opioids receptors in substantia gelatinosa of the spinal cord.18,19 Either administered as a single dose or as a constant infusion peridural opioid administration (Epidural, caudal or intrathecal) delivers concentrated amounts of opioids to the receptors of the cord.

Single dose of opioid administration at the beginning or end of a surgical procedure either in epidural or intrathecal space provides prolonged analgesia for up to 24 hours for in excess of IV opioids or epidural bupivacaine. Through catheters, continuous infusion and repeated intermittent losses can be administered. Catheters can be placed epidurally in thoracic, lumbar intrathecally. Combination of local anesthetic and morphine may potentiate the analgesic effect of spinal morphine. Combination of low dose of morphine 30 μg/kg along with bupivacaine 0.25% given caudally has been reported to give prolonged analgesia lasting about 16–30 hours with minimal or no side effects. Respiratory depression has not been reported with this low dose.20

REGIONAL ADMINISTRATION

Local Infiltration

Wound infiltration with local anesthetic provides pain relief following surgery especially in superficial procedures. The effect may last as long as 4-6 hours with bupivacaine and lignocaine.

Peripheral Nerve Blocks

Peripheral nerve blockade by local anesthetic allows interruption of sensory transmission along specific nerves or nerve groups. Systemic effects often seem with epidural techniques can be avoided since the specific region affected by surgery is targeted and the dose of local anesthetic used is likely to be smaller. Various types of nerve blockade use are given in the below (Table 10.6).

Penile Block

Penile block is being commonly used for circumcision and distal urethral surgeries. A short bevelled needle
Pediatric Surgery—Diagnosis and Management

is inserted in the midline at the penile pubic junction and advanced slightly laterally till fascia is penetrated. At this point, 1-3 ml of 0.25% bupivacaine with out adrenaline is injected and same is done on other side.

Caudal Block

Caudal anesthesia/analgesia is the most widely used neural blockade in children for the management of postoperative pain following surgical procedures on the lower abdomen, perineum and lower extremity. The clinical experience suggests that caudal anesthesia/analgesia is simple to perform, reliable and safe.21,22

Positioning and Landmarks

It is quite easy to perform in children. To aid positioning and performance of the techniques it is customary to give a light general anesthetic. The patient can be positioned in the lateral (sims) position, prone or the knee chest. In the lateral position the lower leg is only slightly flexed at the hip. The upper leg is flexed to a greater extent so that it lies over and above the lower leg. The advantages of lateral sims position include comforts for the patient, comfortable and familiar workstations for anesthesiologist and easy access to the airway.

Procedure

Confirmation of the bony landmark is the key to successful performance of the technique. In most children, the protrusion of sacral cornua can be seen without palpation. The shallow depression of the sacral hiatus can be seen between the cornua. In land marks are not easily visible, the coccyx may be palpated and the finger moved cephalad until the fingertip overlies the sacral hiatus with cornua on each side. The chosen needle (22 or 23 G, 2-3 cm long) is inserted at an angle of 45º–60º to sacrococcygeal ligament. The penetration of sacrococcygeal ligament has a characteristic feel or pop. The anterior wall of sacral canal is contacted and the needle is redirected so that it is line with long axis of the spinal canal. The needle is then advances 2-5 mm further.

Choice and Dosing of Local Anesthetic

Bupivacaine is the most commonly used agent for postoperative pain management, though there are various formulae to calculate the dose. Armitage has reported 98 percent success rate with a simple and easily remembered method of calculating effective analgesic volume of 0.5 ml/kg is used for sacral analgesia 1 ml/kg for lower thoracic analgesia and 1.25 ml/kg of 0.25% bupivacaine for midthoracic analgesia. Caudal morphine in dose of 30–50 mcg/kg has been found to be safe. The duration of analgesia lasts nearly 24 hours but close monitoring for respiratory depression is recommended for a minimum of 24 hours, particularly in infants.

The duration of caudal block analgesia can be extended use of additives like clonidine, preservative free ketamine, and preservative free morphine with bupivacaine. Caudal morphine is not used for day care procedures due to fear of delayed respiratory depression and urinary retention.

POSTOPERATIVE ANALGESIA

The plan of postoperative analgesia is decided before starting of procedures. Minor procedures are managed with infiltration of local anesthetic or regional blocks. Analgesia supplemented with rectal or injectable analgesics. Oral analgesics to be given at regular interval when orally allowed to the child. Major procedures require multimodal treatment for pain relief. Infusion or boluses of mixture of local anesthetic and narcotic through epidural or caudal catheter is the mainstay of severe pain management. Intravenous infusion of morphine or fentanyl via patient controlled or nurse controlled analgesia is an alternative if epidural catheter is not in situ. Morphine, pethidine or fentanyl was also given as rescue analgesic. It has

been observed that addition of NSAIDs rectal/oral by injection will improve quality of analgesia (Table 10.7).

**INHIBITION OF CENTRAL HYPERSENSITIZATION**

**The Concept of Pre-emptive Analgesia**

The surgical trauma creates a barrage of nociceptive afferent transmission which may alter the excitability of both peripheral and central neurons. Under general anesthesia the spinal cord is lightly anesthetized and receives massive afferent nociceptive input from the site of the surgery. Under regional anesthesia the spinal cord receives no nociceptive transmission. Prevention of the afferent “barrage” associated with the surgical stimulus may be accomplished by application of regional anesthetic techniques prior to incision. It has been hypothesized that pre-emptive analgesia can prevent neuroplastic changes within the spinal cord and the attendant physiologic sequelae.

It has also been hypothesized that the pre-emptive analgesia may produce prolong effects that long outlast the initial neural blockade. In laboratory models very high doses of opioids are necessary to suppress central hypersensitization once established. However, small doses of opioid administration prior to the barrage of nociceptive transmission can prevent the center hyperexcitability of dorsal horn neuron. This taken to its extreme conclusion, a single preoperative dose of analgesic could conceivably completely prevent postoperative pain.

The results of the several clinical studies have supported the concept of pre-emptive analgesia.

Mc Quay et al studied the effects of preoperative opioids premedication and regional anesthesia on the time to first request for postoperative analgesia often elective orthopedic surgery. If opioid premedication and regional anesthesia were not used, the median time to request the postoperative analgesia was less than 2 hours. Use of opioid premedication and regional anesthesia extended the median time to more than 9 hours. Pretreatment therefore decreased the need for postoperative analgesia.

To involve the management of pediatric pain, the attitude of doctors, nurses and parents must change. Children should not be denied pain relief as it will be unreasonable to expect a child to cope up with pain of a procedure that are treated with analgesics, local or general anaesthesia in adults. This subject needs further evaluation particularly in view ethnic and socio economic groups. Regional analgesia techniques in children are an important part of anesthesiologist armamentarium today. One thing is very clear that children also need adequate postoperative pain relief “to relieve pain in divine”.

**REFERENCES**

Imaging plays a crucial role in the evaluation of pediatric surgical conditions. In this chapter, we will discuss some of the common imaging procedures, their indications, contraindications and techniques, without going into the specific diseases and their imaging patterns. The procedures covered are: Micturating cystourethrography (MCU), retrograde urethrography (RGU), intravenous urography (IVU), investigation of anorectal malformations (ARM), genitography, ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), magnetic resonance cholangiopancreaticography (MRCP), conventional X-rays and barium studies. Before proceeding further it is important to know about two aspects: Intravenous contrast agents and Radiation protection.

**WATER SOLUBLE INTRAVENOUS CONTRAST MEDIA**

Of the radiopaque atoms examined, only three have so far been proven useful as a basis for the development of contrast media: Barium, bromine and, in particular, iodine because of the favorable position of the K-edge in the absorption spectrum. Of these iodine is the key atom whose properties have been exploited in the manufacturing and clinical application of contrast media. Iodine is the only element that has proved satisfactory for general use as an intravascular contrast agent.

The present day iodinated contrast media can be divided into four categories:

**Ionic Contrast**

a. Ionic monomer, e.g. diatrizoate, iothalamate  
b. Ionic dimer, e.g. ioxaglate

**Nonionic Contrast**

a. Nonionic monomer, e.g. iohexol, iopamidol  
b. Nonionic dimer, e.g. iotrolan, iodixanol

The classification above is based on whether the molecule ionizes in solution (i.e. body water) and whether it is a monomer or dimer. These two properties—ionization and dimerization confer upon the molecule certain advantages and disadvantages and cause a significant impact in clinical application as well. As a rule, nonionic contrast agents are preferred over ionic agents for intravenous injections because of significantly low rate of side effects.

Adverse reactions to these agents can be divided on the basis of the mechanism into: (1) Idiosyncratic anaphylactoid reactions, (2) Non-idiosyncratic reactions and (3) Combined reactions. They can be classified into minor, intermediate, severe life threatening reactions and deaths. These include flushing, nausea, vomiting, headache, urticaria, hypotension and bronchospasm. Although the non-ionic compounds cause lesser incidence of adverse reactions, they are much more costly than the ionic compounds.

**RADIATION PROTECTION**

Ionizing radiation has harmful effects—which may be non-stochastic (acute) and stochastic (chronic). Some of these include cataract, cancer, genetic mutations and even deaths. Therefore, there is a need to keep radiation exposure down to a minimum both for the patient as well as the radiation worker. Some of the measures that should be taken are:

1. One should take care to order investigations involving ionizing radiation only if other non-
radiating modalities like US or MRI cannot provide the requisite information.

2. During performance of X-ray examinations or CT scans, the minimum level of radiation exposure should be used. To reduce radiation, collimation of the X-rays should be done to include only the field of interest.

3. During fluoroscopic examinations, the exposure time should be kept down to a minimum and spot films taken only when required.

4. Use of digital radiography, if available, helps in reducing radiation exposure.

5. Lead aprons should be worn by the persons in the radiation environment (operator, child’s parents, others) for personal protection.

**MICTURATING CYSTOURETHROGRAPHY (MCU)**

**Indications**

- Recurrent urinary tract infections
- Posterior urethral valve
- Vesicoureteral reflux disease
- Neurogenic bladder
- Developmental anomalies like ectopic ureter.

**Contraindications**

- Acute urinary tract infection.

**Procedure**

Sedation is rarely required: The procedure is performed on an outpatient basis. Usually antibiotic cover is provided prior to the procedure and continued thereafter as and when required. Appropriate aseptic precautions are followed when performing the procedure. An initial radiograph of the Kidneys, Ureters, Bladder (KUB) area is essential for the following reasons.

- It provides an idea of the exposure factors in the individual patient.
- Any abnormal radiodensities like calculi can be detected
- Bone anomalies like spina bifida, hemi vertebrae can be identified which may be responsible for urinary problems.

**MCU can be performed in two ways:**

a. **Catheter technique:** After obtaining the preliminary radiograph, the perineum and periurethral area is cleansed using an antiseptic solution. Then the urethra is anesthetized using 1-2% lignocaine jelly and the child is catheterized using a 5 F or 6 F infant feeding tube. Sometimes, there might be resistance in advancing the catheter at the level of the external sphincter, wherein gradual injection of normal saline while advancing the catheter usually helps in solving this problem. After the urinary bladder has been entered 1:1 diluted water soluble contrast medium is injected gradually until full bladder sensation is achieved. Then the catheter is removed and the patient asked to void the contrast. In infants, there is usually spontaneous voiding when the bladder capacity has been achieved and hence it is essential to be ready to monitor the voiding by fluoroscopy and to take spot films.

b. **Suprapubic puncture technique:** An 18G Venflon needle can be placed into the urinary bladder via the suprapubic approach with or without US guidance. The suprapubic area is cleaned with an antiseptic solution and the needle is passed into the urinary bladder. If necessary, US can be used for guidance of the needle. The advantages of this technique are that trauma to the urethra can be avoided and this is especially suitable for very young children. During MCU the following spot films are generally obtained:

- The full bladder film: anteroposterior projection
- The voiding film: Bladder and urethra – bilateral anteroposterior obliques (males) (Fig. 11.1)
  – anterior and occasionally lateral (females)
- Spot films of the kidney area to look for vesico-ureteric reflux
- Postvoid film to assess for residue.

**RETROGRADE URETHROGRAPHY (RGU)**

RGU is performed in boys to assess anterior urethral strictures, postoperative status of urethral reconstructions, infrasphincteric rectourethral fistulas in patients with anorectal malformations and anterior urethral injuries. Water soluble contrast media are used in the same concentration as for MCU. The tip of
a Foley’s catheter is placed in the distal urethra and the balloon is gently inflated in the fossa navicularis. Alternately, an infant feeding tube can be placed at the same location and the tip of the penis pinched gently to prevent leakage of contrast. Contrast medium is then injected from a syringe. The patient is positioned in a steep oblique or lateral projection. Good coning of the area is important for a superior image. It is performed only in boys and accurately evaluates only the anterior urethra. Because of inadequate filling, the urethra proximal to the external sphincter cannot be evaluated satisfactorily.

**INTRAVENTOUS UROGRAPHY (IVU)**

The IVU should not be the first examination of the renal tract; it should be performed only when less invasive methods suggest it may be helpful and then is tailored to the problem at hand. This results in the need for fewer radiographs and a lower radiation dose, and yields specific answers for the clinician.

**The IVU is Indicated in the Following Special Cases**

- Complicated duplex kidney
- To visualize the nondilated ureter in exstrophy bladder
- Intermittent pelvi-ureteric junction (PUJ) obstruction (If US is normal)
- Medullary necrosis (following acute renal failure)
- Calyceal abnormalities.

**Contraindications**

- Acute renal failure
- Neonates in the first 24-48 hours.

**Technique**

Fluid and food are withheld for a few hours prior to the IVU. Only in older children bowel preparation with a laxative like pegelac or dulcolax is performed for 1-2 days before the IVU in order to get a good visualization of the renal areas. Blood urea and creatinine measurements should be obtained before IVU to assess renal function since contrast is contraindicated in patients with high blood urea and creatinine values. A preliminary (plain) radiograph is obtained before intravenous injection in order to:

- Assess radiographic exposure factors
- Detect renal calculi
- Detect nephrocalcinosis
- Identify vertebral anomalies
- Detect bone density alterations as in renal osteodystrophy.

*Nonionic contrast medium is preferred to ionic medium:* Intravenous contrast (IV) injection is made at a maximum dose of 3 ml/kg body weight. The exact timing of the films varies with the indication for the examination since every IVU now carried out is undertaken only to answer a specific question after a full US examination and an isotope study has been carried out (Fig. 11.2). It is important to remember that the visualization of the kidney on the IVU may be delayed in the neonate and radiographs taken at 2, 6 and 18 hours after the IV injection may be useful.

**ANORECTAL MALFORMATIONS**

Imaging plays an important role and is directed to define four things:

- Exact level of anomaly
- Anatomy of the anomaly
- Integrity of the perineal nerve supply
- Muscle mass available for reconstruction.
Plain Radiography

Conventional invertogram

It was first described by Wangensteen and Rice.

Technique

A radiopaque marker is placed at the anal pit. Then the infant is held upside down for at least 6 minutes with hips flexed. X-rays are performed in the lateral and anteroposterior projections with the centering at the level of the greater trochanter. Three lines, namely the PC line, I line, and anal pit line, are considered for interpretation.

An invertogram has a number of potential pitfalls which may give a false impression of the level of anomaly, e.g., due to contraction of the puborectalis at the time of X-ray, escape of air through a fistula from the blind rectal pouch, etc.

The Prone Cross Table Lateral View

The infant is put face down in a prone position with their hips flexed in the genupectoral position for at least 3 minutes. A cross table lateral film is obtained with centering over the greater trochanter. Relation of the level of blind rectal pouch with the PC and I line are assessed, as in conventional invertogram. The advantages of this technique over the invertogram include less time consumption, and more patient comfort.

ULTRASOUND (US)

It can be used to assess the distance of the rectal pouch in relation to the surface of the perineum. The scan is performed in sagittal plane either through the anterior abdominal wall or transperineally, with the infant in supine position. After locating the rectal pouch, the relationship of the distal portion of the pouch to the bladder base is determined. Pouch-perineal distance of < 1.5 cm is indicative of low anomalies. However, the distinction between high and intermediate anomalies cannot be made with this technique. Besides being operator dependent, the technique has a number of possible pitfalls and hence is not in much use.

Computed Tomography (CT)

CT may be used for:

i. CT invertography
ii. CT pelvis, for muscle attachment

i. CT invertography: The baby is placed in prone position for a few minutes. A midline, direct sagittal section is taken after AP topogram.

ii. CT pelvis: The patient is placed in the supine position and a lateral scout film is taken. Contiguous 4 mm axial sections are obtained parallel to the pubococcygeal line, from the superior margin of the pubic bone to the perineum. Intravenous, oral or rectal contrast are not required. CT is useful in assessing the muscular anatomy of the anorectal region both prior to and after surgery.

Magnetic Resonance Imaging (MRI)

It is superior to CT in providing images in multiple images without the risk of ionizing radiation. There is also excellent soft tissue contrast resolution and the anorectal muscle complex can be exquisitely demonstrated. It is important to remember that the use of body coil is associated with poor results due to poor resolution and so it is essential to use special coils like endorectal or wrapped around coils for this purpose.
Prudent set of investigations are required for the diagnosis and follow-up of patients with anorectal malformations. The following provides a guideline for the same:

**Day 1**

Conventional invertogram, prone cross table lateral view, US, CT invertogram.

**Postcolostomy**

- Distal cologram and MCU/RGU—to assess presence, level and type of fistula
- CT or MRI pelvis—for assessment of pelvic musculature.

**Postpull-through in Patients with Fecal Incontinence**

CT pelvis with rectal contrast or MRI pelvis— to assess muscle thickness, muscle damage, retracted fat, eccentrically located neorectum or neorectum lying outside the sling.

**GENITOGRAPHY**

**Indications**

- Ambiguous external genitalia (Intersex disorder).

**Contraindications**

- Local perineal infections.

**Technique**

Perineum is first outlined by placing and taping an opaque catheter in the midline. A radiopaque marker is placed at the external genital opening. Water soluble contrast medium is injected by retrograde route via the external genital opening so as to opacify the internal genital and urethral anatomy, i.e. vagina, uterus, tubes, urethral length, site and junction between the urethra and vagina and the length of the urogenital sinus. It can be performed by two techniques.

**Flush Technique**

This was first described by Schopner. A 10 ml syringe filled with a water-soluble contrast medium is placed at the external opening. With gentle pressure, an injection of 3-4 ml is made under fluoroscopy and spot films are obtained in lateral projection. AP view is only occasionally required. The process may be repeated several times if necessary.

**Catheter Technique**

A single hole catheter is used, whose tip should be placed in the common urogenital sinus. Water soluble contrast is injected via a syringe attached to the catheter and spot films are obtained. Catheter tip must be well compressed by hand to prevent leakage.

**ULTRASOUND**

Ultrasound is a very useful modality in the evaluation of pediatric diseases, both as a screening modality and for characterization of the disease. Ultrasound can be used to detect disease in the head, neck, chest, abdomen as well as to assess vascular system of the limbs. The basic technique and indications in various areas are described below.

**Cranial Sonography: Equipment and Technique**

Standard brain scanning includes sagittal and coronal planes. Non-standard planes can, and should, be used if they are helpful to outline pathologic states.
Currently most brain sonographic examinations are performed through the anterior fontanelle in both coronal and sagittal planes. Anterior fontanelle remains open until about 2 years, but is suitable for scanning only until about 12-14 months. More recently, color Doppler is being used to evaluate neonatal brain and vasculature.

A 5 MHz transducer is generally adequate for evaluation of most neonatal brains through anterior fontanelle. Occasionally, a lower frequency transducer is needed to ensure adequate penetration, especially in larger infants or older infants with closing fontanelles. Higher frequency transducers such as 7.5 or 10 MHz are helpful to evaluate superficial structures in the near field such as extracerebral spaces or cortex or in preterm babies.

Transducers with very small foot plates are well suited for premature infants because of smaller fontanelles. These transducers are also useful when scanning from posterior mastoid area or foramen magnum. Small linear array or convex transducers can provide quality images for scanning in axial plane through the squamous portion of temporal bone. This thin bone window usually requires a 3.5 MHz transducer.

Although cranial sonography can be used in any intracranial pathology, its main use is in the following diseases:
- Hypoxic ischemic encephalopathy
- Hydrocephalus
- Congenital brain malformations

US can also be used to study diseases in the abdomen and pelvis for detection of disease and for characterization of masses as cystic, solid or complex, assess vessels, detect metastases and for guidance of FNAC (Fine Needle Aspiration Cytology) or biopsy procedures. It can be used to detect pleural effusions and for guidance of FNAC or biopsy procedures wherein a chest lesion contacts the chest wall.

**Special Applications of US**

US including color flow imaging and Doppler have been studied in the diagnosis of vesicoureteric reflux, differentiating obstructive and nonobstructive dilatation of the renal collecting system, and in diagnosing high pressure hydrocephalus.

**TRACHEOESOPHAGEAL FISTULA (TEF)**

Plain film of the chest taken soon after birth reveals distended proximal esophageal pouch. In equivocal cases, a thin soft rubber catheter is passed into the proximal pouch and about 5 cc of air is injected. A lateral radiograph, centering on cervico-thoracic area is taken. Dilated proximal pouch with round distal margin is diagnostic. Presence of air in the stomach and the small intestine indicates esophageal atresia with a distal TEF. Use of radiopaque positive contrast in the proximal pouch should be avoided owing to the possibility of aspiration. Swallowed air or nasogastric tube with negative contrast (air) is usually adequate for the diagnosis and to demonstrate the extent of the proximal pouch. If positive contrast examination needs to be done then nonionic isotonic contrast medium or dilute barium is preferred with continuous fluoroscopic monitoring. The best way to demonstrate a H-type fistula is to inject radiopaque contrast (dilute barium or nonionic media) through a catheter with its tip just above the GE junction. Under fluoroscopic guidance, the catheter is gradually pulled out with continuous contrast injection at each level in succession. The patient should be evaluated in the lateral or steep prone position.

**BARIUM STUDIES**

Barium studies are performed in suspected intestinal tract disorders especially abnormalities like hypertrophic pyloric stenosis, colonic aganglionosis (Hirschsprung’s disease) and emergencies like midgut volvulus.

**Hypertrophic Pyloric Stenosis**

Nowadays US is usually the screening modality of choice. Although sonography is usually done without a NG tube, it would be preferable to do the examination with an empty stomach by aspiration through a nasogastric tube. During the study, the child is given a clear feed or preferably, normal saline can be injected through the NG tube. This distends the stomach providing a good window, improves visualization of the pylorus and stimulates peristalsis thereby maximizing pyloric muscle thickening.

In order to obtain a technically satisfactory barium study, a nasogastric tube should be passed and the
stomach emptied. With the patient in the prone oblique position the tube is placed in the antrum so that large amounts of contrast material are not required. Barium is injected via the tube under fluoroscopic control and spot films are taken. Raising the head end of the table would help to distend the pyloric region.

Hirschsprung’s Disease (Fig. 11.4)

Plain films may demonstrate a distal large bowel obstruction. Gasless rectum or at times a small gas filled rectum may be seen, especially on prone films and may help with diagnosis except where digital examination has introduced rectal air. The dilated colon proximal to the aganglionic segment can be recognized by its lumen.

Barium enema is used for confirmation of the clinical diagnosis. It is performed on the unprepared patient by inserting a straight tipped catheter to a point just beyond the anal sphincter. With the patient in the lateral position, barium suspension is introduced slowly, preferably by gravity drip infusion, under fluoroscopic monitoring. The infusion is stopped as soon as the transitional zone is demonstrated. Rapid infusion of barium can distend and mask the transitional zone. An immediate post-evacuation film as well as a 24 hours late film should be done to assess the degree of contrast clearance.

Intussusception

An intussusception is a prolapse of one portion of the bowel into another. The segment of the intestine that prolapses is called the intussusceptum and the receiving segment is the intussuscipliens. In children, the intussusception is usually ileocolic (90%); ileoileocolic intussusceptions make up most of the rest.

If the clinical diagnosis of intussusception is fairly certain, an enema is the most useful initial investigation since it is both diagnostic and therapeutic in all those who show no evidence of peritonism. Sonography can diagnose intussusception as a mass with a dense central echogenic area surrounded by the concentric sonolucent rim. Barium, water-soluble contrast, gas, or carbon dioxide have all been used for reduction, which can be performed either fluoroscopically or under US guidance.

Rarely children with chronic abdominal pain may have recurring jejuno-jejunal or ileo-ileal intussusception. These require barium follow through for diagnosis.

COMPUTED TOMOGRAPHY (CT)

The basic advantage of CT is that it demonstrates tissue anatomy with precision and clarity. The spatial resolution and anatomical detail of CT are superior to that of US. However, it has a lesser contrast resolution than MRI. It is not operator dependent and permits accurate measurement of tissue attenuation.

Patient preparation: Food and liquids should be withheld from all infants and children who will be sedated and/or receive intravenous contrast. This achieves two goals: 1. The child is thirsty enough to drink oral contrast and 2. It diminishes nausea during IV bolus contrast injection. Usually solids are withheld 4 hours and liquids 3 hours before the procedure. Sedation is almost always required under age 5 and might be required in older, uncooperative or anxious children.

Table 11.1 summarizes the important indications for CT examination in the pediatric age group.

MAGNETIC RESONANCE IMAGING (MRI)

MRI is a sectional imaging technique that depends on proton density, T1 and T2 relaxation, flow phenomena, magnetic susceptibility and diffusion. Image quality
is determined by homogeneity of the magnetic field and gradient strength, magnetic field strength and utilization of surface or specifically designed coils to increase signal to noise ratio. The standard imaging planes include the axial, coronal and sagittal planes though there are infinite planes possible and appropriate planes can be chosen according to the body part imaged. The advantages of MRI include good spatial resolution, excellent contrast resolution, multiplanar imaging and the lack of ionizing radiation.

Patient sedation is required in very young patients in order to obtain sufficient immobility during the scan. Table 11.2 lists the indications for MR in children.

### Table 11.2: Indications for MR in children

**Brain**
- Developmental anomalies
- Myelination disorders
- Neoplasms
- Infections, inflammations
- Vascular malformations
- Seizures
- Unexplained hydrocephalus, seizures.

**Spine**
- Developmental malformations
- Neoplasms
- Infections, trauma
- Atypical scoliosis.

**Chest**
- Vascular rings
- Congenital heart diseases
- Mediastinal masses
- Diaphragmatic hernia
- Foregut malformations
- Chest wall pathology.

**Abdomen and pelvis**
- Anorectal malformations
- Congenital anomalies of the genitourinary tract
- Neoplasms, infections
- Liver transplant evaluation
- Budd-Chiari syndrome
- Hemosiderosis.

**Musculoskeletal system**
- Trauma to joints
- Infections
- Neoplasms
- Osteonecrosis.

Table 11.3 compares CT and MRI for their advantages (√) and disadvantages (×):

Special Applications of MRI

In recent times, MRI has been used for demonstration of bile duct anatomy in a fashion that is similar to what is seen on ERCP. The technique is called MRCP (Magnetic Resonance Cholangiopancreatography). It uses heavily T2 weighted images to render the bile ducts hyperintense. 3D reconstruction of these ducts can then be performed and displayed for analysis. It plays an important role in differentiating the various causes of neonatal jaundice, e.g. neonatal hepatitis versus biliary atresia.

REFERENCES

Nuclear Medicine is a medical specialty that uses safe, painless, and cost-effective techniques to both image the body and treat diseases with the help of radioisotopes/radiopharmaceuticals. Pediatric nuclear medicine encompasses diagnostic, investigational and therapeutic applications of nuclear medicine technology in children. An isotope is a variant of an element, having the same atomic number but different atomic weight. The chemical behavior of an element is dictated by its atomic number and therefore all isotopes of the same element have identical behavior. Biological systems fail to recognize the differences between atomic weights and treat all isotopes in the same fashion. Radioactive isotopes are those isotopes, which emit radioactivity. The radioisotope or radiotracers can be detected in vitro or in vivo with ease, because it is possible to detect radioactivity with a great deal of sensitivity and precision by means of modern electronic equipment such as gamma or PET cameras. These cameras work in conjunction with computers used to form images and provide data and information about the area of body being imaged. Nuclear medicine imaging is unique in that it documents mostly organ function and to a lesser extent structure, in contrast to diagnostic radiology, which is based upon anatomy.\textsuperscript{1,2}

Nuclear medicine imaging is among the safest diagnostic imaging modalities available. A patient only receives an extremely small amount of a radiopharmaceutical, just enough to provide sufficient diagnostic information. Radiopharmaceuticals are physiologically innocuous and do not produce toxic or pharmacological effects or allergic reactions; nor do they result in hemodynamic or osmotic overload. In addition, the amount of radiation from a nuclear medicine procedure is comparable to, or often several magnitude less than, that of a diagnostic X-ray.\textsuperscript{3,4} The complex physiology and biochemistry of growth and development, the types of diseases in children, differences in body and organ sizes, radiation dose considerations, and even the behavior of the patients during the examinations all require special expertise, interest, training, dedication, equipment, and facilities for providing care for children, who may range in age from premature infants to adolescents. Sedation is not needed for most nuclear medicine procedures in children, but it is helpful if a child is unable to cooperate, especially when the procedures, such as SPECT or whole body imaging, require the patient to be still for 30-60 minutes. Sedated patients, both inpatients and outpatients, must be closely monitored by a physician or a nurse until they are fully awake.

Administered radiotracer doses in pediatric nuclear medicine have been developed by experience, taking into account the absorbed radiation dose, type of examination, available photon flux, instrumentation, and examination time. There is not a single formula to calculate administered doses in children. Dose estimation for pediatric patients based on adult dose corrected for body weight or body surface area is generally a good guide for most children over 1 year of age.\textsuperscript{1} The administered dose should be the lowest that will make it possible to obtain the needed information from the examination. For example, a skeletal scintigram to detect metastatic cancer in an infant can be performed with 18.5 MBq (0.5 mCi) of technetium-99m methylene diphosphonate (\textsuperscript{99m}Tc-MDP); however, if the problem is the diagnosis
of osteomyelitis, a radionuclide angiogram of the involved region is needed as part of the examination, and a dose of 74-111 MBq (2-3 mCi) should be used. Premature infants and newborns require special consideration and the concept of minimal total dose should be applied. Minimal total dose is the minimal dose of radiopharmaceutical below which the study will be inadequate regardless of the patient’s body weight or surface area.\(^1,3,5\) For example, the usual pediatric dose of technetium 99m pertechnetate (\(^{99m}\)TcO\(_4\)) for radionuclide angiography is 0.2 mCi/kg of body weight. However, a radionuclide angiogram obtained on a premature baby who weighs 900 gm requires a minimal total dose of 2 mCi. Attention to technical performance of the examinations ensures that the doses are as low as possible. This chapter deals with non-nephrourological uses of radiopharmaceuticals in pediatric conditions.

**NUCLEAR IMAGING IN PEDIATRIC ONCOLOGY**

Nuclear medicine plays an important role in the management of childhood malignancy. This is particularly true in the solid tumors of childhood. Scintigraphy is a complementary investigation to other radiological techniques. Scintigraphy is used in the initial diagnosis, staging, assessment of tumor response to treatment, detection of recurrence and the diagnosis of complications.

The major tumor imaging agents and radionuclides used in pediatric oncology are \(^{99m}\)Tc-phosphates, Gallium-67 Citrate (67-Ga), Thallium-201 (201-Tl), \(^{99m}\)Tc-sestamibi (MIBI), and Iodine-131 Metaiod benzyl guanidine (131-I-MIBG). The somatostatin analogue octreotide has been labelled with Indium-111 (111-In) or Iodine-123 (123-I) and has been investigated for use in neuroendocrine tumors namely the pituitary adenomas, carcinoids, pheochromocytoma, medullary thyroid carcinoma, paragangliomas, neuroblastomas, and islet cell carcinomas.

Chemotherapy is very effective for the cure and palliation of cancer; however drug resistance of malignant cells through various mechanisms is a major problem despite the use of multidrug therapy. One mechanism involves the “multidrug resistance” or MDR gene. This gene encodes for a membrane glycoprotein complex (PGP), which causes the active extrusion of certain chemotherapeutic agents from the cell, preventing their effects. Expression of this gene is a poor prognostic factor for children with soft tissue sarcomas and primary bone tumors. Radionuclide imaging can be used for the assessment of chemotherapy resistance. MIBI has been recognized to act as a substrate for the glycoprotein complex coded for by the MDR gene and is actively extruded from the cells expressing the gene. The potential advantage of MIBI tagged with \(^{99m}\)Tc lies in the noninvasive detection of the presence of PGP and therefore, predict response to therapy before initiation of therapy.\(^6,7\)

**Lymphoma**

Lymphoma in pediatric oncology accounts for approximately 10% of pediatric solid tumors; and usually presents with enlarged unexplained painless lymph nodes. The prognosis in lymphoma depends on accurate staging of the disease, adequate primary therapy, early detection of recurrent or nonresponding disease and the early commencement of secondary treatment.\(^8,9\)

Gallium (67-Ga) is well established in the management of lymphoma in children. 67-Ga has a sensitivity of 90%, specificity of 85% and accuracy of 84% in the detection of childhood lymphoma. 67-Ga has been reported to have 100% sensitivity in Burkitts lymphoma of childhood.\(^10\) Bone involvement occurs in 10-15% of lymphoma patients at some time during the disease and can be efficiently demonstrated by 67-Ga scan (Fig. 12.1). Few feel that bone scintigraphy has the same sensitivity as 67-Ga in detecting bone involvement and recommend that 67-Ga only be used in follow-up. Lymphoma may be seen on both bone scan and 67-Ga scintigraphy as focal or diffuse symmetrical metaphyseal abnormalities. 67-Ga has been found to be an accurate monitor of treatment response in lymphoma patients, However, others advocate the use of 201-Tl in lymphoma patients with bone involvement as the 201-Tl reflected response to treatment more accurately than 67-Ga. Accuracy of 88% for mediastinal disease, 82% for cervical and 88% for axillary disease and 81% for supraclavicular disease have been reported for 201-Tl. Use of \(^{99m}\)Tc-MIBI can predict the response to chemotherapy. While MIBI positive cases respond well, MIBI negative cases respond poorly. The somatostatin analogue 111-In
penttreotide (octreotide) has been used in non-Hodgkins lymphoma and Hodgkins disease and has a sensitivity of 87 and 98%, respectively. In follow-up both CT and MRI may have difficulties determining whether a mass is residual active tumor, recurrent disease or fibrotic/scar tissue. Positive uptake of 67-Ga scintigraphy is often the first indicator of recurrent disease.

Osteogenic Sarcoma and Ewing’s Sarcoma

Osteogenic sarcomas commonly occur in the metaphyseal region of the long bones (Figs 12.2 and 12.3). Pain in the region of the primary tumor is the usual presentation. A palpable or visible mass may be present. Ewing’s sarcoma may occur anywhere in the skeleton. It is usually in the bones of the lower extremities and pelvis but may affect flat bones, i.e. ribs, scapula, vertebra and pelvis. There is usually a soft tissue mass associated with the tumor and the initial presentation is usually due to pain, which may be accompanied by fever and tenderness. The bone scan is often requested to exclude osteomyelitis.

Osteogenic sarcoma and Ewing’s sarcoma of bone show intense osteoblastic reaction on bone scintigraphy. The radionuclide bone scan is the primary method to detect skeletal metastases. Photopenic malignant bone tumors have been reported but are very rare. The diagnosis of primary bone tumors is usually made on the plain radiograph. However, CT and MRI are important modalities to define the local extent of tumor. MRI defines the local soft tissue extension and invasion of the bone marrow; however, will often overestimate bone marrow involvement due to edema. CT assesses the bony aspect of the tumor and shows periosteal reaction, cortical destruction and mineralization of the matrix.
Bone scintigraphy is used primarily to detect skeletal metastases and the extent of the primary bone tumor. The bone scan however, does overestimate the size of active tumor due to the increased blood flow. Radionuclide bone scintigraphy will show a vascular primary tumor and variable uptake from patchy irregular bone reaction to a markedly intense focal uptake. Osteogenic sarcoma and Ewing’s sarcoma may present with metastatic disease usually to the lungs and bone. Bone metastases in osteogenic sarcoma are uncommon at diagnosis (2%), but due to longer survival with current therapy, bone metastases are more common after treatment. Patients with Ewing’s sarcoma more commonly have skeletal metastases at diagnosis.

67-Ga has been used but is not accurate in defining the extent of the bone tumor as 67-Ga will accumulate in repairing bone also. However, normal 67-Ga study is highly specific for no active tumor tissue. 201-Tl is a better agent as there is no uptake in reactive bone. 201-Tl is helpful in differentiating benign from malignant bone lesions. In the majority of patients with osteogenic sarcoma, major surgery has been performed often with amputation of a lower limb followed by a prosthesis or allograft limb reconstruction. There may be reactive bone for many months on plain X-ray and bone scan at the operative junction of bone or prosthesis. Increased uptake may be seen at the stump site, in the ipsilateral hip joint and sacroiliac joint on bone scans. There may be increased uptake in soft tissues adjacent to the prosthesis and in the contralateral limb due to altered weight bearing. 201-Tl is particularly useful in these situations as there is no uptake of 201-Tl in reactive bone unless there is recurrence of tumor. Persistent intense uptake at an amputation site usually indicates recurrent disease. Occasionally a destructive bone lesion, e.g. osteomyelitis in the sacroiliac joint may appear similar to a primary bone tumor on X-ray. These are negative on 201-Tl scans indicating a benign lesion.

Assessment of response to treatment is important. Radiological studies are of limited use in predicting response to therapy because they do not accurately reflect the amount of viable tumor cells in residual tissue because of edema, hemorrhage and necrosis in the tumor. 201-Tl more accurately reflects viable tumor burden than CT, MRI, 99mTc bone scans and 67-Ga. Poor tumor response shows persistence of 201-Tl uptake. The early identification of poor responders may lead to a change in therapy or alternate treatment, e.g. radiotherapy or surgery. It has been reported that 201-Tl has sensitivity of 100%, specificity of 87.5 and 96.5% accuracy for detection of recurrent disease after therapy and differentiation from post-therapy changes on other imaging modalities. CT and MRI are found to have a sensitivity of 95%, specificity of 50% and accuracy of 82.7%.

Soft Tissue Sarcomas

Rhabdomyosarcoma (RMS) is the commonest soft tissue sarcoma in childhood and is a highly malignant tumor arising from embryonal mesenchyme. The tumor usually presents with a solid mass. The tumor may metastasize to lymph nodes or hematogenously to the lungs and bone.

Bone and gallium-67 scintigraphy in RMS has a sensitivity of 100% and specificity of 95% for bone metastases. 67-Ga uptake is found in 86% of primary tumors. If the primary tumor is 67-Ga avid then in the detection of metastatic disease, 67-Ga shows a sensitivity of 94% and a specificity of 95%. 67-Ga is found to be useful in detection of local recurrence before other modalities and often prior to clinical detection. Bone scans are reported to be more sensitive than 67-Ga for skeletal metastases but 67-Ga is better for soft tissue metastases. 201-Tl can also be used for this purpose. There is no difference in tracer uptake relating to histologic cell type. Other agent that has been used in Soft tissue tumors have been pentavalent 99mTc DMSA (dimethyl succinic acid).

Neuroblastoma

Neuroblastoma is a malignant disease of the sympathetic nervous system and is the most common solid tumor in the first decade of life. Neuroblastoma can occur anywhere along the sympathetic nervous system from head and neck to pelvis, however occurs most commonly in the abdomen. Fifty percent of infants and 70% of older children have metastases at presentation. The tumor metastasises readily to local lymph nodes, bone, bone marrow and liver. Patients present due to the structural effect of the tumor mass and the consequences of metastases, including bone pain, proptosis or periorbital bruising and anemia or
pancytopenia due to marrow invasion. Humoral affects are rare but may result in diarrhea due to VIP secretion or paraneoplastic syndromes such as opsoclonus-myoclonus syndrome.

Nuclear scintigraphy using 123/131-I-MIBG scintigraphy plays an invaluable role for the detection of metastatic disease anywhere in the body in a single procedure (Fig. 12.4). It is used in conjunction with bone scans, which clearly delineate skeletal involvement and the anatomical imaging modalities (ultrasound, CT and MRI), which provide superior detail regarding attachment and relationship of tumor to vital structures (e.g. vessels, spinal cord and orbits) and the presence of hepatic metastases. MIBG is concentrated by normal sympathetic adrenergic tissue within neurosecretory granules as well as in tumors derived from the neural crest, proportional to the number of neurosecretory granules. Sensitivity is over 90% in patients with neuroblastoma at presentation, with near absolute specificity (99%) due to its tumor specific uptake.6-8 MIBG imaging is therefore essential for the initial staging of disease and has been recommended by the International Neuroblastoma Staging System. Tumor uptake non-invasively establishes the diagnosis and rules out other tumors such as Wilms’ tumor, lymphoma and rhabdomyosarcoma. This is particularly helpful when tumors are inaccessible to biopsy or when histology is non-diagnostic, as may be the case with small round cell tumors of childhood. Although an MIBG positive tumor in childhood is most likely to be neuroblastoma, other tumors of the neural crest, such as ganglioneuroblastoma and, in approximately 50% of cases, ganglieneuroma, pheochromocytoma, medullary thyroid carcinoma and retinoblastoma may also accumulate MIBG.

MIBG studies are also used to assess response to treatment and to distinguish post-therapeutic changes on CT/ultrasound from residual or recurrent viable disease. Recurrent disease is detected in the majority of cases on the MIBG scan; however, recurrent disease may be MIBG negative, particularly when recurrence occurs in the primary site. CT surveillance of the primary site is therefore recommended in addition to MIBG scans during follow-up.

**Langerhans’ Cell Histiocytosis**

Langerhans’ cell histiocytosis (LCH) is pathologically characterised by abnormal idiopathic proliferation of histiocytes and granuloma formation. LCH commonly occurs in childhood and has a broad spectrum of clinical and radiological features. LCH may involve any organ however, affects the skeleton in 60-80% of cases.

The initial workup in LCH should be done by a total body radiological skeletal survey and whole body bone scan. Bone scan should be preferred as the follow-up method. However, lesions not seen on bone scan, particularly in the skull should be followed by X-ray. 67-Ga and 201-Tl have also been used in LCH. More aggressive forms of LCH are more 67-Ga avid. This is particularly in the patients with soft tissue involvement, i.e. lungs, lymph nodes and multiple organ. The use of 201-Tl in LCH may play a role in assessing therapeutic response similar to its application in primary bone tumors.

**Wilms’ Tumor**

Wilms’ tumor shows avid uptake of 67-Ga and 201-Tl in 75% of cases. Bone metastases in classical Wilms’ tumor are rare and mainly occur in patients with clear cell sarcoma, which accounts for 4-5% of Wilms’ tumor patients. However, bone scan are usually performed in patients with Wilms’ tumor at initial diagnosis to exclude metastatic disease.

**Hepatoblastoma**

The main imaging modalities for liver tumors are CT and MRI. 67-Ga or 201-Tl has been used to assess hepatoblastomas and these tumors classically show
avid uptake on scintigraphy. 67-Ga is an important adjunct in the follow-up and detection of recurrence of disease particularly using SPECT. Most patients with liver tumors will have a total body bone scan at presentation to exclude skeletal metastases.

**Endocrine Tumors**

*Carcinoids and Pheochromocytoma*

They are imaged by 123 or 131-I-MIBG (Fig. 12.5). Octreotide can also be used. MIBG has the sensitivity and specificity similar to CT scans for the detection of pheochromocytoma in children. Faint uptake of 131-I MIBG is seen normally in the adrenal glands and must be differentiated from the moderate to intense uptake seen in pheochromocytoma.

*Thyroid Cancer*

$^{99m}$Tc pertechnetate thyroid scan is used in the investigation of thyroid carcinoma and tumor is seen as a cold nodule on scan (Fig. 12.6). $^{99m}$Tc pertechnetate uptake in the neck lymph node, although very rare in the presence of intact thyroid gland, is highly suggestive of metastatic thyroid cancer. Approximately 60% of children with thyroid carcinoma are found to have regional lymphadenopathy and around 25% will have pulmonary metastases at the time of initial presentation. After thyroidectomy whole body scanning with 131-I is done to detect any local and/or distant metastases. Prior to 131-I imaging, exogenous thyroid medications must be discontinued for at least 4 - 6 weeks to allow the endogenous TSH blood levels to rise and to ensure an adequate accumulation of radioiodine by the lesions.

*Adrenal Carcinoma*

67-Ga is found to be very useful in a child with adrenal carcinoma and accurately detects recurrence before other modalities do.

**Brain Tumors**

In childhood, brain tumors account for 15-20% of all malignancies and comprise the most common solid tumors. The spectrum of brain tumors in the pediatric population is diverse and quite different from that seen in adults. In contrast to adult brain tumors, the majority of pediatric brain tumors arise within the confines of the posterior fossa. Anatomical imaging modalities (CT, MRI) provide invaluable information regarding tumor location and relationship to vital structures and the presence of leptomeningeal metastases. However, the appearance of the tumor does not reflect its grade nor can postsurgical changes or postradiotherapy necrosis be accurately distinguished from viable tumor.

201-Tl has been investigated as a marker of tumor behavior and viability posttherapy. In pediatric brain tumors, the intensity of 201-Tl accumulation reflects tumor histological grade, proliferative activity, biological behavior and viable
tumor burden. An index based on the ratio of uptake in tumor compared to normal brain can be calculated and it has been found that an index greater than 1.5 is compatible with high-grade malignancy with 89% accuracy. In evaluating post-therapy changes, 201-Tl has high sensitivity for residual/recurrent tumor, however suffers from low specificity. Supratentorial gliomas occur in children but many are of low-grade and may not demonstrate 201-Tl accumulation. Pilocytic astrocytomas show intense 201-Tl accumulation, which would imply high-grade malignancy in the adult glioma group; however, they are of very low malignant grade. This highlights the importance of carefully correlating the result of the 201-Tl scan with the histopathology before implying a relationship between 201-Tl accumulation and tumor behavior. The relationship between the intensity of 201-Tl accumulation and tumor aggressiveness is not simply related in the childhood brain tumors as a whole as it is with a majority of adult brain tumors. 99mTc-MIBI has also been found to accumulate in a variety of pediatric brain tumors. A major limitation of MIBI is the accumulation of tracer within the choroid plexus, which may prevent diagnosis of adjacent tumor activity. Also, MIBI has lower sensitivity in detecting recurrence in comparison with 201-Tl, especially in low-grade tumors.

**Leukemia**

Leukemia commonly involves the skeleton. Patients may present with bone pain and are referred due to skeletal symptoms or recurrent fevers. A bone scan may be requested to exclude osteomyelitis or arthritis. As bony involvement does not affect prognosis or outcome, radiographic or scintigraphic evaluation of the skeleton is not routinely performed. In patients who have leukemia with focal clinical signs and symptoms, a bone scan will help to determine the cause of pain and exclude other pathologies, e.g. infection, fracture and avascular necrosis. Leukemic changes on bone scan are seen as a diffuse metaplastic uptake of the radiotracer with blurring of the growth plates and is often symmetrical; however focal abnormalities may also be seen. Photopenic areas (reduced radiotracer uptake) in the bone have been described in acute ALL and AML and during treatment particularly with high dose steroids causing avascular necrosis. 67-Ga has been used in leukemia; however, the main application for 67-Ga is in the investigation of infection.

**Lung Cancer**

Lung cancer in children is usually metastatic, including metastatic osteosarcoma, which can occasionally be detected in the lungs by 99mTc methylene diphosphonate (MDP) scintigraphy. Most other neoplastic processes, including lymphomatous involvement, require 67, Ga citrate or 201-Tl scintigraphy.

**NUCLEAR IMAGING IN THE EVALUATION OF PEDIATRIC BRAIN**

Radiotracers used for brain imaging can be divided into several distinct classes either by the type of instrumentation used [for example, single-photon emission computed tomography (SPECT) or positron emission tomography (PET)] or by the function being measured (cerebral blood flow, blood-brain barrier studies, metabolism studies, receptor studies, and so forth).

**Blood-brain Barrier Defects Imaging**

In healthy brain tissue, most hydrophilic radiotracers that are not transported into the brain via active or facilitated transport are excluded by the BBB. However, under a variety of pathological conditions, including cerebral tumors, abscesses, and intracranial injury such as subdural hematoma or intracerebral hemorrhage, the integrity of the BBB is disrupted, and these water soluble tracers can diffuse from the circulation into the damaged tissue.

Presently, 99mTc pertechnetate, 99mTc diethyleneetriaminepentaacetic acid (DTPA) and 99mTc glucoheptonate (GHA) are used for imaging studies of the BBB. 99mTc DTPA has advantages over 99mTc pertechnetate in that it is rapidly cleared from the circulation by glomerular filtration, allowing images to be obtained earlier with better target-to-background ratios. 99mTc GHA offers advantages over both 99mTc DTPA and pertechnetate since it is removed from the circulation even faster than DTPA by both glomerular filtration and tubular secretion, providing even higher lesion-to-background ratios.
Usual administered doses: 0.2 mCi/kg (7.4 MBq/kg); minimum dose 10 mCi (370 MBq), maximum dose 20 mCi (740 MBq).6,8,9

**Abscess Imaging**

X-ray CT and MRI are useful in the diagnosis of cerebral abscesses but cannot always differentiate abscesses from other types of lesions such as tumors, infarcts, or hematoma. Indium-111 labeled granulocytes have been reported to provide a sensitive method for the detection of cerebral abscesses. However, localization of 111-In granulocytes in cerebral abscesses can be inhibited in patients receiving corticosteroid treatment. Also, weak or moderate uptake of 111-In granulocytes is seen in some patients with brain tumors.7,9,10

**Tumor imaging**

**201-Tl**

Thallium-201 (monovalent cation) is widely and commonly used for the evaluation of myocardial perfusion. Besides, it also appears to be the method of choice for grading gliomas, assessing residual viable tumors following radiation therapy, and detecting malignant degeneration of low grade gliomas.

*Usual administered doses:* 0.03 - 0.05 mCi/kg body weight; minimum dose 0.5 mCi (18.5 MBq), maximum dose 2.0 mCi (74 MBq).7

**99mTc MIBI/TF**

These are myocardial perfusion agents, which also accumulate in brain tumors. Like 201-Tl, tumor uptake before treatment may indicate the potential to use this tracer as a marker of residual tumor after treatment. The spectrum of tumor avidity is similar to that of 201-Tl, while clearer identification of boundaries with MIBI/TF may be an advantage in some applications such as radiotherapy port planning.7

**99mTc GHA**

We at AIIMS are using this radiopharmaceutical very successfully, particularly in cases of residual/recurrent tumor post Sx/CT/RT (Fig. 12.7).

Usual administered doses: 0.3 mCi (11.1 MBq)/kg body weight, minimum dose 1 mCi (37 MBq), maximum dose 20 mCi (740 MBq).7

**Cerebral Perfusion**

A positron emission tomography measurement of CBF is done by infusion or a bolus injection of oxygen-15 (O-15). However, theoretically, this tracer is not ideal, and other positron emitting radiotracers for CBF imaging had been developed, including krypton-77 and C-11 Butanol.

**SPECT Measurement of Brain Perfusion**

Tracers used for this purpose must have the following characteristics:

1. Radiotracers must be lipophilic, allowing them to cross the BBB via passive diffusion with nearly complete firstpass extraction in the brain.

2. Their extraction must approximate unity and be independent of flow so that their initial distribution will be proportional to regional cerebral blood flow.

3. They must be retained within the brain in their initial distribution long enough for statistically valid tomographic images to be obtained. After diffusion into the brain, they must be retained by some mechanism such as binding to nonspecific receptors or metabolism to a significantly less lipophilic species that cannot readily wash out of the brain.

4. For high extraction efficiencies to be achieved, log P (a measure of lipophilicity) must be at least 0.5 and the molecular weight of the tracer must be < 650 and preferably < 400 KD.

5. It is also important that the tracer have low plasma protein binding.

**Technetium-99m-hexamethylene propylamine oxime (Tc-99m-HMPAO)**

99mTc HMPAO, a lipophilic complex, is rapidly cleared from the blood after intravenous injection. Brain uptake is 3.5 - 7.0% of the injected dose within 1 minute after administration.1,7 Maximum uptake is at 10 minutes. After diffusion of HMPAO into the brain, it is converted to a second, more hydrophilic complex that cannot diffuse back out of the brain. The formation
of the hydrophilic complex that is trapped in the brain is thought to be the result of a simple chemical reaction with glutathione, which is present in millimolar concentration in brain cells, although other mechanisms have been proposed. Approximately 15% of the initial cerebral uptake is cleared in 2 minutes, the other 85% remains in the brain for 24 hours. Redistribution of HMPAO within the brain does not occur for at least 8 hours and wash out is insignificant—only 0.4%/hr. Extracerebral uptake is distributed throughout the body, particularly in the muscles and soft tissues.

Approximately 30% of the administered tracer activity is found in the gastrointestinal tract a few minutes after injection, and approximately 50% is eliminated by this route in 24 hours. Approximately 40% of the tracer activity is eliminated in the urine within 48 hours.

**Technetium-99m Ethylcysteine Dimer (99mTc-ECD)**

ECD is a lipophilic agent that rapidly concentrates in the brain following intravenous injection at
approximately 6% of the administered dose. Peak uptake is at 5 minutes. After entering the brain, selective enzyme catalyzed hydrolysis of one of the ester groups to a carboxylic acid results in the formation of a negatively charged complex, which can’t diffuse out. The primary route of excretion of this agent is the urinary tract, and approximately 50% is cleared by the kidneys within the first 2 hours after administration. Approximately 11% of the tracer is eliminated via the gastrointestinal tract over 48 hours.1,7

This agent has following advantages over 99mTc HMPAO:

i. A 6 hours shelf life,
ii. More rapid blood clearance (shorter biological half-life,
iii. Lower background activity and
iv. Less radiation to the patient.

Because of the 6 hour shelf life, this radiopharmaceutical can be administered at any desired time required by the clinical problem being investigated. For example, it can be given during an ictal episode to map the regional cerebral perfusion during the ictus. A similar advantage may hold for performing SPECT during the time of abnormal brain activity in other paroxysmal disorders, such as migraine or transient cerebral ischemic episodes.

Cerebral Metabolism

Several metabolic substrates have been labeled with positron emitting radionuclides and used for PET studies of brain metabolism, including tracers for glucose metabolism, oxygen utilization, dopamine metabolism, protein synthesis, and amino acid transport.

Receptor Specific Radiopharmaceuticals

Mapping of brain receptor distribution has been done with PET and can also be achieved with SPECT. Several conditions of childhood may have an important component of receptor dependency. In the common problem of attention deficit disorder, dysfunction of the dopaminergic system may play a major pathogenic role. 123-I iodosobenzamide, a dopamine D2 receptor antagonist detectable by SPECT, may prove useful for investigating these hypotheses in this common disorder of the school going child.

CLINICAL APPLICATIONS

Normal Brain Development

Metabolism is initially more intense in the sensorimotor cortex, thalamus, brainstem, and cerebellar vermis; later it involves the parietal, temporal, and occipital cortex, basal ganglia, and cerebellar cortex, and finally the frontal cortex. By 1 year the pattern resembles that of adult and cerebral cortical areas approximately display a parallel evolution.11,12 These developments can be assessed and followed by Fluorine-18 Fluorodeoxyglucose (F-18-FDG) PET. The cerebellum/mean cerebral cortex index has shown to be higher in the neonatal period, slightly lower between 2 months and 15 years and thereafter is more or less identical to the adults.

Childhood Epilepsy

Epilepsy in children is treated with considerable success by medical means (anticonvulsants administered with appropriate clinical and pharmacologic monitoring). Some patients, however, do not respond to medical therapy. Surgical removal or disconnection of a portion of brain believed to contain the epileptogenic focus may control seizures. Interictal PET studies with temporal lobe epilepsy reveal a characteristic zone of decreased metabolism in the region of the epileptogenic focus. However, ictal studies demonstrate a more focal region of increased metabolism. These ictal and interictal changes in brain metabolism are found to be matched by corresponding changes in perfusion, revealed by SPECT. These functional abnormalities are frequently accompanied by normal or almost normal CT or MRI scans. In other instances the perfusion abnormalities are seen to extend far beyond the limits of structural lesions. Perfusion brain SPECT studies with temporal epilepsy have revealed characteristic time dependent changes in regional cerebral perfusion following a partial seizure (Fig. 12.8). During the earliest postictal period, there is increased perfusion involving the medial temporal lobe, succeeded by hypoperfusion of the lateral temporal cortex, and later of the entire temporal lobe. Ictal perfusion SPECT provides an opportunity to localize an epileptogenic focus. Ictal SPECT must be performed with tracer injection at the onset of ictus. Delayed injections of the tracer may demonstrate activation of secondary epileptogenic tissue and may lead to erroneous conclusion.
**Traumatic Brain Injury**

rCBF studies have a role in those children with brain trauma, who have any neurological consequences in the follow-up, but structural imagings are normal. In these children, usually abnormalities are seen throughout the brain but more frequently in the frontal, parietal and temporal lobes (Fig. 12.9).

**Moya Moya Disease**

Moya moya is a form of cerebrovascular disease occurring predominantly in children and characterized by an angiographic pattern of supraclinoid internal carotid artery stenosis, followed ultimately by a luxuriant pattern of collateral vascularization. This angiographic appearance has been likened to a puff of cigarette smoke. Serial cerebral perfusion studies can document the changes in cerebral blood flow that occur during the course of the disorder. The SPECT abnormalities are partly congruent with MRI and CT findings but show larger perfusion defects than those revealed by the other modalities. Hence brain SPECT offers an effective way of following the natural history of moya moya disease, and its noninvasive nature may offer an attractive alternative to serial arteriography. SPECT may play an important role in evaluating the success of proposed treatments for the disorder, such as superficial temporal artery middle cerebral artery bypass.

**Complications of Extracorporeal Membrane Oxygenation**

In newborns undergoing extracorporeal membrane oxygenation (ECMO) for refractory respiratory failure, 99mTc HMPAO/ECD SPECT can be used to investigate the status of cerebral perfusion. Significant perfusion defects in either the ipsilateral or contralateral hemisphere are documented, whereas only few patients show abnormalities on ultrasonography, CT or MRI.

**Effect of Hypothermia and Hypoxia**

Surgical repair of complex congenital heart disease in very small children is possible today because of advances in anesthesia and techniques of hypothermia with hypoxia. This method, however, carries a risk of brain damage. A known complication of hypothermia with hypoxia is the choreoathetosis syndrome (CAS). In these patients, SPECT may show striking focal rCBF abnormalities at both the cortical (frontal, parietal, and temporal cortex) and subcortical (anterior basal ganglia) levels. The distribution of the perfusion abnormalities is not predictable from clinical examination and CT and MRI are usually normal or show only generalized nonspecific abnormalities. These cerebral perfusion abnormalities may have important implications for developmental outcome in these children.

**BRAIN TUMORS**

Cancer continues to be the second leading cause of death in children under age 15 years, with central...
nervous system tumors constituting the most fatal group of solid tumors in children. Some may be cured with combined surgery and external beam irradiation, hyperfractionated therapy, or stereotactic radiosurgery. The promise of these new approaches to treatment of childhood brain tumor increases the importance of developing accurate methods for the assessment of residual disease after primary therapy.

Both CT and MRI have high sensitivity and specificity in the diagnosis of brain tumors in children, but these structural imaging methods have limitations in their ability to detect tumor viability. CT is often unable to distinguish between tumor presence and nonspecific brain injury. MRI, likewise, frequently cannot differentiate radiation effect from residual or recurrent brain tumor. Functional imaging (SPECT and PET), on the other hand, may detect the presence of active tumor. In combination with CT and MRI, this ability is useful for diagnosing residual brain tumor following therapy and differentiating between recurrent tumor and radiation necrosis.

**Cerebrospinal Fluid Studies**

Radionuclide evaluation of the cerebrospinal fluid (CSF) kinetics includes radionuclide cisternography (Fig. 12.10) and the evaluation of diversionary shunts. It can be helpful in the detection and localization of CSF leaks such as rhinorrhea or otorrhea. Indium-111-diethylenetriaminepentaacetic acid (DTPA) is the agent most commonly used in cisternography. The pediatric dose is 1 mCi for $^{99m}$Tc-DTPA and 50-100 $\mu$Ci for $^{111}$In-DTPA. The technetium-$^{99m}$Tc radiopharmaceutical has a lower radiation dose and better imaging characteristics, but the observation period is limited to 24 hours after administration of the tracer. This is rarely a problem in the evaluation of children’s CSF dynamics. Both agents are administered into the subarachnoid space via lumbar puncture. Other sites of injection include the cisterna magna or a lateral ventricle. Immediately following injection of the tracer, a static image of the area of administration is obtained to ensure proper injection technique. Serial imaging at 1, 2, 4-6, and 24 hours is carried out, including anterior, posterior, and lateral views. In the assessment of CSF leaks, more frequent imaging is required, with attention to patient positioning in order to maximize the chances of identifying “leaking” tracer with CSF.

In CSF diversionary shunts, 70-500 $\mu$Ci of $^{99m}$Tc as pertechnetate in 0.1-0.2 ml is injected in the appropriate site of the shunt tubing, depending on the question being asked. When a CSF shunt is patent, tracer is absorbed rapidly within the body. Rapid absorption of the tracer takes place in the peritoneum with ventriculoperitoneal shunts. Similarly, rapid absorption of pertechnetate occurs in patent ventriculoatrial shunts. Careful technique to avoid extravasation of the tracer is critical. If the shunt is occluded, pertechnetate remains within the shunt tube and is not absorbed. CSF shunt flow can be evaluated visually by observation of the serial images. A region of interest over the injection site permits the measurement of the half time of tracer disappearance. Normal values for $T_{1/2}$ are 0.5-6.0 minutes. CSF flow rates can be calculated if the volume of initial distribution of the shunt reservoir is known. CSF shunt flow rates are normally in the range from 0.2 - 0.3 ml/minute. If the shunt does not seem to flow after a few minutes of observation, the patient may be moved or the shunt reservoir can be pumped and additional images obtained to ascertain whether there is any flow under these conditions.

Fig. 12.10: Cisternography (ventriculography) showing abnormal tracer accumulation in the ventricles (arrow) in a case of communicating hydrocephalus.
IMAGING OF THE THYROID

Thyroid scintigraphy in children is indicated in the evaluation of thyroid and neck masses in order to determine their level of function and in the detection of ectopic thyroid tissue. Radionuclide assessment of thyroid function is used in the 131-I treatment planning for hyperthyroidism in pediatric patients in whom medical therapy has failed or when the patient (or parents) refuses surgery. 131-I whole body scan is very useful in the detection of local recurrence and metastatic disease as well as in 131-I treatment planning and follow up in children with thyroid cancer.

In India, thyroid scintigraphy and uptake for the assessment of children with benign conditions are carried out using 131-I, as 123-I, which is the agent of choice for this population, is very costly and not available. Imaging is done 24-48 hours after the oral administration of 25-50 $\mu$Ci of 131-I. However, for the assessment of metastatic disease and iodine turnover measurement in patients with thyroid cancer prior to treatment, 131-I is more suitable. The biochemical behavior of 131-I is identical to that of stable iodide. Organification defects can also be diagnosed with this tracer using the perchlorate discharge test.7,13

99mTc pertechnetate is trapped by the thyroid in the same fashion as iodide but is not organified. It is released from the gland after trapping and can be washed out of the thyroid by perchlorate. Scintigraphic images must be obtained while 99mTc-pertechnetate is in relatively high concentration in the plasma. Thyroid imaging is complicated by the fact that 99mTc pertechnetate is taken up by the salivary glands as well as the thyroid and is eliminated in the saliva. 99mTc pertechnetate activity in the saliva may be intense enough to overshadow uptake by an ectopic, hypofunctioning gland. Imaging of the thyroid following 99mTc-pertechnetate administration begins 5-10 minutes after intravenous injection of 2-5 mCi of the radiotracer.

Normal Thyroid Gland

The normal thyroid gland reveals a homogeneous distribution of tracer activity (Fig. 12.11). Slight asymmetry in lobe size is common, with the right lobe usually being larger. In most patients, tracer activity in the region of the isthmus is not seen. Rarely, a pyramidal lobe is seen extending up from the isthmus.

Radioiodine thyroid uptake is calculated at 2 and 24 hours after administration of 5-10 $\mu$li of 131-I. Normal values for radiotracer uptake ranges at AIIMS are from 5-15% at 2 hours and from 15-35% at 24 hours.

Hyperthyroidism

Hyperthyroidism in children with a diffuse goiter is usually because of Graves’ disease. In Graves’ disease radiotracer uptake is high; however, when iodine turnover is very rapid, the radiotracer leaves the thyroid and 24-hour uptake values may be normal. Scintigraphy although not needed in children with obvious Graves’ disease, reveals diffusely increased radiotracer uptake with markedly reduced radiotracer concentration in salivary glands (Fig. 12.12). Toxic nodular goiter, either uninodular or multinodular, is another cause of hyperthyroidism. In patients with a nodular thyroid, thyroid scintigraphy can reveal toxic adenomas, which appears as increased focus of radiotracer with decreased/no radiotracer uptake in rest of the gland.13

Thyroid Nodule

Thyroid nodules are classified as “functioning” or “nonfunctioning,” depending on the amount of radiotracer accumulation. In children with thyroid nodules, scintigraphy differentiates solitary from multinodular goiters and can identify lesions not palpable in patients originally thought to have a
solitary nodule. A neck mass that does not accumulate radiiodine may coexist with a normally located, bilobed thyroid gland. The problem for the physician is to determine whether the mass is a lymph node, cyst, hemorrhage, abscess, metastatic deposit, or benign or malignant neoplasm. Ectopic thyroid tissue can be identified if it accumulates the radiotracer (Fig. 12.13). In nongoitrous hypothyroidism, the incidence of ectopic thyroid tissue in children ranges from 22-75%. Therefore, an important use of thyroid scintigraphy in patients with a midline neck mass is to identify and locate functioning thyroid tissue prior to surgery in order to avoid inadvertent excision of an ectopic thyroid gland.13

Subacute (de Quervain’s) Thyroiditis

In subacute (de Quervain’s) thyroiditis scintigraphy helps to distinguish the hyperthyroidism of subacute thyroiditis from that due to Graves’ disease and may reveal patchy radiotracer uptake. The 2 and 24 hour radioiodine uptake is also very low. With clinical recovery, the scintigraphic abnormalities disappear.13

IMAGING OF THE LUNG

Nuclear medicine offers imaging methods to assess regional pulmonary blood flow and ventilation, gas and fluid transport across the alveolocapillary membrane, mucociliary clearance, pulmonary aspiration, and parenchymal disease. Indications for pulmonary scintigraphy in children are pulmonary artery agenesis, hypoplasia, stenosis; pulmonary aplasia, hypoplasia; pulmonic valve stenosis, pulmonary sequestration, pulmonary embolism, alpha-antitrypsin deficiency, congenital diaphragmatic hernia, arteriovenous malformation, bronchopulmonary fistula, pectus excavatum, lobar emphysema, human immunodeficiency virus (HIV) related pathology, cyanosis, asthma, tumor, sarcoidosis, pneumonia, burns, irradiation, cystic fibrosis, bronchial occlusion, infection or inflammation, scimitar syndrome, swyer james syndrome and prior to and/or following lung surgery.7

Pulmonary perfusion scintigraphy is performed with 99mTc labeled macroaggregated albumin (MAA) (Fig. 12.14). Radiolabeled macroaggregates define the pattern of pulmonary perfusion by the principle of increased uptake can result from islands of hyperplastic thyroid tissue, with decreased or absent uptake elsewhere in the gland.
capillary blockade. Radiolabeled particles ranging in size from 10-90 μ occlude precapillary arterioles and some capillaries. Untoward effects are not observed, since only a small percentage (0.1%) of the arterioles is embolized. The biological half-life of the particles in the lungs is approximately 7 hours. Peripheral venous injection of 99mTc MAA is performed during normal breathing. The administered dose of radioactivity and number of particles are adjusted according to the patient’s age, weight, and clinical status. The patient receives 1.85 MBq/kg (50 μCi/kg), with minimum and maximum doses of 7.4 MBq (200 μCi) and 111 MBq.

Fig. 12.14: Normal pulmonary perfusion scan
Nuclear Imaging in Pediatric Surgery

155

(3 mCi), respectively. Newborns should be injected with no more than 50,000 particles, 150,000 at 1 year of age, and 500,000 thereafter to adulthood. Patients with severe pulmonary disease and those with suspected right to left shunts should be injected with smaller numbers of particles (<10,000). Following injection, SPECT or eight view planar images are obtained in the anterior, posterior, right and left lateral, and anterior and posterior oblique projections. Fewer views are adequate when the only purpose of the study is to determine left to right differential perfusion ratios. Multiple views are evaluated by subjective criteria and regional lung perfusion between the two lungs and in various lung regions can be quantified by computer analysis.

To measure alveolocapillary permeability, low molecular weight compounds that can cross the alveolocapillary membrane, such as 99mTc DTPA, can be used to detect membrane abnormalities. Such studies may be helpful in children with immunodeficiency virus. For 99mTc DTPA aerosol studies, the patient breathes the nebulizer output through a facemask. Usually no more than 10% of the 1.11 GBq (30 mCi) of radiopharmaceutical placed in the aerosol device is delivered to the patient. Posterior planar images are obtained, and regional washout rates are measured and used to detect increased permeability of the alveolar epithelium. Normal values are not available for children.

In patients with pulmonary hemorrhage, arteriovenous malformation, or lung sequestration, 99mTc pertechnetate or other 99mTc agents, including red blood cells, DTPA, or sulfur colloid, are used.

Inflammation and Infection

In patients with recurrent localized pneumonia, a 99mTc-MAA perfusion scan can help reveal a possible structural abnormality. Gallium-67 citrate or 111-In or 99mTc granulocyte imaging can document and quantify infections in children. With 111-In oxime, the patient’s leukocytes are labeled and readministered. Imaging is performed after 24 hours. A disadvantage of 111-In white blood cell (WBC) scintigraphy, particularly in children, is the radiation dose to the spleen, liver, and bone marrow. 99mTc HMPAO labeled WBCs or 99mTc antigranulocyte antibodies result in much less radiation exposure than do 111-In WBCs (Fig. 12.15).

The administered dose in the case of 67-Ga is 3.7 MBq/kg (100 μCi/kg). The usual total administered dose of 99mTc HMPAO WBCs is 37-296 MBq (1-8 mCi), depending on patient size and labeling efficiency.7

IMAGING OF THE CARDIOVASCULAR SYSTEM

In children with congenital heart disease, planning appropriate therapy often requires the detection and quantification of left to right shunts, determination of regurgitation in valvular insufficiency, and assessment of right and left ventricular ejection fraction.

First pass radionuclide angiocardiology is used in the detection and quantitation of left to right shunts and in the assessment of right and left ventricular ejection fraction (Fig. 12.16). Gated blood pool angiography is useful for the determination of regurgitation in valvular insufficiency and is the most accurate way to make this measurement.14 Radiouclide angiocardiology can be performed in children of any age, including premature infants. Detection and quantitation of left to right shunting...
require experience, understanding of cardiovascular anatomy and physiology, and meticulous attention to technical details. The method consists of the rapid (<2 seconds) intravenous injection of pertechnetate. Poor bolus injections result in poor studies. Deconvolution methods permit evaluation of shunt studies resulting from bolus inadequacies to a certain degree, but it is better to inject a sharp bolus. Technetium-99m sodium pertechnetate in a minimum total dose of 148-185 MBq (4 to 5 mCi), 7.4 MBq/kg (200 μCi/kg) is often used, but other 99mTc radiotracers can be used as long as the volume injected is small. Ultrashort lived radionuclides such as iridium-191m result in a low radiation dose and permit multiple serial evaluations.

Monitoring the passage of the bolus through the cardiovascular system for 20 seconds is adequate for detection of shunts and measurement of ejection fraction in children. Visual assessment is supplemented by quantification in the diagnosis of shunts, measuring ejection fraction, and detecting major structural abnormalities. Appropriate regions of interest are selected. Left to right shunts can be expressed as pulmonary to systemic flow ratios (Qp:Qs) by analysis of a pulmonary time activity curve.

Ejection fraction of the right and the left ventricles can be estimated rapidly and accurately (Figs 12.17 and 12.18). One must identify the chambers of the right and left heart as the tracer passes through them. Summed end diastolic and end systolic images are utilized to increase the statistical reliability of the results. Ventricular ejection fraction is calculated as the difference of end diastolic counts and end systolic counts divided by end diastolic counts. Parametric images, such as the stroke volume image, can be used to display regional ventricular contraction.

Left ventricular ejection fraction can be obtained in children by gated blood pool angiography. Indications in children are measurement of regurgitant fraction, cardiomyopathies, cystic fibrosis, thalassemia, prelung transplantation assessment, assessment of doxorubicin (Adriamycin) toxicity, postoperative assessment in congenital heart disease. Gated blood pool angiography does not require special attention to the speed or the volume of radiopharmaceutical injected and provides better image resolution because longer observation times are possible. In children, the longer duration of the study, 20-30 minutes, presents problems not encountered by the shorter radionuclide angiography for simple determination of left ventricular ejection fraction. Because of anatomical overlap of the cardiac chambers, there is greater variation of estimated ejection fractions. Right ventricular ejection is difficult to estimate with this method.

Indications for myocardial perfusion scintigraphy are postoperative evaluation of arterial switch operation for TGA (transposition of the great arteries), Tetralogy of Fallot repair, Mustard-Senning operation, Mucocutaneous lymph node syndrome (Kawasaki disease), Anomalous left coronary artery, cardiomyopathies, and thalassemia. SPECT can effectively detect myocardial perfusion abnormalities in patients with anomalous origin of the left coronary artery from the pulmonary artery, which is often accompanied by myocardial ischemia or infarction. Mucocutaneous lymph node syndrome (Kawasaki disease) also impairs myocardial blood flow. In
**Fig. 12.17:** MUGA scan to calculate left ventricular ejection fraction

**Fig. 12.18:** MUGA scan to calculate right ventricular ejection fraction
surgery for transposition of the great arteries, the origins of the coronary arteries are reimplanted and scintigraphy done with Tl-201/99mTc. Tetrofosmin provides unique information about myocardial perfusion.

**IMAGING OF THE MUSCULOSKELETAL SYSTEM**

Skeletal scintigraphy with the 99mTc labeled phosphates is a valuable technique for diagnosing and determining the extent of skeletal disease in children. These radiopharmaceuticals are highly sensitive for demonstrating skeletal pathology, often before radiographs are abnormal. In the absence of pertinent clinical history, this high sensitivity is accompanied by a relatively low specificity for most disorders. To improve specificity, other radiopharmaceuticals are useful in evaluating certain skeletal diseases.

Technetium-99m MDP is commonly used for bone scintigraphy (Fig. 12.19). An intravenous injection of 99mTc-MDP is given in a dose of 7.4 MBq/kg (200 μCi/kg), with a minimum total dose of 18.5 MBq (500 μCi). Blood levels of 99mTc-MDP fall to 4 - 10% of the injected dose by 2 hours and to 3-5% by 3 hours. Optimal imaging is obtained at 4 hours post-tracer administration. By this time, about 60% of the injected activity will have been eliminated in the urine with normal renal function. In selected cases when findings at 4 hours are unclear, imaging at 24 hours may be helpful to elucidate findings. Delayed imaging may be performed either by obtaining multiple “spot” planar images or by using a moving gamma camera. Other useful techniques include pinhole magnification scintigraphy with a 2-3 mm pinhole aperture and SPECT. The importance of using the pinhole collimator to improve spatial resolution in pediatric bone imaging cannot be overemphasized. An example of its usefulness is in the early diagnosis of avascular necrosis of the femoral head.7,15

Bone imaging in children is characterized by high tracer uptake in the region of the physes, reflecting a high level of metabolic activity. Although this may obscure pathology, physeal tracer uptake is normally symmetrical. Patient positioning must be meticulous if one is to use asymmetry as a sign of disease. Abnormally high focal tracer uptake reflects both increased regional blood flow and increased metabolic activity. Focal increases are observed in osteomyelitis, stress reaction or fracture, eosinophilic granuloma, and bone tumors, which may be primary (Ewing’s sarcoma, osteosarcoma) or metastatic. Foci of decreased tracer uptake are observed in early avascular necrosis, early osteomyelitis, acute infarct, simple benign cysts, and radiotherapy fields (very early or late stages).

**Osteomyelitis**

Bone imaging with 99mTc MDP is a sensitive indicator of childhood osteomyelitis (Figs 12.20 and 12.21). Intense tracer uptake occurs within 24-48 hours of the onset of symptoms. In the long bones, the abnormality is usually found in the metaphysis. The three-phase study helps differentiate soft tissue inflammatory involvement from osteomyelitis, with a specificity of 94% and a sensitivity of greater than 90%. When the study is normal or there is little tracer uptake in acute osteomyelitis, the possible cause is a reduction in focal blood flow as a result of edema. In such rare cases, it is helpful to repeat the bone scan after 48 hours or perform other imaging such as 67-Ga or labeled leukocyte scintigraphy. Some believe that in neonatal osteomyelitis there is little tracer accumulation. With proper pinhole magnification, meticulous patient positioning, and attention to technique, the method is highly accurate for neonatal osteomyelitis.
Septic Arthritis

In the absence of concomitant osteomyelitis, septic arthritis is characterized by increased tracer uptake in periarticular areas, a pattern that can be readily differentiated from osteomyelitis. In osteomyelitis, the abnormal tracer uptake is more focal, while septic arthritis results in activity on both sides of the joint together with signs of inflammation in the early images of the radionuclide angiogram. The usual benefit of the study is to exclude concomitant osteomyelitis rather than to make a definitive diagnosis of septic arthritis, which is usually based on joint aspiration.

Avascular Necrosis of Femoral Head

Avascular necrosis involving the proximal femoral capital epiphysis may be seen in Legg-Calve-Perthes disease and other conditions producing increased intracapsular pressure, such as synovitis, high dose steroid therapy, and Gaucher’s disease. An interruption of the blood supply from the medial femoral circumflex artery to the femoral head is believed to be responsible for the changes seen radiographically and scintigraphically. Early detection of femoral head avascular necrosis is important so that treatment can be promptly started and disability minimized. Initially, radiographs are normal. It is only during healing and revascularization that the density of bone increases and modeling and sclerosis become prominent. Absence of $^{99m}$Tc MDP uptake may be demonstrated prior to any plain film changes and may be noted at the time of initial symptomatology. This may involve the entire femoral head or just its anterolateral aspects (Fig. 12.22). Pinhole imaging is useful in establishing a diagnosis. SPECT, particularly coronal images, is essential for detailed delineation of articular structure.

Trauma

After trauma to bone, the reparative response begins immediately and a bone scan can reveal the increased uptake within 24-48 hours of injury, even though a radiograph may rarely be normal for several days after the accident. Usually, the scintigraphic findings are nonspecific, but in some cases a characteristic
appearance of the lesions in the proper clinical setting makes possible a specific diagnosis (e.g., in tibial torsion fractures in toddlers). Another characteristic finding occurs later in some fractures. In reflex sympathetic dystrophy, which is the result of denervation of the limb, one observes diffusely increased or decreased tracer activity throughout the extremity. Bones are often subject to stress in athletes, ballet dancers, or other active persons. When osteoclastic activity exceeds osteoblastic repair, the result can be cortical disruption. In stress fractures, the scintigraphic abnormality can appear as much as 3 weeks before any radiographic abnormalities.

**Bone Cysts and Fibrous Dysplasia**

Bone scans are usually normal in small cysts or are characterized by a zone of decreased tracer activity compared to their surroundings. Increased uptake may occur in the bone surrounding a cyst with associated stress or trauma. Fibrous dysplasia, characterized by the absence of mature bone, affects multiple skeletal regions, chiefly the femora, tibiae, and pelvis. Fractures and deformities are common complications. Typically, skeletal scintigraphy reveals multiple areas of markedly increased focal tracer uptake.

**Osteoid Osteoma**

Osteoid osteoma is the most common benign tumor of bone in children and is characterized by a core of osteoid (the nidus) with a surrounding zone of reactive bone. Osteoid osteomas are most commonly cortically located but can also be cancellous or subperiosteal in location. While plain films are often diagnostic, the radiographic appearance of osteoid osteomas is variable, reflecting differences in reactive bone formation related to lesion location. The typical radiographic appearance of a cortical osteoid osteoma is a small central lucency with surrounding sclerosis and cortical thickening. Skeletal scintigraphy is often requested in patients with suspected osteoid osteomas when the classic radiographic findings are not present or when referred pain results in the initial radiographic examination missing the lesion completely. The typical scintigraphic appearance of an osteoid osteoma is intense tracer localization in the nidus surrounded by less prominently increased tracer uptake in surrounding reactive bone (Fig. 12.23). Intraoperative bone scanning has greatly reduced the recurrence of the disease after surgical resection. After performance of a preoperative baseline study, the same regions are imaged in the operating room during the progress of the surgery. Serial views obtained with a mobile gamma camera with pinhole collimation ensure the completeness of the resection.

**IMAGING OF THE GASTROINTESTINAL TRACT**

**Gastroesophageal Reflux**

Gastroesophageal reflux is a common occurrence in children. The child may present with vomiting, loss of appetite, weight loss, and failure to thrive. There may be irritation, erosion, or ulceration of the mucosal lining of the esophagus, which may cause bleeding. One fifth of patients suffering from gastroesophageal reflux have respiratory symptoms, including allergic bronchitis, asthma, or bronchitis. These symptoms are due to aspiration of refluxed gastric contents. Direct irritation of the esophageal mucosa with acid can cause respiratory symptoms, even in the absence of aspiration. Aspiration of gastric contents causes
coughing, vomiting, dyspnea, apnea, and cyanosis. About two thirds of patients are asymptomatic up to the age of 18 months. The rest exhibit symptoms by the age of 4 years. Less than 5% eventually have esophageal damage.

Gastroesophageal reflux and gastric emptying can be documented by adding $^{99m}$Tc sulfur colloid to food. The minimum dose is 7.4 MBq (200 μCi), and the maximum dose is 37 MBq (1 μCi); or 0.185 MBq (5 μCi) $^{99m}$Tc per ml of liquid food. The radiotracer is mixed with the child’s formula or in milk. The gamma camera is placed under the table on which the infant lies supine. The stomach, chest, and oropharynx are included in the field of view. Serial images are obtained using a 64×64 or a 128×128 matrix at one frame per 30 seconds for 1 hour (Fig. 12.24). The study is best portrayed using a computer generated cinematic display. Levels of activity 5% above background should be portrayed in order to visualize small volumes of reflux. If there is no patient motion, regions of interest are drawn over the gastric and esophageal regions in order to generate time activity curves. Gastroesophageal reflux detected scintigraphically correlates closely with esophageal probe pH monitoring.

Gastric emptying can be evaluated by observing the gastric time activity curve (Fig. 12.25). Normal gastric emptying times are highly variable and depend on the type of meal, patient position, and anxiety. There is no correlation between gastric emptying times and the presence of gastroesophageal reflux. Only significantly delayed or significantly rapid gastric emptying times can be interpreted as abnormal and reported with confidence. The patterns of gastric emptying curves are also variable. The sensitivity of detecting pulmonary aspirations in patients suspected of this condition is low.

**Meckel’s Diverticulum**

Meckel’s diverticulum is a frequent cause of gastrointestinal bleeding in children. Following intravenous administration, $^{99m}$Tc-pertechnetate is rapidly and actively taken up by gastric mucosa, accumulating approximately 20% of the injected dose. $^{99m}$Tc-pertechnetate also concentrates in functioning ectopic gastric mucosa within a Meckel’s diverticulum. Scintigraphy with pertechnetate is quite effective in the detection of such ectopic tissue. The patient should fast for at least 4 hours prior to the examination in order to reduce the tracer activity in the stomach. No sodium or potassium perchlorate should be administered to the patient because it reduces gastric uptake of tracer. Potassium perchlorate can be administered orally after the imaging procedure to decrease thyroidal accumulation of the tracer. Barium contrast studies of the abdomen should not be performed before scintigraphy because the contrast agent will absorb gamma radiation and can interfere
with detection of the ectopic gastric mucosa. Penta-gastrin (6 μg/kg) is administered subcutaneously approximately 15 minutes before administration of the tracer to increase gastric mucosal uptake of the tracer and to reduce background activity. The patient lies supine, with the gamma camera viewing the entire abdomen. The tracer is administered intravenously, and recording begins immediately thereafter. A radionuclide angiogram is obtained with one image per second for 60 seconds, followed by serial imaging at one frame per 30 seconds for 30 minutes. The radionuclide angiogram helps detect highly vascular lesions such as hemangiomas; the serial imaging with 30 second frames is used to detect the ectopic gastric mucosa. If abnormal, intense extravascular accumulation of tracer occurs, multiple projections (right lateral, posterior, obliques) should be obtained in order to better localize the abnormal uptake.

Tracer within functioning gastric mucosa in Meckel’s diverticulum is easily identified by its location. Paralleling gastric uptake of the tracer is the progressive increase in focal activity in the right lower quadrant of the abdomen (Fig. 12.26). Other locations within the abdomen can occur. One must be aware that pertechnetate secreted into the stomach moves into the intestinal tract and also is excreted by the kidneys. These sites can be confused with uptake in ectopic tissue. Abnormal accumulation of radio-pertechnetate in the abdomen can also be seen in intestinal obstruction, intussusception, inflammation, vascular malformations, ulcers, some tumors, and various urinary tract abnormalities. The appearance is different from the typical appearance of 99mTc uptake in ectopic gastric mucosa in a Meckel’s diverticulum. Failure to see ectopic activity does not completely eliminate the possibility of a Meckel’s diverticulum.

Fig. 12.25: Gastric emptying time calculation by generating gastric time activity curve
Rarely, necrosis, fibrosis, ischemia, atrophy, dysfunction of ectopic gastric mucosa, or severe anemia may prevent its detection by pertechnetate imaging.

**GI Bleed**

Abdominal bleeding can be detected by serial blood pool imaging using $^{99m}$Tc labeled red blood cells (Fig. 12.27). In case of GI bleed, compared with angiography and endoscopy, scintigraphy is well tolerated, easy to perform, requires no patient preparation, is low risk, highly sensitive at low bleeding rate (scintigraphy can detect bleeding as low as 0.1-0.2 ml/min, whereas angiography can locate GI bleeding at a rate greater than 1 ml/min) and can detect intermittent bleeding.$^7$ The administered dose of radiolabeled red blood cells is the same as that for gated blood pool scintigraphy. The patient is examined in the supine position, with the camera field viewing the entire abdomen. Following intravenous administration of the blood pool tracer, serial imaging at one frame per 15-30 seconds is carried out for 60 minutes. Additional images at hourly intervals are obtained if the site of bleeding has not been localized during the first hour of imaging. Cinematic viewing of the serial images is often helpful. $^{99m}$Tc-sulfur colloid can also be used in the detection and localization of lower abdominal bleeding. Because of the rapid blood disappearance of the radiocolloid, bleeding can be detected with the advantage of high target to nontarget ratios, but the method is limited to patients with severe, acute bleeding.

**HEPATOBIARY SCINTIGRAPHY IN PEDIATRIC PATIENT**

The relatively non-invasive methods for the evaluation of the biliary system, like ultrasonography, computed tomography, oral cholangiography, cholecystography, provide excellent anatomic information. Hepatobiliary scintigraphy however, is the only technique providing real-time assessment of hepatocytes function and bile progression from the liver to the intestine.$^{16}$ Iminodiacetic acid analogs (IDA) are rapidly taken up by hepatocytes from circulating blood and are excreted into the biliary tree without conjugation.$^{17}$ $^{99m}$Tc-labeled IDA analogs provide liver and biliary tract images showing a progression from uptake to elimination. It can assess vascularity, parenchymal function, biliary drainage, possible presence of a bile leak, obstruction and many other disorders of the liver and the biliary tract in children and specifically in infancy. It has very good sensitivity and specificity for the detection and evaluation of neonatal jaundice (neonatal hepatitis vs biliary atresia (BA)), acute cholecystitis, bile leak, gallbladder dysfunction, trauma, choledocal cyst and liver transplantation. The most widely used IDA is mebrofenin. The recommended administered activity is a fraction of the adult dose (150 MBq) calculated in function of body surface area, with a minimum of 20 MBq in neonates. Patient should fast for at least 3-4 hours before the examination, so that gallbladder is not contracted. When study is done in neonates with hyper-bilirubinemia, it is necessary to administer the oral Phenobarbital (5 mg/kg per day in two divided doses) and/or beta methasone (oral drops) for 3-5 consecutive days prior to the study. Phenobarbital increases the hepatic parenchymal uptake and the biliary excretion of the tracer. The combination greatly reduces the false positive diagnosis of BA.

**Normal Findings**

The scintigraphic appearance of the liver uptake in the abdominal field of view occurs rather rapidly, following that of kidneys and spleen, since the predominant part of liver perfusion comes from the
portal venous system. In any case, in normal subjects, the area normalized ratio of liver to heart uptake at 5 minutes is higher than 1.0. The biliary tree visualization occurs 15 minutes postinjection, while its elimination into the duodenum is generally present at 30-45 minutes and the gallbladder is seen within one hour (Fig. 12.28).

The liver of neonates and infants is round-shaped as compared to that of adults; the gallbladder is easily identified, but not always the right and left main hepatic ducts. Care must be taken to distinguish the signal coming from overlapping structures of the urinary tract; this may be of some difficulty in liver insufficiency, because of the compensatory increase of urinary tracer excretion.

**Persistent Hyperbilirubinemia**

Hyperbilirubinemia can be divided into two main groups, based on the presence of predominant conjugated or unconjugated serum bilirubin levels.

**Fig. 12.27:** Blood pool imaging with $^{99m}$Tc labeled RBC for GI bleed in the splenic flexure (arrow)

**Fig. 12.28:** Normal $^{99m}$Tc-mebrofenin hepatobiliary scintigraphy
Physiologic neonatal jaundice, breast milk jaundice and erythroblastosis fetalis are relatively common causes of unconjugated hyperbilirubinemia. The hepatobiliary scan is not indicated generally in these circumstances. Conjugated and persisting hyperbilirubinemia most often occurs in the presence of biliary tract obstruction, the so-called “cholestatic” or “obstructive” jaundice. This, in neonates, may be due to biliary malformations; however, other causes may be involved, like hepatocellular disorders or bilirubin transport defects. Laboratory investigations easily establish the diagnosis in cases of infection, toxic or metabolic diseases. Ultrasound may well support the diagnosis of biliary anomalies, like choledocal cyst, gallbladder absence or hypoplasia, bile plugs. The evaluation of neonatal jaundice has to differentiate between those diseases, which can improve with Surgery, such as BA, from others in which medical treatment is preferable, such as neonatal hepatitis. The differential diagnosis between BA and neonatal hepatitis cannot be done with confidence without hepatobiliary scintigraphy. The sensitivity of hepatobiliary scintigraphy for BA is reported to be from 91-100% (Fig. 12.29); Percutaneous liver biopsy instead is known to reach 60-90% sensitivity. Moreover, histological similarities often exist between BA and neonatal hepatitis, making the diagnosis difficult. In these instances, surgical exploration of the portal region is indicated. Its correct diagnosis indicates prompt surgical correction, being this of paramount importance for the prognosis of the patient. The tracer appearance in the small intestine by 24 hours imaging, certainly rules out the diagnosis of BA; if no radiopharmaceutical is noted in the bowel, a distinction between inspissated bile syndrome and BA is more difficult to make. However, good point is that both need surgical exploration.7

Common bile duct cyst or choledocal cyst is known to be an uncommon cause of neonatal cholestatic jaundice. Indeed, it is associated with distal biliary tract obstruction and presents a clinical picture that is indistinguishable from BA. Choledocal cysts usually manifest during infancy and childhood, the clinical findings including jaundice, right upper quadrant pain and masses. They are considered congenital because do occur in fetuses and neonates. Their origin may be related to an abnormal connection between the pancreatic duct and common bile duct and chronic reflux of pancreatic juice into the bile duct, resulting in irritation of the duct and subsequent dilatation.

Choledochal cysts appear as cystic or fusiform dilatation of the common bile duct at radiography. Ultrasonography is the best initial method of evaluating the intra- and extrahepatic bile ducts dilatation. Computed tomography is considered to be more accurate in delineating the intrahepatic biliary tree. Early detection and treatment of choledocal cyst in neonates are important for preventing serious complications due to biliary obstruction. Hepatobiliary scintigraphy provides physiologic information on hepatic uptake and accumulation of radionuclide in the dilated biliary tree.6-9 The scintigraphic demonstration of tracer accumulation within the choledocal cyst (delayed 24 hours imaging) serves to exclude other cystic right upper quadrant masses from the differential diagnosis (Fig. 12.30).

Congenital biliary ectasia or Caroli’s disease consists of segmental saccular intrahepatic bile ducts dilatation and may present with hyperbilirubinemia; the complicated form of Caroli’s disease, bile ducts dilatation plus congenital hepatic fibrosis, is more common. Hepatobiliary scintigraphy confirms the diagnosis in most cases, showing multiple photopenic areas in initial images, and then gradual accumulation of tracer in the same areas as radiopharmaceutical is excreted into the biliary system (Fig. 12.31).
Liver Transplantation

Liver transplantation (LT) is an accepted and successful mode of treatment for pediatric end-stage liver disease. Hepatobiliary imaging in children who have undergone LT is of major importance. As already described, it can assess vascularity, parenchymal function, biliary drainage, possible presence of a bile leak, and obstruction. In suspected bile leak, hepatobiliary imaging provides information generally not available by other techniques, except for direct cholangiography. If the amount of intraperitoneal accumulation of the tracer is greater than that entering the gastrointestinal tract, surgery is usually indicated. Hepatobiliary scintigraphy has good sensitivity and specificity for the detection of biliary leak and biliary stricture after transplantation: no patient with normal scintigraphy requires biliary intervention; some patients with biliary leaks and few with strictures suggested by scintigraphy require intervention.

Imaging of the Spleen

Indications for splenic scintigraphy in children include evaluation of abdominal trauma, detection of accessory spleens, polysplenia, asplenia, heterotaxia, functional asplenia, splenosis, infarction, left upper quadrant mass, splenomegaly, splenic abscess, and diaphragmatic eventration.

Specific splenic imaging with $^{99m}$Tc labeled denatured red blood cells is preferable in most instances. The usual dose of $^{99m}$Tc denatured red blood cells is 3.7-18.5 MBq (100-500 μCi) given intravenously 0.5 - 1.0 hour before imaging. Anterior, posterior, right anterior, left anterior, and left lateral projections should be obtained. Delineation of small defects, such as splenic fracture, or small accessory spleens can be made more effectively using a 3 mm pinhole collimator or SPECT imaging.

In abdominal trauma, splenic scintigraphy is effective in diagnosing splenic fracture or rupture. Although, accessory spleens and splenosis can be detected with $^{99m}$Tc-sulfur colloid, $^{99m}$Tc heat denatured red blood cells are the agent of choice in these conditions (Fig. 12.32).

Non-visualization of the spleen means that the spleen is not functioning, not the absence of the spleen. In these patients, splenic scintigraphy plays a role in the identification of functional splenic: Tissue and assists in the decision whether to place the patient on a long-term prophylactic antibiotic regimen. Patients suffering from sickle cell disease may have functional asplenia. Functional asplenia is diagnosed by non-visualization of the spleen with $^{99m}$Tc sulfur colloid or, better, with $^{99m}$Tc denatured red blood cell imaging.
PET IMAGING IN PEDIATRICS

Positron Emission Tomography (PET) is a medical imaging technology, which has an unparalleled capability to generate images of body function and metabolism. In PET, positron-emitting radionuclides are used. Many PET tracers are physiologically identical to natural biological substrates. As a result, a PET tracer in the body follows the same physiological pathways as the non-radioactive natural substrate that it mimics. Quite often, internal chemical or physiological changes related to metabolism predate or exceed changes in the structural appearance of tissue or organ. PET uses internal tracers to measure the rate of internal processes and can often distinguish between normal and abnormal physiology in cases where no anatomical change has occurred. PET applications in children have provided useful insights into the physiology and pathophysiology of various diseases and conditions. As are most nuclear medicine and radiological procedures in children, PET scans are challenging to perform in the pediatric age groups and particular attention to preparation and detail are necessary to optimize image quality.11

REFERENCES

Over the past two to three decades, there has been rapid growth of a new and intrusive subspecialty of Radiology called ‘Interventional Radiology’. Interventional radiology has become an umbrella description of all types of radiological procedures that are invasive in nature. While many of these procedures are therapeutic or curative, others are of purely diagnostic in nature.

It is difficult to classify the various interventional techniques in radiology in a logical and comprehensive fashion. We intend to provide a general overview of common interventional procedures in pediatric practice.

**PRE-PROCEDURE PLANNING**

The most important part of pediatric interventional procedure is adequate planning and good sedation. The sedation protocols and regimes in pediatric patients vary widely. Most pediatric interventional studies require some form of sedation or anesthesia. A physician who is trained to handle the subsequent complications (if any) and intubation should administer the drugs. The patients’ vitals must be monitored continuously during the examination and we usually monitor with a pulse oximeter during entire study. An oxygen saturation of 45% or above is adequate oxygen saturation, however a value below 80% is suggestive of significant desaturation. Premedication using phenobarbitol and meperidine is beneficial in children over 18 month’s. In our institution, we frequently use a cocktail regimen of chlorpromazine, pethidine and phenergan. If there are no contraindications, ketamine also provides a good combination of sedation and immobility. General anesthesia may be necessary if intravenous sedation has failed or in procedures requiring longer time.

**CLASSIFICATION OF PEDIATRIC INTERVENTIONAL STUDIES**

As has been pointed out earlier, it is difficult to classify the vast array of interventional techniques in a rational and comprehensive manner. However, broadly the interventional techniques may be classified into vascular and non-vascular procedures (Table 13.1). Some of these techniques have been described below.

**PEDIATRIC ANGIOGRAPHY**

Pediatric vascular procedures require a number of technical modifications of standard adult angiography. With the advent of Doppler Ultrasound, CT, CT angiography, MRI and Magnetic Resonance Angiography the need for angiography has decreased markedly. Many pediatric angiograms are now performed with an aim of endovascular intervention. Table 13.2 sums up most of the current indications of diagnostic angiography in pediatric patients.

Arterial access, especially in small children, is often the most difficult part of the procedure. Percutaneous cannulation of the femoral artery, using the modified Seldinger technique is the most commonly utilized route. In the newborn, the umbilical artery may be used for arterial access.

It is advisable to use the smallest and least traumatic needles and catheters wherever feasible. The femoral arteries of young children are small, easily
traumatized and prone to thrombosis and spasm. The puncture is usually made 1 cm below the inguinal crease with needle directed nearly horizontally to enter the common femoral artery just below the inguinal ligament. Small gauge needles (19-22G) are used, depending upon patient’s size and weights. They can accept small guidewires. When repeated catheter exchanges are anticipated, use of 4-5 Fr sheaths are recommended. Most of the pediatric interventional procedures can be accomplished with 3 and 4 - For catheters. A bolus of 100 U of heparin per kilogram of body weight is given as soon as the catheter has been inserted.

At the end of the procedure, the catheter is removed. If the catheter cannot be easily withdrawn, it may indicate spasm of the artery. Infiltration of lidocaine around the artery or intra-arterial injection of dilute nitroglycerine will usually relieve the spasm. After removal of the catheter, pressure is applied to puncture site for 10-15 mins. to stop the bleeding. Peripheral pulses of the lower limbs must be monitored for 24 hours after the study.

In experienced hands, major complications of pediatric angiography are rare. Major complications are usually observed at the site of puncture. Thrombosis of femoral artery is a grave complication, which may necessitate immediate surgery. Spasm of the artery and excessive bleeding from the puncture site are also seen occasionally. The other potential complications are false aneurysm formation, AV fistula, infection and systemic embolization. Infants and small children are particularly susceptible to dehydration, fluid overload and hypothermia.

PEDIATRIC VENOGRAPHY

The venography in pediatric patients is sometimes done to look for venous element in venous malformations or in cases of varicosities to look for Klippel-Trenaunay syndrome or deep vein thrombosis (Figs 13.1A to C).

PEDIATRIC VASCULAR INTERVENTIONS

Angioembolization

Angioembolization has been described extensively in the radiological and surgical literature. Various embolising materials both temporary and permanent are used for this purpose. Most common indications of embolization in children are listed in Table 13.3.

The technique of embolization in children is similar in general to those used in adults. It requires superselective catheterization of supplying arteries. Small arterial sheaths and catheters, especially microcatheters of variable stiffness are used. For
Fig. 13.1A to C: Klippel-Trenaunay syndrome right leg A. Axial T1 MR shows atrophy with patchy increase in signal intensity affecting all muscle groups. There is increase in the fat in intermuscular planes (small arrow). One Klippel-Trenaunay vein (large arrow) is also seen. B. MR angiogram shows Klippel-Trenaunay veins as well as their communications with the popliteal and superficial femoral vein. C. Ascending phlebogram shows two Klippel-Trenaunay veins, one communicating with the popliteal vein (arrow) and the other with the superficial femoral vein (arrow). (hypoplastic deep veins in the leg are also seen)

short-term embolization, autologous clot is often used. The most commonly used agents are Gelfoam and Ivalon (polyvinyl alcohol particles). For long-term occlusion, isobutyl cyanoacrylate, steel coils and detachable balloons are used. The soft tissue venous malformations can also be treated by percutaneous injection of sclerosing agent like alcohol, sodium tetradecyl sulphate, etc. (Figs 13.10A to D).

Transcatheter embolization provides a quick and relatively simple means of therapy and avoids potentially difficult surgery. The hazard of embolizing tissues other than the target organ is a constant concern in the interventional radiology and account for most of its significant complications.
Angioplasty

The percutaneous transluminal angioplasty (PTA) is used infrequently in children due to the absence of atherosclerotic disease.\textsuperscript{16} PTA, however, has been successfully employed in treatment of renal artery stenosis.\textsuperscript{16,17} Postrenal transplant anastomoses and surgically created access fistulae have also been treated. Venous obstructions, such as catheter related stenosis, IVC stenosis and hepatic venous stenosis (Budd-Chiari syndrome) also constitute the indications of PTA.

This procedure involves passing of a balloon catheter through the area of vascular stenosis. With constant monitoring of the pressure within the balloon, successive dilatation of stenosis is performed under fluoroscopic guidance.

The hazards of PTA include arterial spasm, occlusion and perforation, embolization to the target organs and intimal dissection.\textsuperscript{16}

PTA has many advantages over surgery. It is usually performed under local anesthesia. The length of hospital stay is short and repeat procedure can easily be performed if the stenosis recurs.

Thrombolysis

Majority of pediatric vascular occlusion is the result of catheterization.\textsuperscript{6} Thrombolytic therapy is effective
Fig. 13.4: Common hepatic angiogram in a case of hemobilia following a road traffic accident showing a bleeding vessel in right lobe of liver (upper images). Post embolization angiogram is not showing leakage of contrast (lower images).

Fig. 13.5: Left renal angiogram in a case of postrenal biopsy with massive hematuria is showing a small aneurysm near lower pole. Postembolization angiogram is not showing the aneurysm. The hematuria was stopped after embolization.

Figs 13.6A and B: A. Right renal angiogram in a case of post-pyelolithotomy with hematuria is showing a large aneurysm. B. This aneurysm was embolised with steel coils. Postembolization angiogram is not showing the aneurysm (the hematuria was stopped after embolization).

in restoring lower extremity circulation in 70-84% of patients with femoral artery thrombosis after cardiac catheterization. Other indications include central venous thrombosis, neonatal aortic thrombosis, renal vein and dural sinus thrombosis, pulmonary artery thrombosis and other vascular anastomosis.

The techniques of administration include systemic high-dose infusion of streptokinase, urokinase and selective direct infusion into the clot. Low-dose direct clot infusion is used in the presence of contraindications to high dose IV thrombolytic therapy and after failure of IV treatment. The bleeding from the

This shunt was embolized by releasing steel coil after inflating 10 mm balloon at anastomotic site (there was complete occlusion of surgical shunt after embolization procedure).
arteriotomy site is rare in children undergoing thrombolytic infusion.²

Intravascular Foreign Body Retrieval

The need to remove foreign bodies is well documented. Sepsis, thrombosis, myocardial perforation and systemic embolization have all been reported¹⁶ as complications of retained foreign bodies. Most frequent device encountered is a broken CVP catheter. Subclavian IV lines, ventriculo-atrial shunts and bullets have been removed angiographically, obviating a major surgery. Loop snare technique²⁰ is probably the most widely used method. It involves positioning the introducing catheter near the foreign body and snaring with the closed loop. Two other popular approaches are modified bronchoscopic forceps and an adaptation of Dormia basket.¹⁶

New Applications

Transjugular liver biopsy is indicated in the presence of undiagnosed severe liver disease complicated by coagulopathy.¹⁶ Transjugular intrahepatic porto-systemic shunting (TIPS) may be performed in patients with GI bleeding from esophageal varices, not controlled by endoscopic sclerotherapy²¹ (Figs 13.11 to 13.14C).

Fig. 13.10A to D: Venous hemangioma of axilla with supraclavicular extension. A. The mass is mildly hyperintense to muscles on T1, B. and hyperintense on T2. C. On DSA the mass is not vascular with mass effect over axillary artery with splaying of its lateral thoracic and subscapular branches. There is no venous filling. D. Percutaneous aspiration and injection of contrast shows multiple dilated vascular spaces. (The pain disappeared and the size was reduced after injection of sclerosing agent through the same needle)

Fig. 13.11: Diagrammatic representation of technique of transjugular biopsy shows that the biopsy is obtained by passing the needle through the wall of the hepatic vein. The shaded area is the hepatic mass and the needle shown is quick core biopsy needle

A. Transjugular portal hepaticovenogram showing that the main portal vein is replaced by multiple periportal collaterals with marked hepatofugal flow in left gastric vein, which is dilated, B and C. A wall stent has been placed after dilating one of the periportal collateral.

Radiologic insertion of central venous catheters is becoming more common. The procedures involve the use of sonographic or venographic guidance of venous cannulation and subsequent fluoroscopic catheter placement.

PEDIATRIC NONVASCULAR PROCEDURES

In many clinical situations non-vascular interventional procedures can provide an effective alternative to surgery without being as invasive and usually with less morbidity and rapid recovery. It is important to review all preprocedure imaging studies before starting the interventional procedure. Review of previous images is helpful in planning the correct and safest approach to the abnormality. It is important to distinguish viable from necrotic tissue, for biopsy. A vast number of procedures can be easily performed using ultrasonography (USG) and fluoroscopy. At our center, we prefer to use USG wherever possible as it
provides real time guidance. However, very small lesions, parenchymal lung lesions and bony abnormalities require the use of CT guidance as these abnormalities cannot be imaged using USG. Some of these procedures are described below.

**Aspiration and Drainage**

The common indications of aspiration are thoracentesis, paracentesis, ultrasound guided hip aspiration for the diagnosis of septic arthritis and aspiration of abscesses (e.g. amoebic and pyogenic liver abscess). The common indications for drainage are intra-abdominal and pelvic abscesses, obstructive hydronephrosis, lung abscess and empyema. Less frequently encountered indications are drainage of lymphoceles, infected biliomas and urinomas.

These procedures are done under real time guidance using USG or under the guidance of CT. The aspiration needle is inserted into the abnormality for aspiration and drainage procedures, taking care to avoid neurovascular structures and bowel loops. Spinal needles (18-22G) or Chiba needles are frequently used for aspirations depending on the viscosity of the fluid. In drainage procedures, the initial puncture is done by Chiba needle. With a modified Seldinger’s technique, over a 0.018” wire, a 4-Fr coaxial dilating system (Micropuncture introducer set, COOK) that accepts a 0.038” guide wire is placed. After sequential dilatations, 8 to 14-Fr catheter is placed in the collections.

**Biopsy Procedures**

The accurate positioning of biopsy needles and instruments in the areas of interest has been greatly facilitated by improvements in imaging equipments in recent years. The accurate guidance of biopsies by biplane angiography, ultrasound, CT and, more recently MRI has made it possible to obtain samples from sites previously thought inaccessible. Most of these biopsies in pediatric patients can be accomplished under sedation and local anesthesia.

The indications of percutaneous biopsy in children may be to determine and establish the cause of general organ dysfunction (hepatitis, glomerulonephritis etc.), to determine the pathology of a tumor or infections process (Figs 13.15A to C).

In adult patients, cytology from a fine needle aspiration (FNAB) is often adequate to diagnose carcinomas. In children, however, frequently there is a need to obtain a core biopsy because neoplasms are often sarcomas and round cell tumors. In addition, there may be a need to establish cytogenetic findings,
which aid in diagnosis and prognosis of tumor for example neuroblastoma.\textsuperscript{2}

We always try to utilize real time ultrasound image guidance to biopsy the lesions. Lesions of solid abdominal viscera (liver, kidney) or of retroperitoneum are easily amenable to US guided biopsies. Biopsy of thoracic lesions, bony lesions and lesions which are not well visualised on USG are best performed using CT guidance.

Solid core biopsies at our center are usually performed with 20-16G needles with either trucut action or spring loaded automated needles. Bone biopsies (e.g. vertebral biopsy) is performed with a 14G trephine needle. FNAB can be performed using Chiba or small gauge spinal needles.

Biopsy techniques should be used with the great caution inpatients with a bleeding diathesis or who are on anti-coagulant therapy. Inpatients in whom hemorrhage is a likely complication, the biopsy track can be embolized at the end of the procedure.\textsuperscript{25}

The potential complications of biopsy procedures include infection, hemorrhage, tumor dissemination along needle tracks and in adverting puncture of adjacent organs. In clinical practice, the incidence of serious complications following biopsy procedures by experienced operators is low.

**PROCEDURES RELATED TO GASTROINTESTINAL TRACT**

**Percutaneous Gastrostomy (PG)**

Towbin RB et al. has developed an effective technique for percutaneous placement of (Sacks-Vine) gastrostomy tubes in infants and young children.\textsuperscript{26} The indications of percutaneous gastrostomy include patients with major swallowing difficulties or debilitating diseases where maintaining adequate nutrition can be a major problem. Majority of the techniques described in the literature involve inflating the stomach with gas or fluid-filled balloon, followed by puncture of the inflated organ through the anterior abdominal wall. The complications of PG include looping of guidewires and catheters in the peritoneum, dislodgement of catheters, acute gastric dilation and leakage of the gastric contents.

**Dilatation Procedures**

Balloon catheter dilatation of tracheobronchial stenosis in infants and children has been successfully performed for both congenital and postsurgical strictures of the airways.\textsuperscript{1} Balloon dilatation of esophageal strictures in children is a very successful form of treatment of congenital stenosis or postoperative stricture following repair of tracheoesophageal fistula.\textsuperscript{26}

**Removal of Foreign Bodies**

Removal of foreign bodies (e.g. coins) from the esophagus with the help of balloon catheters have also been reported.

**PERCUTANEOUS TRANSHEPATIC CHOLANGIOGRAPHY (PTC) AND PERCUTANEOUS TRANSHEPATIC BILIARY DRAINAGES (PTBD)**

In patients with jaundice, the two most important imaging techniques relevant to potential drainage procedures are ultrasound and direct-contrast cholangiography. A percutaneous cholangiogram is carried out prior to biliary drainage. If the bile ducts are known to be dilated, it is best to apply suction while gradually withdrawing the needle through the liver until bile is aspirated; this is preferable to intermittent injections of contrast medium, which might obscure the image. Puncture of right-sided ducts can easily be done under fluoroscopic guidance; however, left-sided ducts are better punctured with US guidance. Initial puncture is usually done with a 21 or 22 G needle followed with sequential changes of increasingly larger guidewires and catheters.\textsuperscript{27} If an external drainage is desired, a catheter with multiple side holes is placed deep in the biliary tree. It is best to use an entirely closed biliary drainage system,\textsuperscript{28} as this is associated with significant reduction in the incidence of bacteriemia following the procedure. In many cases, the stage of external drainage is superseded by the establishment of external-internal drainage at the first session: A catheter is advanced through the stricture, and side holes above and below the obstruction bypass the obstruction and drain internally into the duodenum. The indications of PTBD are same as in adults, both preoperative as well as palliative (Figs 13.16A to 13.17).

The postoperative period is very critical and carries specific problems. Early in this transitional period, the patient recovers from anesthesia and regains homeostasis. Later the patient repairs the operative and disease injury. Very often, early rehabilitation starts before discharge and continues until the patient is ready to resume normal duties. The postoperative care varies depending upon the severity of disease, nature of the operation, and the patient’s health, age, and special needs. Many patients need prolonged postoperative care in the hospital. Sometimes, the patient can be discharged early if close follow-up and extra help at home is assured. Patients with same day surgeries are discharged after brief observation and verification of normal spontaneous respiration, consciousness, and intact gag reflex. Patients, operated with regional anesthesia are usually discharged faster than those operated under general anesthesia. Adequate postoperative pain management and follow up are integral parts of the postoperative care. The patient and guardians should be educated about possible complications, their initial treatment, and telephone numbers or places of contacts, where they can come in case of deterioration.

TRANSPORT TO INTENSIVE CARE UNIT (ICU)

The patient can be observed postoperatively in different locations (PICU, SICU, NICU) depending upon the needs and facilities of an individual institution. A case could be made to transport critical patients to the ICU under mild anesthesia where they can be awakened and deparalyzed in a more controlled environment. This decreases the problems of transition during transport. The transport to ICU should be in a well-controlled manner. Equipment for emergency resuscitation should always be carried, even for transports over short distances. The transport kit should contain a working laryngoscope, a pair of extra endotracheal tubes (current size and a size smaller), bag and appropriately sized mask, stylet, oxygen source, and important emergency drugs. Similarly, it is important that a team, well versed in resuscitation, should accompany the patient during the transport, preferably with ICU nurse and respiratory therapist. Prior to transport, the endotracheal tube (ET) should be secured in good position. Similarly, no patient should be transported until temporary pulmonary and cardiovascular stability is established. Adequate monitoring of the patient during transport is of utmost importance. Heart rate (HR) and oxygen saturation must be monitored; if available and indicated, carbon dioxide (CO₂) (transcutaneous or endtidal) and blood pressure (BP), indirect or invasive, should also be monitored. If ventilating with a bag and mask, it is important to use a manometer to avoid excessive pressures. Extracautio should be taken with exchanging monitors and medication drips on admission to ICU. Only one monitor or vital drip should be changed at a time. For closer control of ventilatory pressures, equipment like the Neopuff® or portable ventilator is preferred over manual bag and mask ventilation.

The importance and need of communication between the caretakers in the operating room (OR) and the ICU cannot be overemphasized. The patient’s intravenous fluids, anesthesia, sedation, drugs, vasomotor stability, urine output, laboratory examinations, temperature, and ventilation problems during the operation should be discussed in detail.
patient’s need for equipment, intravenous fluids, medication drips, ventilation settings, chest tubes, and any other special items should be related to the ICU staff before the transport is initiated. This enables the ICU staff to plan a smooth admission. The ICU staff should set up equipment well before the patient’s arrival. It is important to continue the same level of support after transport as during it, unless the clinical condition demands otherwise. Then changes should be made slowly to adjust to the patient’s changing needs. To maintain stability, small but frequent changes are preferred over large and sudden ones. Making one change at a time, instead of several, allows assessment of its net effect. The intensivist’s detailed communication with the surgeon and the anesthesiologist greatly aids initial assessment. Some variability in vital signs during transport and admission to the ICU is universal. Usually these changes are transient and do not require specific treatment.

**INITIAL ASSESSMENT**

Ventilatory assessment should begin by observing the chest movement. Lungs are auscultated to assess the condition of the lungs and the position of the ET. Although pressures used during manual positive pressure ventilation are good guides, one should not try to duplicate those exact pressures on the ventilator. Breathing patterns with mechanical ventilation differ from those with manual bag ventilation. Oxygen (O₂) and CO₂ monitors can help the intensivist optimize ventilator settings. If facilities are available, bedside lung function testing (tidal volume, percent leak, compliance, resistance, and pressure volume curves) can greatly help to reduce ventilator complications. Otherwise, adequate but not excessive chest movements assure optimal tidal volumes. A chest X-ray on admission is mandatory to assess position of the ET, diaphragm, chest tubes, drains, and vascular catheters. In addition, it enables evaluation of heart size, evidence of air leak, plural fluid, atelectasis, pulmonary vascular markings, edema, and other pulmonary conditions.

Simultaneously, the cardiovascular assessment includes heart rate (HR), its rhythm, murmurs, BP, pulses, central venous pressure (CVP), and capillary filling. The abdomen should be assessed for distension, erythema, discoloration, bowel sounds, tenderness, or masses. Measuring the abdominal girth at regular intervals gives a good objective measure of abdominal distension. The neurological exam is important even with the use of narcotics, anesthesia, and muscle relaxants, because markedly abnormal or asymmetrical tone, movement, or pupillary reactions may still indicate a catastrophic complication needing further evaluation.

It is better to wait for 20-60 minutes before initiating laboratory studies to assess baseline ventilation and metabolic status. They should include arterial blood gas (ABG), serum glucose, electrolytes, blood urea nitrogen (BUN), creatinine, complete blood count (CBC), differential, and platelets. The hematocrit may be spun in the unit to get an immediate result. If bleeding excessively, investigate disseminated intravascular coagulation (DIC) by a DIC-panel including prothrombin time (PT), partial thromboplastin time (PTT), fibrinogen, and fibrin split products (FSP) or D-Dimer. Suspect multiorgan failure in case of prolonged hypoxic or ischemic insult during or before surgery and baseline investigations of liver, kidney, heart, and brain may be indicated.

Precise urinary output measurement is an important monitoring tool in evaluating renal and indirectly, cardiac function. It also helps to assess electrolyte and fluid needs. Unfortunately, iatrogenic neuromuscular blockade, anesthesia and sedation hamper voluntary micturition. It is advisable to insert a urinary catheter before surgery to measure urinary flow, during and after surgery, in critical patients and the patients with prolonged or complex surgery. A closed drainage system is mandatory to ensure the system’s sterility. Once the patient regains the ability to micturate voluntarily, the catheter should be removed promptly.

**MONITORING**

The level of monitoring varies greatly depending upon the level of observation needed and available equipment. Basic monitoring addresses ECG (heart rate and rhythm disturbances). Particular bed assignment to the patient may also depend on the needs of the patient. Monitor the blood pressure (BP) by continuous direct (Intra-arterial line) or intermittent indirect methods. The frequency of BP monitoring depends upon the condition of the patient. Most patients need to be assessed every fifteen to twenty
minutes until stable. Adequate cuff size is very important in order to accurately measure BP. It is also important to change the site of the cuff periodically. The indwelling intra-arterial catheter is the most accurate method for measuring continuous BP. Most commonly, the radial artery is used. Alternatively, the posterior tibial or dorsal pedis artery may be used. Axillary or ulnar arteries are also used occasionally. Avoid using the brachial and temporal arteries. The frequent calibration of arterial lines is necessary to maintain accurate measurements. When confronted with abnormal BP, a dampened arterial line should be suspected; measurements should be verified with other methods while the arterial line is recalibrated.

BP is slightly higher in peripheral arteries due to increased resistance.

The central venous pressure (CVP) is used to assess intravascular volume and right ventricular function. Trending rather than any absolute number is important. The tip of the catheter should be in the Superior Vena Cava (SVC) close to right atrium (RA). The catheter is usually inserted percutaneously via subclavian, jugular, or femoral veins. Rarely other veins are also used; the catheter may be inserted by cut down as well. Continuous O₂ saturation, partial pressure of oxygen and carbon dioxide in blood (PO₂, PCO₂), pH monitoring by indwelling catheter is possible by keeping the tip in the RA, PA, aorta or peripheral artery. Its cost is prohibitive except in the extremely critical patient who needs frequent blood gases, when it saves money, blood, and infection chances.

The pulmonary artery (PA) is used to measure pulmonary capillary wedge pressure and cardiac output. Mixed venous oxygen (PVO₂) measures the oxygen saturation in the pulmonary artery. Decreased PVO₂ is secondary to either increased metabolic demand or decreased cardiac output (decreased oxygen delivery). Sometimes, the RA blood sample is used, as a substitute of sample from PA line, although it is not a true mixed venous sample. Cardiac output can be measured using Fick’s M method.

Approximate Arterial (Art) O₂ Content/100 ml = 1.34 × Hgb × Art O₂ sat (ml of O₂)

Approximate venous (Ven) O₂ content/100 ml = 1.34 × Hgb × Ven O₂ sat (ml of O₂)

Oxygen consumption = Arterial oxygen content–venous oxygen content

Thus, oxygen consumption = Cardiac output × 1.34 × Hgb (Art O₂ sat–Ven O₂ sat)/100

Or, Cardiac output = K × (Art O₂ sat – Ven O₂ sat)

Where K= constant assuming oxygen consumption stays constant

Thus, cardiac output is inversely proportional to the difference between arterial and mixed venous saturation. Increased mixed venous O₂ saturation indicates improved cardiac output.

The cardiac echocardiogram is also a useful tool to assess cardiac output, cardiac contractility, and blood volume in a hypotensive patient. End diastolic volumes are good indirect measure of intravascular volume and venous return. Visualizing closely touching ventricular walls (the “Kissing’s sign”) is indicative of low ventricular filling. Tricuspid regurgitation, increased right-sided volumes and pressures, and atrial or ventricular septal bulging toward the left, indicates pulmonary hypertension.

Initially monitor respiration rate at least. It is also important to assess retractions, which are usually secondary to metabolic acidosis, upper airway obstructions, secretions, worsening respiratory status, and atelectasis. The respiratory rate may decrease falsely due to drugs (e.g. narcotics) rather than improving in respiratory status. Fever, anxiety, pain, agitation, drugs, hypoxia, obstruction, or worsening lung disease can increase the respiratory rate.

Intermittent ABG remains the gold standard for evaluating the patient’s ventilation and oxygenation. Because this information reflects the patient’s status at the moment of sample draw and can change fast, continuous trending monitors are used in addition to isolated ABG sampling. Capillary or even the venous samples can be used to assess pH and ventilation status but they cannot assess oxygenation. The transcutaneous (TCM) monitoring to measure CO₂ and O₂ or alternatively endtidal carbon dioxide (ETCO₂) and pulse oximetry can be used as a very important means for continuous evaluations of the ventilation and oxygenation. Verify these measurements periodically with blood gas evaluations. Pulse oximetry is a simple
and noninvasive means of pulmonary monitoring but it is not useful in extreme PO₂ ranges. For example, O₂ saturation may not change much when the PO₂ exceeds 100 torr, although it indicates a significant change in clinical condition. Pulse oximetry may not work if perfusion is very low. TCM measurement is perfusion dependent. Decreased perfusion will artificially increase CO₂ and decrease PO₂ readings. TCM can also be used to trend change in perfusion by observing the electricity (milliamperes) needed to keep the probe temperature constant. Increased milliamperes used indicates improved perfusion due to increased cooling of the probe by blood. The trend, rather than any absolute number is more useful. Evaluating the differences of CO₂ and PO₂ in TCM and arterial blood gas can also be used to assess perfusion. Increasing differences in TCM and ABG indicate worsening perfusion, unless it is due to TCM malfunction. Similarly, false high O₂ and low CO₂ may be due to an air leak at the TCM site.

Many devices are currently available to measure continuous or intermittent lung functions. Peak Inspiratory Pressure (PIP), Peak End Expiratory Pressure (PEEP), Mean Airway Pressure (MAP), fraction of the inspiratory oxygen (FIO₂), tidal volume (TV), minute ventilation and intermittent mandatory ventilation (IMV) are used to monitor progress in pulmonary disease. Similarly, compliance, resistance, pressure volume curves can be used to find optimal pressures and inspiratory time (IT). Ideally, IT should be five times the time constant (TC). TC is the product of compliance and resistance. At higher IMV, a shorter IT may be preferred to give enough time to expire. Increased tidal volume leak (inspiratory volume minus expiratory volume) measurement, continuous or intermittent, can give clues to the worsening compliance or obstruction in the ET tube. Increased PIP requirements may indicate atelectasis, pneumonia, edema, pneumothorax, secretions, and obstructed ET tube or ventilator circuit. Noninvasive ETCO₂ is also helpful to measure CO₂ continuously. There are some technical difficulties in measuring ECTO₂ in the very small patients. Normally, there is a 5-10 torr gradient in between the arterial carbon dioxide pressure (PCO₂) and ECTO₂ due to mixing of anatomical dead space. Increased gradient indicates increased dead space, e.g. atelectasis, pulmonary embolism and excessive PEEP. Failure to reach plateau or an extremely low ETCO₂ may indicate bronchospasm, as there is minimal expiratory volume or ET slipping into esophagus. Similarly, extremely low cardiac output conditions can also show artificially low ETCO₂ despite very high PCO₂ as not much CO₂ is excreted into alveoli. Ventilator leak may cause artificial decrease in ETCO₂ also.

Pulmonary artery catheterization is used to measure cardiac output (COP), intracardiac and pulmonary artery pressures. It is also used to continuously monitor mixed venous oxygen saturation and for ventricular pacing. Multiple lumen catheters are available in different sizes (5-7 Fr). Because of desired minimal distance required between different ports to use thermodilution method for COP measurement, it can be used only in preteens or teens. However, a single lumen, thin catheter inserted in the PA, RA, or RV during cardiac surgery is often used in small children including neonates to measure pressure and blood sampling. Small children need special order custom-made catheters with small distance between proximal and distant ports. It has different lumens for right atrium, pulmonary artery occlusion pressure, pulmonary artery blood pressure, floatation and occlusion of balloon and distal thermodilution sensor (for COP). Some also have fifth port for mixed venous oxygen saturation, right ventricular pressure or pacing. Pulmonary artery occlusion is an indirect reflection of left ventricular end-diastolic pressure (LVEDP). The safety or efficacy of these applications to reduce mortality and morbidity in pediatric population is not yet well documented. Similarly, small catheters in the left atrium (LA) put during cardiac surgery have been used to measure LA pressures in critical small children briefly. One should use them with special care as it could generate emboli.

Level of consciousness, pupillary reactions, and responses to verbal commands constitute the basic neurological monitoring. Various methods of monitoring intracranial pressure (ICP) are used to calculate cerebral perfusion pressure (CPP) in head injury and neurosurgical patients. CPP can be calculated by subtracting the ICP from the mean arterial blood pressure (MABP). ICP can be measured noninvasively using external appliance attached directly to the open fontanel of the newborn. Direct ICP measurement is invasive and its use requires the benefits to exceed the risks. Usually it is limited to
The computerized tomogram (CT) determines increased ICP. Nuclear brain scan and transcranial Doppler flow studies can also evaluate cerebral blood flow. Intermittent or continuous EEG monitoring helps diagnose and modify therapy for seizures in comatose patients.

COMMON PROBLEMS OF POSTOPERATIVE CARE

Metabolic Problems

Patients receive minimal potassium (K) during surgery. Excessive fluids if administered could also dilute serum K. Furthermore, increased urination secondary to excessive fluids or diuretic, could lower the serum K. Alkalosis, as a result of inappropriately excessive ventilation or HCO₃⁻ administration, also decreases serum K. Conversely, metabolic and respiratory acidosis, tissue damage, hemolysis, and decreased renal function (direct or related to cardiovascular insufficiency) can cause hyperkalemia. It is important to have a baseline potassium level postoperatively and reassess it depending upon metabolic, cardiovascular, and renal stability. It is important to establish a reasonable urine output before adding potassium in intravenous fluids. Depending upon the emergency hyperkalemia is treated by holding K, using sodium exchange resins (sodium polystyrene sulfonate), and insulin along with glucose. In critical patients, it is temporarily dealt with by raising pH and Ca infusion. Sustained effects are achieved by dialysis only. In few cases, salbutamol has also been used successfully to reduce serum K for few hours. Because hypokalemia is much easier to treat than hyperkalemia, it is also advisable to keep the serum K at a low normal level until cardiovascular and renal stability is assured. If impending renal insufficiency cannot be ruled out but there is hypokalemia, warranting treatment, infuse 0.5 mEq/kg potassium chloride (KCl) over 1-2 hours. Potassium can never be given by intravenous push, as it can cause death by asystole. Potassium should be kept in a remote secure place such as the pharmacy, separate from routine medications, to avoid accidental intravenous administration.

Hypokalemia can cause ileus and cardiac arrhythmias, more so if the patient is also taking digoxin. One must consider the patient’s metabolic status at the time of blood sampling for potassium and ionized calcium (Ca). The serum K or ionized Ca can change significantly with the pH of the sample without much change in whole-body K or total Ca. Alkalosis decreases and acidosis increases both K and ionized Ca. In general, 2-4 mEq/kg/day of K is needed.

Depending upon the amount and type of fluids received during surgery and renal function, the patient may become hypo- or hypernatremic postoperatively. Review of the anesthesia record and discussion with the anesthesiologist can help anticipate the sodium (Na) status and future Na needs of the patient. The sodium status should also be confirmed on admission. Avoid allowing the serum sodium to rise above 155 mEq/L, but if it is present, it should be corrected slowly over 12-24 hours to prevent cerebral edema and subsequent seizures. A sudden decrease in the serum sodium decreases the serum osmolality faster than the osmolality of brain cells, therefore causing cerebral edema by shifts of water. Loop diuretics decrease the serum sodium by increasing Na losses. Suspect inappropriate antidiuretic hormone (ADH) secretion in unexpected hyponatremia. The diagnosis is supported if the serum osmolality falls below 280 mOsm/L while the urine osmolality greater than 400 mOsm/L and is treated by restricting fluids. Increased urine output, diuretics, third spacing, or low intake also causes hyponatremia. The usual Na intake is 3-5 mEq/kg/day.

Magnesium, phosphorus, and calcium should be assessed postoperatively in critical patients, and these may be low due to low intake. Patients with hypoxic insult are at increased risk for hypocalcemia due to endogenous phosphate release. Total calcium may be spuriously low in the case of low serum albumin. Although ionized calcium is a better measure of calcium activity, it is affected by the pH of the sample. Alkalosis will lower the ionized calcium and vice versa. In case of persistent and treatment resistant hypocalcemia, the serum magnesium should be measured, as hypocalcemia is difficult to treat in a patient with hypomagnesemia due to altered parathyroid function. In newborns with persistent hypocalcemia, especially with congenital conotruncal heart disease, one should also consider DiGeorge’s syndrome. Generally, it is diagnosed with chromosomal analysis and patient phenotype. Not all cases of DiGeorge’s syndrome are complicated by
hypocalcemia, or have abnormal chromosomes. Calcium is a potent cardiotonic drug, and hypocalcemia may adversely affect myocardial contractility. Treatment consists of either calcium gluconate or calcium chloride. When calcium is needed urgently, calcium chloride is preferred because all of the calcium is available in the ionized form immediately. Conversely, with calcium gluconate, the calcium ion is released slowly as the gluconate is metabolized. Because of their different molecular weights, the calcium chloride requirement by weight (mg) is only one-third that of calcium gluconate, to deliver the same number of milliequivalents. Calcium chloride is also more irritating than calcium gluconate, so it must be given slowly after diluting, then infused preferably in a central line. When calcium is infused into a peripheral IV, patency of the IV must be confirmed to avoid severe chemical burns in the case of infiltration. There is some concern about long-term aluminum toxicity from calcium gluconate formulations in parenteral nutrition (excessive aluminum is leached from the glass container of calcium gluconate as an impurity). Alternatively, calcium chloride contains very little aluminum.

Hypotension, decreased perfusion, decreased cardiac output; increased metabolic demand, and cold stress can cause metabolic acidosis. Mostly this is self-limited and is treated by treating the primary cause. Renal dysfunction and renal tubular acidosis may also contribute to metabolic acidosis. Use of sodium bicarbonate or sodium acetate should be reserved for extreme cases, using small aliquots and frequent blood gases to avoid overcorrecting. The maximum amount of bicarbonate needed to buffer acidosis is calculated by the following equation:

\[ \text{mEq of } \text{HCO}_3^- = \text{weight (kg)} \times (0.3) \times (\text{base deficit}) \]

Sodium acetate has a slow onset but prolonged effect. Acetate is metabolized, outside liver, in isomolar ratio into HCO_3^- It also increases the patient’s buffer capacity. Excessive use of bases (HCO_3^-/acetate) or diuretics may cause metabolic alkalosis due to excessive excretion of chloride. If NaCl or KCl is contraindicated, hypochloremia is treated with ammonium chloride (NH_4Cl), lysine chloride, or arginine chloride. Similarly, tromethamine (THAM) may be used to buffer acidosis instead of the sodium or potassium salts, but renal toxicity often limits its use.

**Hyperglycemia**

Hyperglycemia from surgical stress, even with adequate pain management, is extremely common in the immediate postoperative period. Such hyperglycemia is usually self-limited to 4-8 hours. Because they can cause hyperglycemia, intravenous lipids should be avoided until the glucose is more stable. Steroid use can complicate hyperglycemia further. Most postoperative patients should receive 5% glucose initially to keep the blood glucose below 250 mg/dL. The nondiabetics patients rarely need insulin. Tight control of diabetic patients improves their outcome significantly. Head trauma patients require even tighter glycemic control (less than 150 mg/dL). When needed, insulin should be given intravenously rather than subcutaneously because of uncertain perfusion in the postoperative patient. If resistant to intermittent insulin, a continuous insulin drip with a sliding scale may be considered. When infusing insulin, the blood glucose should be monitored frequently enough to avoid hypoglycemia. Spontaneous hypoglycemia in nondiabetics outside NICU is rare and often treated easily with increased glucose intake. Critical or symptomatic hypoglycemia should be treated by 2 ml/kg of 10% glucose in infants and 1 ml/kg of 25% glucose in older children. The serum glucose should be closely monitored until stable. If resistant to intermittent insulin, a continuous insulin drip with a sliding scale may be considered.

**Clotting**

Immediate postoperative focal bleeding is usually surgical in nature, especially if closure is done in markedly hypotensive patients, because bleeding recurs at untreated bleeding points when the hypotension resolves. On the other hand, generalized oozing from mucosal surfaces or wounds, or excessive bleeding during needle sticks, suggests DIC. In a patient with excessive bleeding, PT and PTT are measured. Suspect surgical etiology if the bleeding continues despite normal PT, PTT and platelets. Most patients do not bleed despite slight increases in PT and PTT and decrease in platelets. Platelet counts as low as 50,000/mm^3 in the immediate postoperative period and 20,000/mm^3 in the delayed postoperative period are rarely a cause of bleeding. In actively bleeding
patient, platelets are maintained above 100,000/mm³. Newborns have slightly prolonged PT and PTT compared to adult norms, and premature infants have even more prolonged values. These studies should be repeated after treatment or for clinical deterioration. D-dimer and FSP persist 24-48 hours after successful treatment of DIC. A “corrected PTT” excludes the effect of endogenous or exogenous inhibitors like heparin, which sometimes contaminates the blood specimen. The PTT is corrected by repeating the test on the same sample after mixing with an equal volume of normal serum. A normal corrected PTT indicates true prolongation due to deficient clotting factors, because the PTT becomes normal with factors of normal serum. On the other hand, persistence of prolongation suggests an inhibitor like heparin. Use fresh frozen plasma (FFP) only to treat lab documented (PT or PTT at least 1½ times normal) and clinically suspected DIC. Because of its risks and cost, never use FFP as a blood volume expander or protein source.6 The usual dose is 10-20 ml/kg. If kept in the refrigerator, one can use thawed FFP for up to 24 hours. Cryoprecipitate may be considered in a patient with restricted fluids or DIC associated with marked fibrinogenemia. One or two units of platelet concentrate per 10 kg body weight are given for thrombocytopenia (< 50,000/mm³) in a bleeding patient. The newborns receive 10-20 ml of platelets per kg. Failure to significantly increase the platelet count within one hour after transfusion indicates a refractory state from antiplatelet antibodies or hypersplenism. In such cases, HLA-matched platelets may be used. However, fast destruction in few hours indicates sepsis or DIC. Risks of transfusion, including producing antiplatelet antibodies, should be weighed against the temptation to transfuse platelets in a non-bleeding thrombocytopenic patient. The amount of blood replacement in an actively bleeding patient depends upon rate of bleeding. The actively bleeding patient requires both volume and hemoglobin, supplied by whole blood or a combination of FFP and packed red blood cells (PRBC). Usually 7-8 ml/kg of whole blood or 3-4 ml/kg of PRBC increases the hemoglobin (Hgb) by 1gm/dL and the hematocrit by 3-4%. The potassium load of old PRBC presents a problem in patients needing massive transfusion or having renal insufficiency. Such patients should receive washed PRBC. Washed cells may also be indicated in severe allergic reactions. Massive blood transfusion can produce granulocytopenia, thrombocytopenia, and labile clotting factor deficiency. There is no evidence of any beneficial effect of prophylactic platelet transfusion while massive blood transfusion.

**Renal**

Blood urea nitrogen (BUN) and serum creatinine measurements are good measures of fluid status and renal function. Absorption of blood from the gut can artificially elevate the BUN. Significant renal dysfunction can occur before the serum creatinine rises. Decreased BUN and creatinine may reflect decreased muscle mass. The frequency of follow up depends upon the initial laboratory values, cardiovascular stability, renal function, and the use of nephrotoxic drugs such as gentamicin.

Oliguria and anuria are the most common renal problems in the postoperative period. Their diagnosis is confirmed by palpating the absence of a full bladder because of failure to empty. It is mostly prerenal in nature due to decreased renal perfusion, secondary to hypotension. Increased vasoconstriction, iatrogenic or otherwise, makes oliguria worse. Rarely it may be secondary to thromboembolic phenomenonae in the renal vessels, especially in patients with deep catheters. Renal ultrasound or renal scan can be used to visualize them. Acute tubular necrosis may develop after prolonged ischemia or hypotension. Ureteral obstruction or intra-abdominal leakage is rare. Blockage of the urinary catheter or inaccurate measurement or recordings of urinary volumes are other causes of oliguria.

Principally oliguria treatment addresses the primary causes, like hypovolemia and hypotension. Inotropes are used to treat poor cardiac contractility, but it is prudent to also avoid excessive vasoconstriction from high dosages dopamine, epinephrine, or norepinephrine. Renal dose dopamine (2-5 mcg/kg/min), along with a loop diuretic, is a useful addition to treating the primary cause. A bolus of 10-20 ml/kg normal saline, with or without small dose of loop diuretic, may be tried, even if hypovolemia is not that evident. If the anuria continues despite maximal treatment, fluid intake is decreased to insensible water loss and urine output.

Polyuria is extremely rare. Mostly it is caused by the polyuric phase of acute tubular necrosis. Rarely
diabetes insipidus, following head injury or surgery, can produce polyuria. Adequate fluid and electrolyte replacement is necessary to avoid dehydration and electrolyte imbalance. Usually one-half to three-quarters of the urine output is replaced. Mild polyuria may also develop due to excessive fluid intake, diuretics, and during the recovery phase following the third spacing (capillary leak syndrome). Serum electrolytes should be followed closely in these patients.

Urine specific gravity, blood urea nitrogen (BUN) and serum creatinine measurements are a good measure of blood volume (fluid status) and renal function. Absorption of blood from the gut could artificially elevate the BUN. Significant renal dysfunction can occur before the serum creatinine rises. Decreased BUN and creatinine reflects decreased muscle mass. The frequency of follow up depends upon the initial laboratory values, renal function, and the use of nephrotoxic drugs such as gentamicin.

**Hypothermia**

Hypothermia is a relatively common problem during and immediately after an operation. Usually it is due to cold operation rooms or excessive exposure of the patients or their bowels. Relatively cold intravenous fluids, especially if given in large amounts can also contribute to hypothermia. It is also caused by cardiovascular instability. Infants, especially premature or malnutrition children are more prone to hypothermia. Core temperature is routinely assessed by rectal, sublingual or tympanic membrane temperature. In critical patients, it is best assessed by temperature probes in pulmonary artery or urinary bladder. Hypothermia can complicate postoperative care significantly. It is associated with metabolic acidosis due to decreased perfusion. It compromises the patient’s coagulation system. Both the PT and PTT may be elevated despite normal coagulation factors. Further, the patient may bleed excessively during hypothermia despite normal PT and PTT also. Low temperature also decreases platelet functions. It also decreases cardiac function and may contribute to bradycardia or arrhythmias. Intense vasoconstriction may even cause hypertension and significant tissue hypoperfusion leading to metabolic acidosis. This metabolic acidosis is usually further exaggerated during warming as reperfusion collects the lactic acidosis of vasoconstricted tissue; but this decrease in pH may not be a sign of deterioration. Therefore, sufficient fluids should be given during rewarming to compensate for the vasodilatation and increase in vascular volume. A decrease in temperature increases the hemoglobin’s affinity for oxygen because of the leftward shift of the hemoglobin dissociation curve. Although it increases the oxygen saturation at the pulmonary level, delivery of oxygen to tissues decreases due to decrease of oxygen release. Shivering should be avoided to prevent its associated sudden increase in oxygen demand. Cerebral profusion also decreases significantly during hypothermia. It also affects immune systems adversely at many levels, thus increasing the risk for infections and sepsis. It depresses liver functions including drug metabolism. It also impairs insulin release thus causing hyperglycemia. As always, prevention is much better than treatment. Even mild decrease in temperature can have significant effect on clotting. Increasing ambient room temperature, keeping most of the body including the head dry and covered and warming infused fluids and gases to room temperature will prevent hypothermia in many cases. Warming devices like The Bear Hug®, warm water bags or mattress, etc can prevent hypothermia as well. Postoperatively, aggressively treat it using warming blankets and heating lamps. On the other side, mild hypothermia may have some protective effects against decreased availability of oxygen by decreasing oxygen demands. The role of cooling the head in an asphyxiated patient is not well defined yet.

**Endocrine**

Exact mechanisms of the effects of different hormones due to stress and its effects on the healing and immune systems of the patients are very complex and not well understood yet. Rarely mild adrenal insufficiency may cause hypotension, hyponatremia, hyperkalemia, hypothermia, and eosinophilia postoperatively. Hyperpigmentation in a patient may indicate primary adrenal insufficiency. The patients who have received glucocorticoids in last 12-18 months are at high risk for secondary adrenal insufficiency and will need replacement therapy for stress. Dosage and duration of steroids will define the chances of adrenal suppression.
Pediatric Surgery—Diagnosis and Management

Corticotropicin (ACTH) stimulation test can help diagnose it. It is performed by measuring plasma cortisol concentration immediately before and 30 minutes after small dose of alpha 1-24 corticotrophin. If in doubt or while waiting for results, give hydrocortisone or hydrocortisone 60 mg/M²/dose initially, IV then give 30 mg/M² every 4-8 hours depending upon the patient sickness. It is weaned over 4-7 days. The patients receiving high chronic dose glucocorticoids, for asthma or autoimmune disease, need double or triple the daily usual dose for several days until stable. Wean to presurgical dose in 5-7 days. Perioperative coverage depends upon dosage, duration of glucocorticoids therapy, and nature and length of surgery. One should weigh negative effects of glucocorticoids on immune systems, growth, and healing against benefits. Role of growth hormones for improved wound healing, weight gain and positive nitrogen balance in selected cases is still controversial. Prolonged catecholamine used may cause decreased response in adenergic receptors, and then non-adenergic inotropic agent should be used. Hypocalcemia could be multifactorial, including illness-associated hypoparathyroidism, change in vitamin D metabolism, hypomagnesemia, and change in acid base status. Certain stress responses including fever actually enhances immune functions so should not always be truncated.

Cardiovascular

Neuromuscular blockade and the sedative effect of anesthesia decreases the metabolic demand thus protects the heart during anesthesia. The postoperative patient’s metabolic demand increases due to the decreasing anesthesia and increasing catecholamines due to pain, anxiety, and agitation despite reasonable pain management.

Tachycardia is a cause and effect of increased metabolic demand. It may be due to decreased perfusion, blood volume loss, hypotension, hypoxemia, airway obstruction, and the stress of pain, anxiety, and agitation. Certain drugs used during anesthesia like pancuronium and atropine can cause tachycardia. Rarely it may be due to direct irritation of SA node, if a tip of central line is in right atrium. It may also be due to tachyarrhythmia and can be diagnosed by EKG.

The absolute number defining bradycardia is age dependent. It is much less common but have much more serious consequences. It may also be due to excessive sedation. Bradycardia, if due to hypoxemia, is always critical and needs immediate relief. Heart block especially in postcardiac surgery can cause bradycardia that can be diagnosed by EKG. Sudden increases in blood pressure due to any reason also cause bradycardia, though transient, due to negative feedback by carotid bodies. It is also important to consider the preoperative baseline as many athletic patients may have low baseline heart rate. During deep sleep and pain relief, heart rate may fall significantly. Many drugs can also decrease heart rate. Neostigmine without atropine, when used to reverse muscle relaxants, causes bradycardia and will be relieved by atropine only.

Hypertension is rather rare and usually due to pain, anxiety and agitation. Hypertension due to excessive volume infusion, especially colloid, is rare, mild, and transient. Excessive use of pressors or its sudden accidental bolus during drip change is a common cause of transient hypertension in ICU. Patients on steroids can also become hypertension. Steroids increase sensitivity of dopanergic receptors for endogenous and exogenous catecholamines. Renal vaso-occlusive disease, especially when patient have central catheters, should be ruled out by ultrasound and serum rennin levels. Severe hypertension if not treated can cause cardiac failure and worsen respiratory status. The hypertensive crisis is initially best treated by sodium nitroprusside. It could be titrated easily for the desired effect, because of its quick onset and short duration of action. Once the BP is controlled, an angiotension converting enzyme (ACE) inhibitor is commonly used for the subacute hypertension management.

Hypotension is an emergency and always need immediate intervention. Decreased cardiac output or decreased vascular tone is the most common cause of hypotension. Decreased venous return or decreased myocardial contractility causes decreased cardiac output. Decreased venous return may be secondary to increased intrathoracic pressure (ventilation), decreased blood volume, or decreased vascular tone. Inadequate fluid intake or excessive losses including third spacing due to leaky capillaries can cause decreased blood volume. Routine chest X-ray may give many clues for causes of hypotension. Small heart on
routine chest X-ray, provided it is not due to excessive intrathoracic pressure, indicates decreased blood volume. Similarly, large heart may point toward dilated, poorly contractile heart. Hyperexpanded and hypoluent lungs may indicate increased intrathoracic pressure. Chest X-ray may also rule out any air leak, which can be the cause of hypotension and needs urgent treatment. In case of sudden severe hypotension, along with deteriorating ventilation and oxygenation, a tension pneumothorax or cardiac tamponade should be suspected. Signs of mediastinal shift and unilateral decreased breath sounds help make the diagnosis of tension pneumothorax. Similarly, fast thready pulses, engorged neck veins, distant muffled heart sounds, and initial tachycardia followed by terminal bradycardia may indicate cardiac tamponade. In small infants with thin chest wall, transillumination may help make the diagnosis of air leak. However, negative transillumination does not rule out air leak. If suspicion is very high and patient is extremely critical, trial of needle aspiration may be indicated and may be life saving. Patients with central line tips in heart are at higher risk for cardiac tamponade. Most often, a chest tube is needed after needle aspiration, but if a patient appear stable, it may reasonable to wait, especially when the patient is on high frequency oscillator. Blood volume expansion may partially compensate for decreased venous return during early phases of air leaks.

Preferably hypovolemia should be treated by crystalloid and if indicated blood products. Use of 5% albumin should be avoided as in sick child with leaky capillaries it immediately leaks into third spaces and takes water to extravascular spaces and this edema is difficult to manage later. Pressors are used for poor myocardial contractility. Dobutamine increases cardiac output and tissue perfusion yet it may not always improve hypotension. On the contrary, dopamine in moderate and high doses increases BP. Due to vasoconstriction it may not necessarily increases or sometimes even decreases the cardiac output and the tissue perfusion. Epinephrine and norepinephrine though potent drugs and always increase the blood pressure. These should be avoided until last effort, as BP elevation benefits may not be enough to justify their use, due to negative effects of vasoconstriction and increased metabolic demand associated with tachycardia. Mild hypotension in congestive heart failure patient can be treated by milrinone (Primacor), as it increases cardiac contractility but decreases the peripheral resistance, so giving dual benefits. Load it with 50-100 mcg/kg over 15-30 minutes then use continuous drip at 0.5 - 0.75 mcg/kg/minute. Dopamine in low doses (2-5 mcg/kg/min) has renal effect, while in higher doses (10-20 mcg/kg/min) has more vasoconstrictive effect that may have negative effect on cardiac output and glomerular filtration rate (GFR). Often, a combination of these drugs is needed to get the optimum effect. Sometimes, both pressors and after load reducers, like nitroprusside, are used to increase cardiac output. There is sudden peripheral venous pooling after neuromuscular blockade. It causes the hypotension, tachycardia, hypoperfusion, and occasionally desaturation and hypercapnia. Fluid bolus can compensate decreasing venous return, because of venous pooling. Third spacing due to leaky capillaries in sepsis or ischemia can decrease blood volume significantly and needs extra fluids to maintain normal blood volume. CVP and pulmonary artery pressure monitoring help assess blood volume in critical patients. Trends rather than any absolute numbers in CVP measurement are used. In extremely compromised patient, an intra-aortic balloon pump is placed in aorta via femoral artery, in between left subclavian and renal artery. It is inflated in diastole to support perfusion of vital organs proximal to balloon.

Pulmonary

Desaturations or hypoxemia and hypercapnia are the commonest pulmonary problems of the postoperative time. Both can be due to accidental extubation, slipping ET into the main stem bronchus, aspiration, secretions, ET blockade, hypoventilation. It may also be due to lack of changes in the ventilator settings in response to changing conditions of the lung, or changing metabolic needs of the patient after wearing off of neuromuscular blockade and anesthesia. Furthermore, agitation, fighting against ventilator, inadequate relief of pain, pneumothorax, pneumopericardium, and hydrothorax can also cause hypoxemia and hypercapnia. It can also be due to premature extubation, atelectasis, laryngeal edema, excessive narcotics or resurgence of reversed narcotic or neuromuscular blockade. Pulmonary edema due to excessive water intake, heart failure, renal failure and increased negative intrathoracic pressure in retracting
patient can cause initially hypoxemia and ultimately hypercapnia also. Similarly, pulmonary hemorrhage and infections can also cause these problems. Lot of evidence has accumulated recently regarding the negative effects of hyperventilation, especially in newborns. It is always iatrogenic, thus evaluate ventilation plan every time PCO₂ is less than 30-35 torr. Similarly, keeping PO₂ high increases morbidity and can be catastrophic in premature newborns.

VENTILATOR MANAGEMENT

Detailed management of individual ventilator is out of the scope of this chapter. Still concise general principles of ventilation will be discussed here. Mechanical ventilation is usually indicated for inability to oxygenate, ventilate, or keep airway open. Spontaneous breath, with negative intrathoracic pressure in inspiration is very different from ventilator breath. As a principle, use ventilator as an adjuvant rather than replacement of spontaneous breathing and aim for gentler and minimal ventilator therapy. Prefer ventilator, nasal continued positive airway pressure (CPAP), and nasal cannula or oxyhood in reverse order. Avoid unnecessary use of sedation and muscle relaxants considering genuine pain relief.

In general, mean airway pressure (MAP) increase by any means improves oxygenation unless there is an excessive intrathoracic pressure causing V/Q mismatch. MAP is the average pressure of the airway during respiratory cycle. Alternatively, increasing FIO₂ improves oxygenation. Usually positive end expiratory pressure (PEEP) of five is enough and then positive inspiratory pressure (PIP) is chosen to achieve enough visual chest movement or desired measured tidal volumes. Tidal volumes are the volume of gas moved in and out during a single breath. Normally 8-10 ml/kg in children and 5-7 ml/kg in newborns are adequate tidal volume.

Initially, start at rate of 20-25 breaths per minute, and then change it to attain desired CO₂. Increasing breathing rate or intermittent mandatory ventilation (IMV) is the commonest means to lower PCO₂. Lung expansion, seen in chest X-ray, may also help monitor pressure settings on ventilator. Usually high diaphragm, especially with high FIO₂, may indicate need to increase pressures and vice versa. Often, FIO₂ can be decreased by increasing MAP or vice versa. In general, somewhat balance is maintained between FIO₂ and MAP, although occasionally two definite strategies favoring either high FIO₂ or high MAP are used.

High lung volume or alveolar recruitment strategy is used in patients with high FIO₂, who often have diffuse alveolar collapse causing V/Q mismatch. Initially, it was proposed for high frequency oscillation ventilator (HFOV), its principles can be used in conventional ventilation also. In this strategy, PEEP and MAP are slowly increased, which allow FIO₂ lowering. During this, lung expansion through 10th posterior rib is achieved, which opens collapsed alveoli. Usually FIO₂ is decreased to 0.4 (40%) during this, and then MAP is decreased slightly without need to increase FIO₂. If significant or sudden increase (5-10%) in FIO₂ requirement occurs with further decrease in MAP, probably too much MAP was decreased. MAP should be increased again to open the recent atelectasis until FIO₂ is decreased. After one-two hours lower the MAP slowly.

On the other hand, air leak strategy is used in a patient with air leaks. In this, higher FIO₂ is tolerated so MAP can be kept lowers. High MAP and tidal volumes are the major factors in production and continuance of air leaks. Lungs are kept at no more than eighth posterior rib expansion.

Usually a PEEP of five is enough but a PEEP up to eight can be safely used in selective case in noncompliant lung requiring high FIO₂. Normally increasing PEEP increases oxygenation and decreases ventilation by reducing Tidal volumes. However, in an atelectatic lung raising PEEP may open new alveoli thus increasing the lung’s tidal volume and decreasing PCO₂.

PRESSURE SUPPORT VENTILATION (PSV)

Certain predetermined pressure is delivered above PEEP, to support each spontaneous breath, triggered by the initiation of breath. It is a useful tool to wean the patient from ventilator. It also helps patients who are fighting ventilator or are on very low IMV rates. Pressure support depends upon the needs of the patient and slowly weaned as the patient contributes more. Once PSV is around 10 cm of water, it could be stopped just before extubation. Depending upon the spontaneous breathing rate even a small pressure support may contribute significantly to MAP and ventilator support. It is also used to reduce WOB by
compensating for the resistance of ET and respiratory system in low IMV. Similarly, each spontaneous breath can also be supported by predetermined tidal volumes.

**High Frequency Oscillation Ventilator (HFOV)**

HFOV uses tidal volumes much smaller than dead space at extremely high rates (360-900 breaths/seconds). It is mainly used to treat resistant hypercapnia, prevention and treatment of air leak syndromes. Its role in decreasing chronic lung disease is not established yet. In this mode also, increase in MAP and FIO2 are the main means to improves oxygenation. Increase in amplitude (ΔP) improves ventilation. Frequency of breath has minimal and paradoxical role. Increased frequency increases PCO2, because it decreases the IT that reduces the tidal volumes significantly. In small infants, the ET size change can make a big difference in ventilation.

**Use of Nonendotracheal PEEP (CPAP)**

Atelectasis reduces functional residual capacity (FRC) that significantly. Function residual capacity (FRC) is a volume of gas left after normal breath, increases work of breathing. Patient adapts to it by decreasing TV and compensates reduced TV by increasing respiratory rate. Increasing PEEP will reverse it by clearing, atelectasis and recovering FRC. Change in pressure (ΔP) needed for a particular TV (ΔV) will decrease thus decreasing WOB, retractions, and increasing compliance (ΔV/ΔP). PEEP also distends airway that can reduce airway resistance, which decreases respiratory work. Low-level PEEP can help expiration even in chronic obstructive lung disease patients by distending the airway. However, higher PEEP may hurt these patients by overdistending lung and increases V/Q. Optimum PEEP for a patient has to be individualized and changes with changing conditions of lung. Need for close titration and frequent evaluation cannot be over emphasized.

PEEP also helps patients with diffusion problems due to pulmonary interstitial disease like pulmonary edema or pneumonia. Nasal prongs or facemask could apply PEEP. Complete seal is very important in facemask. PEEP may cause significant gastric distension especially at higher level. Stomach could be decompressed by gastric tube in these cases.

Although most patients needs PEEP of 5-8 cm of water but rarely PEEP up to 15 cm of water have been successfully utilized. Excessive PEEP causes hyperinflation and increases V/Q ratio reducing arterial PO2. It also decreases the venous return to heart and decreases cardiac output, which increases the oxygen extraction, seen by decreasing mixed venous oxygen saturation. Difficulty in expiration secondary to excessive peep increases work of breathing and metabolic needs of patient. It may significantly increases the dead space lowering ventilation, but this increase may not appropriately show on endtidal CO2 due to dilution by increased dead space. Appropriate PEEP in a sick lung may become excessive as the lung compliance improves. Although in general, PEEP helps inspiration but it makes expiration difficult. Nevertheless, it can help expiration in reactive or malacic airway patients by keeping airway open. Decreased venous return by PEEP due to its transmitted pressure on veins could be partially compensated by increasing preload with fluids. However, consider the deleterious effects of increasing fluids. Barotrauma of PEEP is minimal on a spontaneously breathing patient specially when compared to alternatives like intubation.

**Work of Breathing (WOB)**

Although the ET size depends upon the size of the patient still at times one of the two ET sizes could be chosen for a particular patient. Smaller size ET could increase work of the breathing significantly. As discussed earlier optimal PEEP can decrease WOB significantly. Pressure support ventilation can also lower the work of breathing. Ventilators with demand flow, which have different flows for inspiration and expiration, decrease work of breathing. Keeping the patient slight upright (brings diaphragms down), decreasing edema (diuretics) or correcting atelectasis by increasing PIP or PEEP can also decrease the work of breathing. Similarly, sometimes bronchodilators can significantly decrease WOB.

**Atelectasis**

Atelectasis may be focal or diffuse. Reduced lung volume helps its differentiation from edema or consolidation, on chest X-ray, but still it is not always that easy. FRC decreases significantly in spine position,
which increases likelihood of atelectasis postoperatively. It also increases the risk of infection. Early ambulation, mobilization, deep breathing exercises and incentive spirometry can help to maintain the FRC. Nasal or facemask CPAP may be used alternatively in patients who cannot cooperate. Effective pain control also helps maintain FRC as pain may inhibit cough mobilization and discourages deep breathing. General anesthesia, obesity, diaphragm dysfunction, abdominal and thoracic surgery also decrease FRC. Closing capacity is the lung volumes at which small airway begin to close during expiration. Residual anesthetics and narcotics inhibit respiratory drive and decreases ventilatory response to hypercapnia and hypoxia. Defense mechanism of cough, mucociliary transport are also impaired postoperatively, increasing risk of pulmonary infection. Lack of humidity, intubation and high FIO2 further hampers mucociliary transport. Atelectasis decreases force of cough that in return increases atelectasis. It can be treated by chest physiotherapy (CPT), hydration, bronchodilators, and postural drainage. Occasionally a brief treatment with mucolytics may be used in selected patients. Rarely bronchoscopy is needed in persistent atelectasis. Atelectasis, infection, and pulmonary edema worsen the existing chronic lung disease and prolong ventilatory support. Obesity, smoking, existing chronic lung disease, pre-existing URI, and prolonged anesthesia increase the risk of pulmonary complications.

**Nitric Oxide (NO)**

Nitric oxide has good dilatation effect on pulmonary circulation with effect on systemic circulation.\(^\text{16}\) Its prompt and short duration of action, along with it ability to be delivered directly into alveoli makes it an excellent choice for treatment for pulmonary hypertension. It is mixed with the inspired oxygen in very low concentration. Usually, NO in 5-20 parts per million (ppm) dose affectively reduces the pulmonary artery pressure. NO up to 80 ppm has been used for brief time but higher doses rarely have higher effect but significantly increase the chance of toxicity due to methemoglobinemia. These patients should be monitored for methemoglobinemia and nitric dioxide (NO2). Methemoglobinemia when present is treated by methylene blue. Use NO in minimal affective dose. Some times, NO although initially ineffective with conventional ventilation may response positively with high frequency ventilation due to recruitment of alveoli so NO can act on more surface.

**Extubation**

Decision to extubate should be deliberate and not a hurried one. Assessment of preoperative lung condition, nature of secretions, gag reflex, conscious level, sedation needs, residual neuromuscular blockade and level of needed ventilator support should help make decision to extubate. When patient is extubated in ICU, it is advisable to wait until initial chest X-ray and initial blood gas is done. The chest X-ray helps to rule out atelectasis and assess overall lung condition. Clear the atelectasis completely before extubation.

If the neuromuscular blockade is reversed recently, wait for at least an hour to avoid return of neuromuscular blockade. Mixture of neostigmine (0.025-0.1 mg/kg) and atropine (0.02 mg/kg) is usually used to reverse neuromuscular blockade. However, we have usually been able to reverse it using neostigmine alone by diluting dose in 2-5 ml solution and administer slowly over 5-10 minutes. This way we could avoid tachycardia and drying of secretion caused by atropine. Neostigmine increases bronchial secretion so suction the ET after using it.

When surgery is done around or on trachea and larynx, surgeon should be consulted regarding time of extubation. Similarly, prospective of abdominal distension should be considered before extubation also. Avoid aspiration by emptying stomach and stopping feed during this transient period. Similarly, when extensive surgery is done on chest and abdomen, pain management and altered breathing pattern may delay extubation considerably.

When there is history of difficult intubation, laryngeal and vocal cord edema and potential difficulty for reintubation should be considered before extubation. Benefits of steroids (dexamethasone 0.5-1 mg/kg/day in four divided doses) use should be weighed against negative effect on healing and metabolism. Usually two doses each are given before and after extubation.

Patient may be placed on humidified air or O\(_2\) after extubation. If there is any inspiratory stridor, retractions indicating laryngeal edema, nebulized racemic epinephrine can be used. These treatments if
beneficial and tolerated without excessive tachycardia or hypertension can be used as often as every hour for short period. Rarely a mixture of helium and oxygen is used as inspired gas, for lower gas density of helium as compared to nitrogen makes this admixture easy to breath through edematous airway.

**Obstructed Endotracheal Tube**

While partial obstruction of the ET may pose only a subtle difficulty in ventilation, complete obstruction can cause major emergency needing prompt relief. Thick secretion and mucus are the most common culprits. Kinked ET or other ventilator tube may also cause obstruction. Small size ET, if used in children and infants’ can complicate it further. Sudden deterioration in ventilation and hypercapnia are earlier indications of obstructed tube. Partially obstruction may initially increase oxygenation by increasing FRC but ultimately oxygenation also deteriorates. Lack of observed chest expansion, marked retractions and decreased breath sounds, on auscultation suggest near complete obstruction. Decreased tidal volumes especially expiratory also indicate obstruction. If obstruction is below ET in airway, large leaks will be observed and similarly obstruction in one of main bronchus will indicate decreased breath sounds on that side. Mediastinal shift may differentiate bronchus obstruction that can lead pneumothorax. Total bronchus obstruction will lead to collapse but partial obstruction may cause hyperinflation due to the ball-valve action.

When ET obstruction is suspected, it should be immediately suctioned with a big catheter. Failure to pass suction catheter confirms major obstruction. On the other hand, if suction catheter continued to be advance much more than usual, one may suspect accidental extubation. Bronchoscopy may be of great help if immediate bronchoscopic examination to diagnose and treat, obstruction is possible. Otherwise, ET should be replaced immediately. Sometimes, suction with a bigger catheter on direct laryngoscopy is indicated to remove the big mucus plug that could not be suctioned through ET.

**Reintubation**

All equipment needed for intubation with different size ET’s and laryngoscope blades should be kept, in a single mobile case, in the ICU that can be immediately pulled to the patient’s bedside for intubation. The patient can be effectively ventilated with bag and mask, using manometer, until equipment and personnel are available for intubation. Deep oral suction also helps airway patency. Intubation should be attempted only after directly visualizing vocal cords in full view. Blindly pushing ET can do serious harm. While miller (straight) blade is put under epiglottis to extend its tip to glottis, Macintosh (curved) blade is placed in valecula. Choosing a relatively bigger ET reduces airway resistance and work of breathing.

ET position is usually certain when an experienced personnel intubates under direct visualization. Still bilateral auscultation is mandatory to confirm equal bilateral breaths for normal ET position. If advanced too far ET commonly moves to right main bronchus. It causes significantly reduced breaths on left side. ET tube in position should always be confirmed by chest X-ray. If available, a capnograph or disposable CO₂ detector can be used, in doubtful cases, to rule out esophagus intubation. Intermittent CO₂ detected in expired air over many breaths confirms endotracheal intubation.

**INFECTION**

Infection plays a major role in the postoperative period. Strict hand washing before and after touching the patient remains the hallmark of prevention of infection. Universal precautions should be strictly followed. Sterility, including cap, gown, mask, gloves and drapes, is very important during invasive procedures including inserting deep lines. Fever always brings attention toward infection. Decreased temperature may be the presenting symptom of sepsis in neonates and debilitated patients. Changes in the cardiovascular, respiratory or mental status also indicate sepsis. Leukocytosis, leukopenia, thrombocytopenia, and left shift on differential count are reasonable causes to look for infection. Detailed physical examination is the most important means in quest of infection causes. Change in color (purulent) and amount of endotracheal secretions raises suspicions of pneumonia, leading to Gram stain and culture of tracheal secretions. Chills and rigor often indicate bacteriemia. When present, central lines are always suspected as the cause of sepsis and should be
removed or replaced if symptoms persist. Wound and suture lines should be carefully evaluated. Sometimes, rather moderate abscesses are not evident until surgical wound or suture line is explored. Abnormal abdominal examination with ileus, tenderness, or redness may indicate abdominal pathology. If redness or pus is present around the insertion site, remove the line. In case of thrombophlebitis, the vein should be pressed toward insertion site. In severe case, surgical excision of the vein should be considered. Urine culture, Gram stain will help diagnose UTI. Suspect meningitis or cerebral abscess if there is mental alteration or seizures. CBC, chest X-ray, tracheal aspirate, and one or two sets of aerobic and anaerobic peripheral blood culture should be done in sepsis suspect patients. The central line blood cultures should be done only at the time of insertion or in addition to peripheral blood culture. Complete blood count usually shows leukocytosis but leukocytes count may be depressed in overwhelming infection and patients on chemotherapy or steroids. Thrombocytopenia is usually a late sign in sepsis and more often indicate Gram negative or fungal sepsis. We have seen isolated thrombocytopenia in the otherwise asymptomatic surgical newborns due to very small abscesses, which were found only on detailed examination of the suture line. The platelets dramatically improved after opening these abscesses. Chest X-ray may help diagnose pneumonia, fluid effusion and lung abscess. An X-ray may be negative early in the disease. Abdominal investigation starts with plain KUB film, which may show free air, ileus, bowel displacement showing mass effect, or collection of peritoneal fluid pushing bowel in the center. Persistent sentinel bowel loop in same place may be the only indication of abscess. Elevated right diaphragm may indicate subphrenic abscess. Ultrasound and CT scan are indicated in the difficult cases. In difficult patients with suspect abscess, interventional radiologist can aspirate it percutaneously under ultrasound guide. Nuclear scan can also be used to investigate abdominal abscess. Gram stain and cultures of ascitic fluid can help tailor the therapy. Severe cardiovascular collapse usually accompanies alternation in mental status and if it is out of proportion to cardiovascular instability or accompanied by signs of focal neurological deficit then lumbar puncture (LP) is indicated. CT scan or MRI may be useful, if brain abscess is suspected. Consider blind laparotomy if abdominal pathology is highly suspected despite negative investigation as it can be lifesaving.

Initial increase in indirect bilirubin, in the first week of postoperative period, is usually not related to infection. On the other hand, direct bilirubin accompanied by clinical picture of sepsis indicates infection. The bilirubinemia associated with infection usually appears and resolves fast. Direct bilirubinemia secondary to total parenteral nutrition (TPN) related to cholestasis is seen at least after 2-3 weeks of TPN and is slow and progressive. Worsening of lung disease during sepsis is due to pneumonitis or the increased capillary leak by the toxic or ischemic effects of sepsis. Clinically both act by decreased compliance and increased diffusion block, needing high pressure and FIO₂. The tracheal aspiration examination shows large amount of neutrophils and organisms in the pneumonia. If only one organism predominates it helps establish diagnosis and treatment of pneumonia. Chest X-ray showing focal changes also gravitates toward pneumonia; but generalized opaqueness does not rule out pneumonia. In case of valvular disease patients with sepsis, echocardiogram investigation of the heart should be done to rule out vegetation. New or changing nature of murmur may be due to vegetation.

Routine blood or tracheal aspirate cultures are not that helpful. However, index of suspicion should be very low in a patient with the central lines or ET. Never the less, colonization if known by previous cultures may help you to cover the right organisms in case of deterioration. Yeast and staphylococcal infections are usually undulating. Although a broad coverage is started initially, treatment should be narrowed down depending upon the culture results and clinical response. Monitor drug levels of antibiotics like vancomycin, and gentamicin in patients treated for more than 48 hours. High trough level indicates need for increased duration between doses and low peak indicate need of increasing dose. The patients with third spacing have higher volume of distribution and needs less frequent doses but higher dosage for the drug levels to be in the therapeutic range. Evidence is accumulating in favor of higher but less frequent dosage for higher efficiency and lower toxicity.
PAIN MANAGEMENT

Although, the pain relief has been the main stay of medicine since early times, but lately there is increased awareness to the pain. Most of the times still, the pain is not adequately treated. The pain management, in a nonverbal postoperative patient is an amalgam of science and art. It becomes even more complicated in a critical patient with vasomotor instability, because of decreased margin of safety. Furthermore, confusion, hesitation, anxiety, individual variability to tolerate pain, and new environment make it even harder to assess the exact status of the pain. Inadequate relief of the pain and anxiety can increase metabolism, prolong hospitalization, delay extubation and healing. Increased oxygen consumption, because of pain, can worsen the ischemic condition of heart and body. It may cause hypercoagulability and adversely affects immune system. It can cause water retention due to increased ADH and rennin secretion. It may also delay return of bowel function. Severe pain decreases ambulation, cough and ventilation, which increase the chances of atelectasis, pneumonia, and thromboembolic complications. It can also alter responses to acute and chronic pain, later in the life. The important signs as tachycardia, hypertension, and tachypnea can be wrongly assessed during clinical assessment of the patient.

Preoperatively, discuss the pain management with the patient and family to relieve anxiety and make plans for the postoperative pain. The importance of pain prevention and need for continuous relief of discomfort cannot be over emphasized. Once the pain is well established, it takes much larger dose to control. Sometimes increased catabolism, because of decreased insulin with the pain, causes hyperglycemia. Periodic pain reassessment after treatment can confirm its adequate effect. Nonpharmacological methods of pain relief are as important as medications. Simple processes like, parents holding patient’s hand during blood draw have shown to soothe even newborns. Multidisciplinary team approach, including physician, nurse, parents, pharmacist, and many other allied health professionals, is the best approach. Pain assessment is considered as fifth vital sign and should be assessed and recorded whenever vital signs are taken. There are many approaches to assess the pain; commonly used, one to ten pain-scale is most practical. The pain level of ten is the most severe pain and zero score being no pain at all. Usually a pain level of four and more warrants intervention. Most commonly, opioids as morphine and fentanyl are used for the pain. Sudden respiratory deterioration along with reduced chest movement just after fentanyl suggests chest wall and laryngeal rigidity, which can be promptly reversed with naloxone. For early onset and predicted levels, secondary to independence from absorptive process, prefer intravenous route in acute pain. Chronic pain is treated by long acting preparations including transdermal opioids. Occasionally, an intramuscular route can be used according to the choice and needs of the patient. In acute pain, continued infusion avoids yo-yo phenomenon but it needs close observation to prevent its toxicity. On the other hand, the too infrequent doses can cause breakthrough pain.

The patient controlled analgesia (PCA) is ideal for pain control in the older postoperative patient. In this, the patient controls pain by self-administering medication by small boluses in addition to a baseline drip. Usually, two-third the anticipated daily dose is given as a continuous infusion and remained one-third dose is given as many boluses by pressing a button. PCA has been used successfully in young children as young as seven years old. It is important in these cases that only the patient administer the bolus. The parents should abstain pushing button to administer medication by assessing pain on the child’s behalf. Either these cases have no baseline infusion or very low dose baseline infusion is used to avoid accidental overdose.

Opioids with local anesthetics infusion, through the epidural catheter, can decrease the individual doses and side effects in selected high-risk patients. Similarly, nerve blocks by local anesthetics are also used effectively to reduce postoperative pain. Nonsteroidal anti-inflammatory drugs (NSAID) can help wean opioids in mild-to-moderate pain conditions. It acts mainly inhibiting prostaglandins and decreasing inflammatory reactions at tissue injury site. Although, benzodiazepines do not have any analgesic effects, still they help release anxiety and it’s secondary pain. When using benzodiazepines in addition to opioids, especially in the newborns and unstable patients, be aware of its additive effect on respiratory and cardiovascular depression.
Nonpharmacological methods of massage, soothing music, quiet environment, acupuncture, and hypnosis are used more often nowadays. Pain management teams and consultative services are becoming common sites in the most US hospitals. The pain transmission through efferent peripheral nerve can be blocked by regional and local anesthesia. Intrathecal and epidural anesthesia blocks pain at spinal cord level. Nonnociceptive input from larger myelinated nerve fibers can prevent entry of nociceptive stimulus. The pain can be assessed indirectly by physiological response of heart rate, blood pressure, respiration, diaphoresis, face grimace, and tearing, or crying. The patient can also verbally communicate by direct description of pain or using visual analog scales. It is important to use standardized approach to have consistency in pain assessment and pain management.

Proper recording of periodic pain assessment, treatment rendered and pain reassessment to evaluate its therapeutic response has become an important part of the postoperative charting. Physician may consider writing orders; to give pain medications at regular intervals rather than as needed doses in the immediate postoperative patient. Patient with as needed orders may not receive adequate pain relief as some nurses may feel uncomfortable giving narcotics. Different opioids agonists activate separate opioid receptors. Individual pain tolerance and pharmacological variability can make ideal drug administration, with minimal breakthrough pain and toxicity, very difficult. The tolerance to opioids (except constipation) develops rather soon. Thus, increased doses may be needed for the same therapeutic response only after few days.

NEUROMUSCULAR BLOCKADE

Many times neuromuscular blockade, from the operation room, is continued in the ICU in critical patients for stability. Sometimes, it is also used in a patient fighting ventilator or when patient movement causes clinical instability. It can be administered intermittent or by continuous drip. Never use it without adequately addressing pain, anxiety, and breathing issues. The neuromuscular blockade causes decrease in peripheral vascular tone and peripheral venous pooling, which may cause decreased blood return, lower cardiac output, hypotension, and tachycardia. Infusing fluid bolus to increase blood volume can compensate it effectively. Intermittent doses make above mentioned changes every time the patient receive the dose and could initiate a cardiovascular instability in a critical patient. It can also make sudden changes in oxygenation and ventilation. Conversely, the continuous drip has the potentials of using excessive dose. Similarly, during continuous drips, drugs may accumulate in secondary compartment (e.g. fat), which may increase the prolonged duration of action even after drip is stopped.

Neuromuscular blockade also decreases the lymphatic drainage, causing progressive edema by third spacing. It can be avoided by closely monitoring the status of blockade by nerve stimulation test or decreasing the dose periodically to evaluate the continued need of the blockade. The aim of the treatment is using the minimum level of neuromuscular blockade required. Reverse neuromuscular blockade with neostigmine and atropine.

TOTAL PARENTERAL NUTRITION (TPN)

TPN provide nutritional requirements in supplement to enteral feeding to maintain basal metabolism, avoid negative nitrogen balance, promote optimal repair of injured tissue, and growth. Continue maximum tolerated enteral feeding, how small it may be. Enteral feeding is held postoperatively in all critical patients for variable periods. In these patients, TPN becomes essential to avoid catabolism and promote healing and positive nitrogen balance unless adequate enteral feeding is expected soon. It is even more important in malnourished and growing children. The patient has negative nitrogen balance in the immediate postoperative period. There is not enough good evidence that starting TPN very early can prevent or reverse this catabolism. Still, a case could be made to start TPN after few hours, once the hyperglycemia resolves indicating against catabolism. It can be given as peripheral intravenous solution if enteral feeding is expected within 7-10 days. Peripheral route limits the glucose concentration (12.5%) and calories administered, especially in patients with restricted fluids. On the other hand, give hypertonic solutions (1000-1500 mOsm/L) via central line only. More than 20% glucose or 4% amino acids are used rarely.
Amino acids are essential to compensate the catabolism of stress and injury. Fasting newborns lose 1.2 gm/kg/day of proteins (1% of body protein mass) for every day without TPN. This deficit soon becomes difficult to catch despite maximal TPN. It can be avoided by early TPN use. Usually, non-protein calories are increased slowly along with increasing protein intake. Ideal ratio between non-protein calories and grams of nitrogen is 150-200:1. In sick patients, it may decrease up to 100:1. One gram of nitrogen is found in 6.25 gm of protein, which can constitute nearly 30 g of wet muscles. Newborns and infants require 3-3.5 g/kg/day of protein. Older children need slightly less proteins (2.5-3 g/kg/day). Adults need only 1-2 g/kg of proteins daily. Protein requirement is higher than average in premature newborns, surgical cases and patients with malnutrition, excessive protein loss, stress, and sepsis. One gram of protein produces four calories. Start with 1.5-2 g/kg of amino acids and quickly advance to full requirement in 1-2 days. The premature newborns have transient higher BUN and creatinine when they are on full protein intake but it does not have any long-term deleterious effect. Replacing some chloride with acetate easily treats premature newborns, which may have some metabolic acidosis on higher dose of amino acids.

Fat is provided by intravenous, isomolar and dense caloric lipid emulsions. The lipids can prevent essential fatty acid deficiency. It decreases the irritative nature of protein solution. Thus, relatively hyperosmolar solutions can be used peripherally if given with lipid emulsions. Lipid metabolism produces less CO₂ than carbohydrate for similar amount of calories. Thus, lipids may be preferred in a patient with difficulty in excreting CO₂. In addition, fewer calories are wasted when fat is synthesized from triglycerides rather than carbohydrate. 20% lipid solution is better tolerated than 10% solutions. 20% lipid emulsions contain one Kcal/ml. Initially start 1-1.5 g/kg of lipids daily and increase daily depending upon serum glucose. Lipid infusion increases serum glucose. Lipids more than 3-3.5 gm/kg/day are rarely used. Although, lipids are relatively contraindicated during sepsis, thrombocytopenia, and hyperglycemia and in a newborn with indirect hyperbilirubinemia, still one gram/kg of lipids can be used in most patients.

Glucose solution is used as the preferred source of energy. Commonly 4-6 mg/kg/min, depending upon age and activity, of glucose is needed to maintain basic metabolic rate. The patients who do not tolerate even this much glucose infusion are considered catabolic. Protein and lipids are held in these patients. Initially start 6-9 mg/kg/min of glucose infusion and then increase glucose intake depending upon serum glucose levels on previous days up to 24 mg/kg/min. Monohydrate glucose used in intravenous solutions provides 3.4 Kcal/g.

When TPN is infused through a central line, 0.5 units/ml heparin is added to increase the patency of the catheter. Most commercially available vitamins and trace-element preparations adequately provide the daily requirements. Copper and manganese intakes are reduced in the cholestatic patients because of decreased excretion. The patients with increased gastrointestinal losses may need increased zinc intake.

The patients who are discharged home with TPN, total daily TPN is infused over 10-14 hours daily during night. The TPN is consolidated slowly over many days monitoring serum glucose. Infusion is terminally tapered over 1-2 hours to avoid hypoglycemia caused by abrupt stopping of glucose solution. Utilize drug incompatibility charts to administer drugs in TPN. Alternatively, infuse the compatible drugs very close to the patient.

Monitor frequently serum electrolytes, BUN, creatinine, glucose until stable TPN with stable electrolytes is achieved. Then monitor once weekly. Serum triglycerides are measured to verify tolerance of lipids initially when lipids are given in a high dose. Similarly, CBC is monitored routinely once weekly for scouting anemia and infection. Liver functions could be screened by weekly direct bilirubin measurement. If cholestatic jaundice is suspected, detailed investigation of the liver by enzyme assay, ultrasound and nuclear scan of gallbladder and liver is indicated, to rule out other causes. Infection plays the major role in cholestasis secondary to TPN. Enteral feeding, lowering glucose load and infection prevention are the most important methods in its prevention. It has been also treated with cholecystokinin, ursodeoxycholic acid, cyclic TPN, and gut decontamination. In conclusion, postoperative care is a complex mixture of managing medical, surgical, social, and psychological problems of a patient after surgery. It’s planning starts before surgery in assessing and discussing the potential postoperative problems and
may continue at home as prolonged rehabilitation. Close monitoring, complication prevention and their treatment, and adequate pain management are its important parts. Social support of family including arrangements of teaching in the convalescent patient should be incorporated in the postoperative care.

REFERENCES

The pattern of surgical infections in children is changing and this requires the need to define the problems in surgical infections and to find out efficient means to prevent varieties of bacterial, fungal and viral infections. Despite the use of modern antibiotics, there is significant persistence of postoperative and nosocomial infections due to increase in the definitive surgical procedures in neonates, surgical procedures in grossly premature and very low birth weight babies whose immune mechanisms are not well developed, development of new and complex surgical techniques, complex invasive, therapeutic techniques and preoperative resuscitative measures like extracorporeal membrane oxygenation (ECMO) and surgery in immunocompromised children. The aim of the treatment in a child with infection is to destroy the microorganism without significantly harming the child.

Antisepsis surgery in the Listerian era involved chemicals like carbolic acid, iodine, etc. This was followed by various heavy metals and dyes like mercury, trypan, prontosil, etc. Epoch making research by Sir Alexander Fleming gave way to the first antibiotic – Penicillin. Strictly speaking, the term antibiotic is applied only to the naturally occurring substance produced by one microbial species that is capable of inhibiting the growth of another microbe. Whilst the term antimicrobial agent is used to the synthetic substance that inhibits the growth of the microorganisms. Such a distinction is rather academic and hence many authors use them interchangeably. Antibiotic is a substance that is capable of inhibiting the growth of bacteria (a prokaryotic cell). Fungi are eukaryotic cells and the agents which inhibit their growth are called as antifungals. Agents inhibiting viral replication are called as antivirals.

**ANTIBIOTICS**

Antibiotics either stop multiplication or destroy the bacteria acting at various levels of bacterial cell structure, metabolism and/or nucleic acids. Broadly mode of action is:
1. By destroying the bacterial cell wall – *Bactericidal*.
2. By preventing multiplication of the cells – *Bacteriostatic*. Here, the bacteria are prevented to replicate and this eventually permits the host immune mechanism to over come the infection.

**Exact Mode of Action**

*Interference with Cell Wall Synthesis*

Inhibition of cell wall synthesis affects osmotic gradient across the cell membrane and the microbe swells up and bursts. *Penicillins* bind to the cell membrane enzymes involved in synthesizing peptidoglycan, and Vancomycin prevents cell membrane cross linkage process. Gram-negative bacteria have less peptidoglycan in their cell membrane and therefore are not amenable for treatment by penicillin.

*Disruption of the Cell Membrane*

Fungal cell membrane is rich in cholesterol and the agents like *Nystatin* disrupt the cell membrane. Human cells also have cholesterol and hence most of the potent antifungals are restricted as topical agents.

*Interference with Nucleic Acid Synthesis*

Nucleic acids are the building blocks of the nucleotides and any interference with their synthesis would stop the growth of the bacteria. Trimethoprim prevents the synthesis of folic acid in the bacteria, *Rifampicin* inhibits
the transcription of DNA into RNA. Gyrase is an enzyme, which is involved in the coiling and uncoiling of the DNA strands, and it is affected by the quinolones.

**Interference with Protein Synthesis**

Few antibiotics selectively bind to the bacterial ribosomes thereby affecting the protein synthesis. Most aminoglycosides affect protein synthesis.

**Pharmacokinetics of Antibiotics**

When an antimicrobial is introduced in the body it gets distributed into two compartments, the vascular (central) and the tissues (the peripheral) compartments. What ever be the route of administration the vascular compartment is filled either by vascular, oral or intramuscularly route.

The amount of drug available in the vascular compartment as percentage of the total dose given is termed *Bioavailability*. The drug diffuses from the vascular to the peripheral regions and then undergoes metabolic changes or excreted. Part of the drug reaches the vascular compartment by redistribution. When the drug is administered the drug reaches the peak in serum concentration in phase one called *alpha phase* from where the drug gets distributed into the tissues. The rise in the tissue concentration, which is initially lower than the vascular compartment but subsequently goes above, is called the *beta phase* where the drug gets eliminated by metabolism or excretion.

### MAIN GROUPS OF ANTIBIOTICS

**Penicillin**

Penicillin was discovered and initially manufactured by fermentation process and the need to make the drug by chemical means resulted in the manufacture of synthetic penicillins where side chain to the Beta lactam was altered with broader spectrum of activity. Penicillin is active only against gram-positive cocci whereas the synthetic penicillins are active against gram-negative organisms also. The cell wall of gram negative bacteria is more complex and resistant to conventional penicillin. Synthetic penicillin can more readily penetrate outer lipid membrane of gram-negative bacteria and hence are effective against gram-negative bacteria. Salient features of this group are summarized in Table 15.1.

**Cephalosporin**

The cephalosporins have chemical structure similar to the penicillins and the most important agents are summarized in Table 15.2.

**Other Beta Lactams**

*Monobactems* (e.g. Imipenem) are effective against a wide range of gram-positive and gram-negative organisms and do not cause hypersensitive reactions in patients who are sensitive to penicillins.

Table 15.1: Important penicillins and their spectrum and uses
Carbapenems, in addition to the above spectrum, are also effective against anaerobes. These agents have a broad spectrum of action except Pseudomonas and Proteus mirabilis. Important disadvantage is that the therapeutic-toxic ratio is low and myoclonic seizures can develop.

Meropenem is closely related to imipenem and has been approved for use in children. It has greater activity against gram-negative bacteria and lack of association with seizures which is a distinct advantage.

Aminoglycosides

Aminoglycosides are active against all gram-negative organisms. Anaerobes are resistant to aminoglycosides. These drugs are generally used in combination with another antibiotic to provide activity against broad spectrum. Aminoglycosides are not absorbed orally and hence need to be given parenterally. However, given orally they are useful in gut “Sterilization”. The drugs available are – Gentamicin, Amikacin, Tobramycin and Netilmycin, etc. Many of this group are active against Pseudomonas. Nephrotoxicity and otoxicity are main drawbacks and hence should be used with caution. Drugs with lesser toxicity and same spectrum if available should be chosen and aminoglycosides should be used as a second line therapy based on culture and sensitivity reports.

Macrolides

These drugs inhibit bacterial protein synthesis by binding to the ribosomes reversibly and hence these are bacteriostatic. These agents are effective against most gram-positive organisms and a range of anaerobes. They are also effective against intracellular pathogens such as chlamydia and rickettsia. Erythromycin is commonly advised for children who are sensitive to penicillins.

Quinolones

Quinolones have wide spectrum of activity including gram-negative aerobic coliforms and those organisms that tend to get localized in the intracellular regions like Salmonella, Mycoplasma, and Chlamydia. Though initial fears have been expressed on the role of these drugs on joint cartilage damage in children, the drug has been used in critical situations including meningitis in newborn and infants. Ciprofloxacin, Ofloxacin, Pefloxacin, Enoxacin are good even when administered orally. Trovofloxacin is a fluoroquinolone with an exceptionally broad spectrum of activity.

Glycopeptides

Vancomycin is active only against gram-positive organisms. They are poorly absorbed from the gut and Vancomycin given intramuscularly is very painful and hence needs to be given intravenously. Rapid infusion
results in flushing of upper body called red man syndrome. Ototoxicity has been reported. It can be used in penicillin hypersensitive patients for treatment or prophylaxis of Staphylococcal endocarditis. Anti staphylococcal drugs like Vancomycin and Teicoplanin are very effective against most methicillin resistant strains of Staphylococci.

**Sulphonamides**

These are synthetic chemicals that interfere with para amino benzoic acid (PABA), an enzyme involved in the production of folic acid, which is essential ingredient for the production of nucleic acids. They are very popular as topical preparations especially in burns. Trimethoprim does also affect folic acid synthesis and because it enhances the activity of the sulphonamides, it is generally used in combination as Co-trimoxazole. This is excreted in urine and is useful in urinary tract infections especially as a chemoprophylactic agent.

**Imidazoles**

Metronidazole is the original drug of this group and it is the drug of choice for anaerobes. Most of the anaerobes are sensitive and is the drug of choice in such situations since resistance to metronidazole is rare. It is well absorbed from gastrointestinal tract with the bioavailability of 90%. It could penetrate abscesses and interferes with nucleic acid synthesis of the bacterial cells. It can be used for oral bowel preparation for GI surgery. Tinidazole is another similar drug with longer half-life.

**Antifungal Therapy**

Viruses are intracellular organisms and utilize the host cell to replicate themselves. Important antiviral agents are summarized in the Table 15.3.

**PROPHYLAXIS**

Antibiotics are used to protect children at risk during surgery. Prophylaxis aims to protect the child from local infection as well as distant infection. This has a particular role in children who are vulnerable for infective endocarditis. The objective for quality standard for antimicrobial prophylaxis in pediatric surgical patients is to provide an implementation mechanism that will facilitate reliable administration of prophylactic antimicrobial agents to children undergoing operative procedures in which such a practice is judged to be beneficial and to provide a guideline that will help local hospital committees to formulate policies and set up mechanisms for their implementation. A prophylactic antibiotic does not reduce the chances of infections if proper surgical principles are not adhered to. A good antibiotic will not cover a bad surgery. In choosing the antibiotic the endogenous and exogenous flora likely to cause infection should be considered and appropriate antibiotic chosen. It is preferable to choose a single antibiotic rather than multiple combinations unless the type of surgery needs it. Proven antibiotics should be chosen and additional new antibiotics should not be introduced unless there is proof of its efficiency in a

Timing of Antibiotic Prophylaxis in Pediatric Surgery

Intrapartum prophylactic measures are necessary to prevent infections to the newborn baby as it prevents infections from the amniotic fluid and genitalia of the mother. After birth, the chosen antibiotic should be administered at the time of induction of anesthesia so that maximum tissue concentration of drug is present at the site of surgery. If the surgery is prolonged a repeat administration of antibiotic should be given depending on the half-life of the drug initially used. Full dose of chosen antibiotic should be used so that its concentration is more than minimal inhibitory concentration (MIC) and minimal bactericidal concentration (MBC). Prophylactic antibiotics need not be continued in the postoperative period, unless the host defenses are compromised or a drain is kept or a prosthesis is implanted. Antibiotics, however, may be continued if a focus of infection is found at the time of surgery or there is a high risk of infection. If the same drug is used for prolonged period for prophylaxis, it is pertinent to aware of the resistant strains that might develop. The decision to change the antibiotics is purely based on the clinical course, evidence of overt or covert infection. Ideally it should be based on the emerging resistant strains. A good antibiotic should have wide spectrum of activity both against aerobic and anaerobic organisms, should be least toxic, should have high degree of diffusion in the tissues with bactericidal action, and should be at an affordable cost to the patient. The agent is selected depending upon the site of surgery. For example, children undergoing resection and end-to-end anastomosis of bowel would require protection against aerobic coliforms and anaerobes. So the agents used would be — A penicillin/cephalosporin to kill gram-positive aerobes, an aminoglycoside to kill gram-negative organisms and metronidazole to protect against anaerobes. It should be given close to the time of incision to ensure that the levels of the agents are adequate during the bacteriemia. Prophylactic therapy is generally not continued beyond 24 hours after surgery.

Antibiotic Resistance

Bacteria are described as sensitive to a particular antibiotic if their growth is inhibited or they are killed by a concentration of the drug in the body that could be achieved by the usual dose regimen. Resistant bacteria are not inhibited by this concentration of the agent. The bacteria can acquire resistance to antibiotics by means of one or more of the following mechanisms:
1. By altering the permeability to the agent at cell membrane level.
2. By producing enzymes that inactivate the agent (e.g. Beta lactamases destroy penicillins and cephalosporins).
3. The drug may be actively expelled from the cell.
4. By plasmids: Plasmids are small molecules of DNA independent of the chromosome, which can be replicated between cells by conjugation, transformation, or transduction. Plasmids provide a highly effective means of spreading resistance genes, both within a species and to other species.
5. By transposons: Transposons are specific sequences of DNA that can insert into both plasmids and chromosomes, and can transfer or jump between them. They have a potential to carry genes encoding for resistance to a wide variety of antibiotics and play a key role in the dissemination of antibiotic resistance, especially where species develop resistance to more than one drug. Multiple drug resistance (MDR) is a term used to describe bacteria that have developed resistance to several antibiotics.

Agricultural use of antibiotics, wide spread use of antibiotics, unnecessary prescription of antibiotics and prolonged usage of antibiotics have contributed to the drug resistance and this has become a significant health problem today.

Intrapartum Prophylaxis

Prophylactic intravenous ampicillin-sulbactam has been shown to reduce intra-amniotic fluid infection and this is likely to decrease the potential consequences of it to the newborn baby. HIV infection is becoming one of the major serious neonatal infectious diseases in many parts of the world and 40-80% of perinatal HIV transmission occurs during or close to intrapartum period. Antiviral agent – Zidovudine is reported to reduce transmission risk by 70%. In this
regard, WHO/UNICEF expert group recommends the following:\(^3\)

Zidovudine, 200 mg thrice a day, is recommended from 14 weeks of pregnancy. A loading dose of 2 mg/k over first hour is followed by maintenance dose of 1 mg/k/h over intrapartum period. The newborn baby, once delivered, is administered syrup Zidovudine (2 mg/k every 6 h for 6 weeks).

Mothers with symptomatic genital herpes infection have a significant risk of infecting the newborn baby. Acyclovir, 400 mg thrice a day, is started from 36 weeks of pregnancy and it is given until delivery to reduce this risk.\(^4\)

**SPECIFIC PROPHYLAXIS IN PEDIATRIC SURGERY**

An ideal prophylactic agent should target the entire spectrum, easily administrable, well tolerated and should have minimal side effects. Children would like to have a single oral dose of the drug rather than multiple doses/parenteral preparations.

The factors that influence efficacy of the prophylaxis regimen are related to the potential pathogen, the prophylactic agent and the host and these are summarized in the Table 15.4.

### Intravascular Catheters

*Staphylococcus epidermidis* is a normal commensal and the infection with this pathogen is likely to occur in newborn babies. Premature babies, very low birth weight babies and babies receiving parenteral nutrition are more vulnerable. Studies have shown that low dose vancomycin significantly reduces such infection.\(^5\)\(^-\)\(^7\)

Mupirocin is a topical antibiotic with high anti-staphylococcal activity. Mupirocin applied to the insertion site significantly reduces the risk of *Staphylococcus aureus* skin and catheter colonization, exit site infection, *Staphylococcus bacteriemia* in with intravenous catheters.\(^8\) A randomized, multicenter, double blind trial has shown to decrease complications associated with central venous catheters by Vancomycin and Ciprofloxacin in addition to heparin used as a flush solution.\(^9\)

### Bacterial Endocarditis

All children, who are at risk of endocarditis, undergoing any intervention that is likely to produce bacteraemia are given prophylaxis.\(^10\) Poor oral hygiene and oral infections need to be tackled before any elective surgical procedures. Perioperative prophylaxis (from shortly before surgery to about 10 hours) is recommended. Alpha hemolytic *Streptococci* are the most common organisms responsible for endocarditis after upper respiratory, oral and upper GI procedures. The drugs recommended are: Amoxcillin (50 mg/kg) given orally 1 hour before the surgery or Ampicillin (50 mg/kg) IV/IM 30 minutes before the surgery. For children hypersensitive to penicillin *Azithromycin* (15 mg/kg) orally 1 hour before the procedure is recommended. Prophylaxis for genitourinary (including endoscopic interventions/voiding cystourethrography) or GIT surgery should cover enterococci. *Ampicillin* (50 mg/kg) PLUS *Gentamicin* (2 mg/kg) intravenously 30 minutes before the procedure is recommended. For children hypersensitive to penicillins, *Vancomycin* (20 mg/kg) by infusion (starting 1 ½ hour before surgery and lasting for 1 hour) and *Gentamicin* (2 mg/kg) intravenously 30 minutes before the procedure is recommended.

In addition to the above, children who undergo surgical procedures where in prosthetic material is likely to be placed inside the body, should receive...
Vancomycin perioperatively and not more than 48 hours after the procedure.

**Antimicrobial Prophylaxis for Urinary Tract Infections**

Many of pediatric urology patients require prophylactic antibiotics to prevent recurrent urinary tract infections. Though treatment of acute UTI is based upon the urine culture reports, the chemoprophylaxis is straightforward and generally involves choosing from a short list of antibiotics. There are good published guidelines and in December 2000, an expert group meeting of the Indian Pediatric Nephrology recommended the following guidelines.11-14 The recommended drugs are summarized in Table 15.5.

The expert group meeting also reached the following consensus regarding the indication and duration of the chemoprophylaxis that depends upon number of episodes of infection, reflux status and renal scarring. The committee also felt that there is no role for cyclic therapy. The recommendations are summarized in Table 15.6.

Circumcision in boys, particularly in infants with VUR, has been shown to reduce the risk of urinary tract infections.15 A review of 18-year experience from Royal Free Hospital School of Medicine has shown that long-term nitrofurantoin is effective, safe and tolerable in urinary infections.16

**Asplenia/Splenectomy**

Functions of the spleen may be deficient in congenital asplenia syndromes, surgical removal for hyperplenism/trauma or auto splenectomy in sickle cell disease. Absence of spleen predisposes to overwhelming post splenectomy infections (OPSI). Approximately 80% of fatal infections occur within 2 years of splenectomy and 80% of the infections are due to bacteria with capsular polysaccharides – *Streptococcus pneumoniae*, *Hemophilus influenza* and *Nisseria meningitidis*.17-18

Penicillin V, given twice daily, significantly decreases the frequency of invasive pneumococcal infections. Penicillin prophylaxis would definitely decrease the chances of pneumococcal sepsis but does not completely eliminate the risk of fulminant sepsis as the resistant strains are well known. Erythromycin/Trimethoprim Sulfamethoxazole combination are alternatives for children hypersensitive to penicillins. Chemoprophylaxis is recommended for all children, especially for those under 5 years of age, for at least 1 year following splenectomy. However, prophylaxis

| Table 15.5: Chemoprophylaxis for urinary tract infections in children |
|---|---|---|
| Agent | Dose | Remarks |
| Cephalexin | 10 mg/kg/d | Drug of choice in infants below 6 months of age |
| Co-trimoxazole | 1-2 mg/kg/d of trimethoprim | Not recommended for infants below 3 months of age. Avoid in G-6 PD deficiency |
| Nitrofurantoin | 1-2 mg/kg/d | Avoid in G-6 PD deficiency Avoid in renal insufficiency |

| Table 15.6: Indications and duration for chemoprophylaxis for UTI |
|---|---|---|---|
| Main finding | Additional finding(s) | Age of child | Duration/Remarks |
| First episode of UTI | | | |
| No reflux, No renal scar | | < 2 years | 6 months ‡ |
| No reflux, No renal scar | | > 2 years | No prophylaxis |
| Grade I and II reflux | | < 5 years | Until 5 years of age |
| Grade III and U/L grade IV | | < 5 years | Until 5 years of age |
| Grade III and U/L grade IV | | > 5 years | Surgery |
| B/L grade IV, grade V | | < 1 year | Until 1 year of age |
| B/L grade IV, grade V | | > 1 year | Surgery |
| No reflux, renal scar + | | All ages | 6 months. ‡ |

| Recurrent UTI | | | |
| No reflux and no scar | | All ages | 6 months |

Legend:

‡ [After 6 months of treatment, if no reflux and no scar are found – stop chemoprophylaxis].
is continued indefinitely in immunocompromised children.

**Prophylaxis Related to the Specific Surgical Interventions**

Epidemiologists have stratified surgical procedures based on the risk of infection as—

1. **Clean cases:** There are primarily elective cases in which wound is primarily closed without any drain and respiratory, alimentary, or genitourinary tracts are not breached. The expected infection rate in this category is less than 2%.

2. **Clean contaminated cases:** Respiratory, alimentary, or genitourinary tracts are breached and/or the wound is drained. The expected infection rate in this category is around 5%.

3. **Contaminated cases:** Gross spillage from gastrointestinal tract, gross infection, or open traumatic wounds are present. The expected infection rate in this category is around 15%.

4. **Dirty cases:** Perforated visceria at the site of operation, delayed treatment of traumatic wounds, or gas gangrene is present. The expected infection rate in this category is around 40%.

Generally, clean operations such as herniotomy, orchidopexy does not require antibiotics. However, even in clean operations if prosthesis is being contemplated, then antibiotic cover is necessary. Antibiotics should also be used in all immune compromised children and children who are at risk for infective endocarditis.

**Pediatric Neurosurgical Procedures**

Insertion of ventriculo-peritoneal shunt is one of the most common pediatric neurosurgical procedures and most infections manifest within 15 days to 2 months of surgery.\(^\text{19}\)

Coagulase – negative *Staphylococci* are the most common organisms and account for 70% of shunt infections. A meta-analysis of 12 randomized controlled clinical trials has indicated that short-term perioperative antibiotic prophylaxis at the time of shunt insertion significantly decreases the postoperative infections.\(^\text{19}\)

Duration of this perioperative prophylaxis should not exceed 48 hours. A single dose of second generation cephalosporin has been shown to be enough in shunting procedures.\(^\text{20}\)

**Pediatric Oral Surgery**

Preoperative local decontamination by Povidone Iodine solution has been found to be beneficial in a randomized clinical trial.\(^\text{21}\) Perioperative prophylactic coverage with Ampicillin/Ampicillin/Azithromycin (in Penicillin sensitive children) is sufficient for cleft lip and palate surgery and recently cefuroxime has been shown to be better than the conventional antibiotics.\(^\text{22}\)

**Pediatric Thoracic Surgical Procedures**

Monotherapy prophylaxis utilizing a third generation Cephalosporin is acceptable which is started 30 minutes before surgery and is given for no more than 48 hours. However, prophylactic antibiotics are continued if thoracostomy tubes, vascular catheters or endotracheal tubes are placed until their removal. In 1995, a survey of North American academic centers with pediatric cardiovascular surgery programs revealed that most popular regimen was monotherapy with a first or second generation cephalosporin used for less than 2 days or until transthoracic medical devices were removed.\(^\text{23}\)

**Pediatric GI Surgery**

Bacteria are involved in the pathogenesis of necrotizing enterocolitis (NEC). Presently, oral administration of non-absorbable aminoglycosides like Kanamycin is not recommended to prevent NEC. Though oral Vancomycin given for 48 hours before introduction of oral feeds in neonates at risk has been shown to of benefit until multicentric trials prove it conclusively, it is better not to recommend this drug routinely for prevention of NEC.\(^\text{24}\)

A single dose of cefuroxime (30 mg/k) at induction of anesthesia has been reported to reduce infection in infantile pyloromyotomy.\(^\text{25}\)

A single dose of intravenous vancomycin prophylaxis in permanent peritoneal dialysis catheter placement is reported to be superior to single dose of cefazolin in reducing the risk of postoperative peritonitis.

**Appendectomy**

In a suspected or overt inflammation confined to appendix alone, a single dose of antibiotic at the time
of induction of anesthesia is enough. Cefazolin and Metronidazole will cover the usual pathogens of the appendix. If it is perforated or evidence of localized or generalized peritonitis is present a third generation cephalosporin along with an aminoglycoside and metronidazole is started. Generally Metronidazole is stopped after 5 days and others after 7-10 days depending on the clinical course and evidence of persistence of infection. Study from Karolinska Institute had concluded that a single preoperative dose of Metronidazole alone significantly decreases the rate of postoperative infectious complications in children with appendicitis. No further improvement was noted if cefuroxime was added in that study. 26

**Pediatric Colorectal Surgeries**

Antibiotic prophylaxis is necessary not only to prevent wound infection but also to minimize the complications such as leaks at the site of anastomosis and wound dehiscence. It is imperative to decrease the bacterial load by promoting purgation. Wash outs with Polyethylene glycol (PEGLEC) — 25 ml/kg/h for 4 hours or with normal saline — 10 ml/kg is very important. Perioperative prophylaxis with a third generation cephalosporin along with an aminoglycoside and metronidazole provides a good cover.

Antibiotics may be used empirically in situations without waiting for the culture reports in clinical situations like lacerations, liver abscesses, peritonitis, etc based on the earlier knowledge of the type of organism and the antibiotic sensitivity. Anaerobic cover is also required in situations like liver abscess where the cavity will harbor amoebae and anaerobic bacteria.

Many children develop febrile neutropenia during chemotherapy for cancer. In lower risk neutropenic children receiving anticancer therapy, oral Cefixime given for 4 days after 72 hours of intravenous Ceftriaxone plus Amikacin has been shown to be safe and cost effective compared to the conventional protocols. 27

**Pediatric Transplantation Surgery**

Perioperative prophylaxis is very important in children undergoing transplantation as they are predisposed to infections arising out of immunosuppressive therapy. Nystatin is started few days before the transplantation to prevent oropharyngeal candidiasis. 28 Standard antibiotics – a third generation cephalosporin and an aminoglycoside along with Metronidazole are followed by long-term Trimethoprim – Sulfamethoxazole combination to prevent pneumocystis carinii pneumonia. Few transplant centers are adding antiviral prophylaxis by administering ribavirin as well. 29

**TOPICAL AGENTS**

Mupirocin is a topical antibiotic with high anti-staphylococcal activity. Mupirocin applied to the insertion site significantly reduces the risk of *Staphylococcus aureus* skin and catheter colonization, exit site infection, *Staphylococcus* bacteriemia in hemodialysis patients.8 Nasal mupirocin has been reported to be an effective method of controlling Methicillin resistant *Staphylococcus aureus* outbreak in neonatal intensive care unit.30

Povidone Iodine gel alcohol (PGA) is reported to be an effective skin-preparation formulation for use.31 A topical antimicrobial gel containing cetrimide, bacitracin and polymyxin B sulfate has been shown to reduce the incidence of clinical infections in minor accidental wound.32 It needs to be seen whether this has any applicability in the routine surgical wound.

Although, short duration prophylaxis is scientifically proven to be cost effective and provides maximum benefits in most of the elective surgeries, many centers in this country do prolong the antibiotic usage. We hope that this review article would convince us to adhere to the recommended prophylactic regimens. In addition to the antibiotics, we should remember Sir William Osler’s aphorism – Soap, water and commonsense are the best disinfectants. Antibiotics are not the panacea. For example, it has been shown that systemic antibiotics do not consistently eradicate gram-negative bacillary airway colonization in mechanically ventilated newborns.33 This shows the importance of preventive measures like proper hand washing, etc. In future, computerized pediatric anti-infective decision support programs are likely to benefit clinicians dealing with infections in children.34
REFERENCES

The incidence of major fungal infection in recent years has paralleled the increasing use of immuno-suppressive drugs, broad-spectrum antibiotics, indwelling catheters and prostheses. Severe burns, hyperalimentation, renal failure and other debilitating conditions also predispose to invasive mycosis.\textsuperscript{1,2} The immature immune system of neonates is partially responsible for same specific disease and pose unique management problems. These infants are increasingly stressed to degrees not previously seen in intensive care nurseries. The frequent uses of longterm indwelling catheters contribute to the potential for fungal infection in pediatric population.\textsuperscript{3} An aggressive diagnostic approach is particularly important and tissue specimen is often necessary to establish diagnosis. Meticulous surgical techniques and minimization of the predisposing factors are crucial in the prevention of these infections and prophylactic antimycotic agents may be of value in selected high risk patients. Some mycotic wound infections can be managed effectively without systemic therapy but when systemic agents are needed, Fluconazole is used for most patients because of its efficacy. However, for the most critically ill patient Amphotericin remains the treatment of choice.\textsuperscript{3}

**BACKGROUND**

Prior to the 1960, invasive opportunistic fungal infection was a rare diagnosis. The recovery of *Candida* from human tissue or body fluids was viewed as contamination and was of little importance. Fungemia was seen in patients with severe burns and in patients with malignancy, usually at the time of terminal events. Despite this timing, the fungal infection was not thought to increase the risk of mortality. The invasive potential of *Candida* was documented in 1968 when Krause et al\textsuperscript{4} recovered *Candida* in both urine and blood following the ingestion of the organism into normally functioning intestines. Subsequently autopsy studies in the 1970 proved that *Candida* could infiltrate solid organs without causing clinical organ dysfunction.\textsuperscript{5} In 1980, clinical studies demonstrated *Candida* as an important pathogen that could affect the outcome in critically ill patients.\textsuperscript{6} Currently, the management of fungal infection is equally important as that of bacterial infection in the intensive care unit.

**EPIDEMIOLOGY**

*Candida* is the most commonly found fungus in isolates. The National nosocomial infection surveillance system of the centers for disease control (CDC) reported that the incidence of *Candida* as a nosocomial pathogen is increasing steadily.\textsuperscript{7} During the past decade, *Candida* has increased in rank from the eighth to the fourth most common nosocomial pathogen isolated from blood, and accounts for 8-15% of all hospital acquired bloodstream infections.\textsuperscript{8} This 480% rise is second only to coagulase negative *Staphlococcus*.\textsuperscript{9} The morbidity and mortality associated with these infections is striking, with a median intensive care unit/hospital stay increasing by 30 days and death rates rising from 30-80%.\textsuperscript{10}

**Fungi**

The medically important fungi are divided into two categories, *pathogenic fungi* and *opportunistic fungi*. The pathogenic fungi or virulent fungi, which include Histoplasma, Blastomyces and Coccidomyces, are
usually located in endemic areas and cause infection in hosts with a normal immune function. Opportunistic fungi like Candida, Torulopsis, Aspergillus, Mucormycetes, Eryptococcus and Phycomycetes are often commensial with humans and are less virulent. The genus *Candida* and *Torulopsis* are the major pathogens causing nosocomial fungal infection in surgically ill patients. The various subtypes of *Candida* are:

i. *C. albicans*, colonizes the mucosal tissue of gastrointestinal and genitourinary tracts. It is the primary fungal pathogen isolated from blood, tissue and other body fluids.

ii. *C. tropicalis*, is the second most common species responsible for fungal infection and is commonly seen in patients with hematopoietic malignancies and diabetes. It is often associated with the presence of a characteristic embolic lesion. Biopsies of these lesions can prove dissemination of the infection.

iii. *C. parapsilosis*, the third most common isolate and is best known for its association with hyperalimentation and indwelling catheters. It is commonly seen in patients with solid tumors. This organism appears less virulent and its infection has a better prognosis.

iv. *C. krusei* is being reported in 1-3% of isolates. It is an important pathogen among patients with neutropenia in hematological malignancies. This organism is resistant to fluconazole.

*Torulopsis*: It can be found colonizing mucosal surfaces of the gastrointestinal and genitourinary tracts in human. *T. glabrate* is thought to be less virulent and its infection is associated with a high mortality rate of 50-70% and has a predilection for causing renal infection in diabetes patients.

**RISK FACTORS AND PATHOGENESIS**

The most common risk factors to acquire a fungal infection are, severity of illness (APACHE II SCORE > 10, ventilator use > 48 hours), use of broad-spectrum antibiotics, indwelling central venous catheters, malnutrition, immunosuppression and burns.

**Broad-spectrum Antibiotics and Fungal Translocations**

Presumably antibacterial antibiotics suppress the growth of the normal intestinal flora and therapy promotes the overgrowth of *Candida*. When bacteria counts decrease secondary to suppression by antibiotics, the *Candida* is then able to bind and take the first important step toward translocation.

Decreased intestinal mucosal integrity caused by surgery, low perfusion of the bowel and endotoxin release caused by sepsis, increases the risk for translocation of fungi across the mucosal membranes. Other sites of the digestive system (pancreas, liver, gallbladder) have been implicated as sources of fungal invasion.

**Central Venous Access**

The overgrowth of *Candida* in the gastrointestinal tract coincides with skin colonization, any break in the epithelial barrier are important risk factors in the development of fungal invasion.

**Nutritional Support**

TPN has been shown to reduce complement-mediated fixation of immunoglobulins and suppress macrophage function. It also produces intestinal mucosal atrophy, possibly secondarily to deficient glutamine content in TPN fluid. These factors along with presence of central venous catheter increase the risk for the development of fungal infection.

**Immunosuppression**

Immunosuppression can result from major surgery, trauma, burns, cancer, bacterial sepsis, hypoperfusion, corticosteroids, chemotherapy, diabetes and post-transplant immunosuppressive therapy. The immunocompromised state leads to increased risk of invasion by opportunistic pathogens. Defence against fungal invasion at both superficial and deeper lesion layer is provided primarily by cellular immune function.

**Burns**

These patients have increased susceptibility to the fungal infection and dissemination because of following factors:
- Loss of mechanical barrier
- Gastrointestinal mucosal atrophy
- Prolonged ileus
Decreased number of complement system, CD3, CD4 and CD8 T cells
Decreased phagocytic function
Decreased interleukin 2 production and receptor affinity
Increased complement degradation products and burn specific polypeptides
Use of antibiotics and indwelling central venous and urinary catheters

Overall risk factors for disseminated fungal infection and acute renal failure are:
- Age > 40 years
- Second and third degree burns
- Antibiotics for > 7 days
- Treatment with three or more antibiotics
- Gram-negative sepsis
- Acute peritonitis
- Intra-abdominal abscess
- Diabetes mellitus
- Malignancy
- Multiple organ trauma
- Parenteral nutrition
- Serum glucose > 200 mg/dl
- Severe head injury
- Steroids

High-risk > 3 risk factors
Low-risk < 3 risk factors

**DIAGNOSIS**

Once the diagnosis of fungal infection is entertained, the most difficult task is to differentiate colonization from invasion/disseminated disease. A firm laboratory diagnosis is difficult. Histological examination demonstrating both forms of Candida, yeast and pseudohyphae is considered diagnostic. Except for skin and burn wounds, the acquisition of tissue for histological diagnosis may require an invasive procedure. Therefore, the diagnosis of invasive/dissemination relies more on inferential rather than direct tissue evidence of disease.

The initial workup for the patients suspected of having fungal invasion/dissemination starts with sampling of many sites (e.g. urine, sputum, open wound, drain site, stool, stomach contents) for evidence of colonization. Although blood culture is routinely done, its interpretation can be misleading for several reasons. First, *Candida* is difficult to grow and concomitant bacterial infection may decrease its recovery from blood cultures. Second, only 50% of patients with invasive candidiasis have positive blood cultures and positive cultures do not necessarily indicate dissemination. Methods of increasing sensitivity of blood cultures include lysis centrifugation and sampling of arterial instead of venous blood. Lysis centrifugation increases the yield of positive cultures by 30 - 40%. Positive cultures of urine, drain sites, burns, open wounds or peritoneal fluid at the time of surgery are difficult to interpret. Each may be indicative of colonization only but may be indicative of invasive disease in the appropriate setting. Candiduria can occur in absence of candidiasis, but candidiasis without candiduria is highly unlikely.

**DIAGNOSTIC CRITERIA FOR DISSEMINATED FUNGAL INFECTION**

**Definitive Criteria**
- Culture of fungus from tissue (e.g. kidney or lungs)
- Endophthalmitis
- Burns wound invasion
- Culture from peritoneal fluid.

**Likely Criteria**
- Two positive cultures at least 24 hours apart, without a central venous catheter
- Two positive blood cultures with a second obtained more than 24 after removal of central venous catheter.
- Three or more colonized sites.

**FUNGAL INFECTION OF URINARY TRACT**

Is relatively uncommon in infants and children. However, their incidence has shown an increase in recent years; probably because of better survival of LBW and premature babies. The major risk factors include prematurity, LBW, contamination of urethral catheters, long-term antibiotic therapy, and obstructive uropathy.

Three groups of fungi may lead to urinary tract infection:

i. Opportunistic fungi like candida, aspergillus and cryptococcus
ii. Environmental fungi including coccidiodes, blastomyces and histoplasma and
iii. Rare fungi like mucormycae

*Candida* is the most common causative agent in UTI. The urinary tract may be involved primarily but is usually implicated secondary to systemic fungal infection. The kidneys are affected in more than 85% of cases.22

Patients may present with urosepsis and its common manifestation is oliguria or anuria secondary to a fungus ball obstructing the urinary tract. Diagnosis is based on clinical features, urine examination and serum precipitin titers. The presence of a fungal bezoar may be confirmed by demonstrating an echogenic mass on ultrasonography or a filling defect in the collecting system on an intravenous urogram. Observation of the mycelial or yeast form of a fungus on microscopic examination or a colony count of more than15000/ml on culture of a properly collected urine specimen is diagnostic.21

Treatment of fungal UTI has been highly difficult principally due to lack of a effective and safe antifungal medication that can achieve adequate concentration in the urine. This choice is further limited by a state of compromised renal function. The initial step in management includes removal of any indwelling catheter and discontinuation of antibiotic therapy. As fungi thrive at a low pH, alkalinisation of urine with sodium bicarbonate may be helpful.21 Upper urinary tract obstruction by a fungal bezoar often necessitates nephrostomy drainage in addition to antifungal therapy.

### TREATMENT AND PROPHYLAXIS

The successful treatment of fungal infection requires a combination of the surgical principles of drainage and debridement and systemic therapy with antifungal agents. In addition the removal of infected vascular access catheters and sometimes prosthesis is necessary to cure infection. Currently, there are three indications for the use of antifungal therapy:

i. *Prophylaxis*: Use of antifungals prior to colonization in high-risk patients.
ii. *Early presumptive treatment*: Initiation of treatment after colonization is documented in order to prevent invasion and dissemination.
iii. *System therapy*: Treatment of documented invasive or disseminated fungal disease.

The action of most antifungal agents is targeted at the cell membrane, which is vital to cell function and viability. The major cell membrane inhibitors are:

- **Polyenes**: Amphotericin- B and Nystatin
- **Azoles**:
  - Imidazoles—Ketoconazole, Miconazole and Fluconazole
  - Triazoles—Itraconazole
- **Antimetabolites**: 5 Fluorocytosine

**Amphotericin-B**

Is a lipophilic fungicide produced by *Streptomyces nodosus*. Selective permeability to ions especially potassium and vital metabolites account for its lethality. Currently it is the drug of choice for invasive and disseminated fungal infection in critically ill patients. It is active against *Candida* and *Torulopsis*, and resistance is rare. Its route of administration is intravenous, intrathecal or intravesical as a colloid suspension with deoxycholate. To avoid hyper-sensitivity related reactions, which occur in 20% of patients, it is mandatory to give a test dose of 1 mg and observe for allergic reactions for at least 20 minutes before administration of therapeutic doses. Blood levels are not influenced by renal or hepatic failure. However, the dosage should be decreased or treatment stopped if renal function deteriorates.

Side effects include fever, rigors (incidence decrease with pre-treatment), renal toxicity, hypokalemia, hypomagnesemia and occasionally mild anemia.

**Nystatin**

Its primary use is as a topical agent in the treatment of cutaneous fungal infection and infected burns and as a rinse in the treatment of thrush. It should not be administered parentally because of its toxicity. It is not absorbed from the gastrointestinal tract and hence its main efficacy is in reducing overgrowth at that site.

**Ketoconazole**

It is administered orally and requires gastric acidity for its absorption. It is highly bound to plasma proteins and metabolized in the liver. Its use as a systemic therapy in the surgical patients is debated. For prophylaxis, 200 mg once a day significantly reduces colonization. Side effects include gastrointestinal intolerance, decreased steroidogenesis leading to
gynecomastia and occasionally adrenal insufficiency. It is a hepatotoxic drug therefore, weekly transaminase monitoring is recommended.

**Miconazole**

It is mainly used as a topical agent but it is sometimes used intravenously.

**Fluconazole**

It is well absorbed from the gastrointestinal tract regardless of the pH and its bioavailability is excellent (> 90%) by oral and intravenous route. Because it is excreted in urine, its dosage requires adjustment for creatinine clearance in presence of renal failure. Hepatotoxicity has also been reported.

**Itraconazole**

It has greater than 70% bioavailability following oral ingestion. Absorption is increased by foods, decreased by antacids and not influenced by H₂ blockers.

Drug interaction includes decreased levels of rifampicin, theophylline, digoxin, cyclosporin phenytoin and oral hypoglycemics. Clinically, it is the drug of choice for the treatment of endemic fungi (Histoplasmosis and Blastomyces).

**5-Fluorocytosine**

Usual dosage is 5-150 mg/kg/day in four divided doses. Toxicity are related to alteration in hematological parameters.

**REFERENCES**

Ethics and medicine were born together. In the olden days when medicine was learnt by apprenticeship, the founding fathers formulated a set of rules on the basis of which pupils were selected. This was necessary in view of the closeness and intimacy that the physician enjoyed with his patient. The incumbent had to be of a good moral character, respect his teachers, be fair to his peers and kind to his patients. He had to act in the best interest of the patient and avoid doing any harm.

Infact the Hippocratic Oath (500 BC) remains even today the mother of all oaths and prayer of physicians. Its three cardinal principles:

a. Beneficience  
b. Nonmalfecience and  
c. Autonomy remain enshrined in all later modifications, which became necessary due to change of circumstances and advances of science.

A modern version of the Oath is detailed as follows:

THE WORLD MEDICAL ASSOCIATION DECLARATION OF GENEVA (1985)

Physicians’ Oath

• At the time of being admitted as a member of the medical profession.
• I solemnly pledge myself to consecrate my life to the service of humanity.
• I will give to my teachers the respect and gratitude which is their due.
• I will practice my profession with conscience and dignity; the health of my patient will be my first consideration.
• I will maintain by all the means in my power, the honour and the noble traditions of the medical profession; my colleagues will be my brothers.
• I will not permit considerations of religion, nationality, race, party politics or social standing to intervene between my duty and my patient.
• I will maintain the utmost respect of human life from the time of conception, even under threat, I will not use my medical knowledge contrary to the laws of humanity.
• I make these promise solemnly, freely and upon my honor.

With science advancing at a rapid pace it is likely that the oath will be changed from time to time.

Hippocratic forbiddance to abortion is likely to be transgressed by people struggling to keep population levels down and by women who feel that it infringes upon their fundamental right. Be that as it may the principles enunciated by Hippocrates remain supreme.

Another piquant situation can arise with a patient coming for an HIV test: If postitive, do we tell only the patient and or/his spouse?

The Pediatric Surgeon faces a more complex situation. His patient is too small to take autonomous decision. So in his place the parents act as proxy. Also, beneficience may be limited to treatment of a single defect. The child may still remain with other defects (duodenal atresia and trisomy), similarly beneficence to one twin may mean maleficence to another, when you have to treat conjoint twins and only one is salvagable. Chemotherapy is the greatest thing that has happened to cancer treatment in the last fifty years. It is especially effective in pediatric malignancy. Yes, it has side effects (beneficence is tainted by maleficient). In situations like neural tube defects, pre and perinatal surgery, intersex and advance malignancy ethical issues are apt to arise. These are discussed briefly in the ensuing pages.
RIGHTS OF PATIENTS

‘Treat me right’ is the title of a book written by Ian Kennedy, a medico legal authority, in which he discusses fundamental rights of patients. He further elaborates that the patient is entitled to good treatment delivered in a competent manner. Even in India, the constitution grants right to life as a fundamental right (Article 21). The Supreme Court has elaborated that right to life includes proper diagnosis, proper medicine, proper attendance. It also precludes any unfair or wrong treatment. In dealing with emergencies, it has instructed primary centers to be well equipped, district hospitals to be upgraded, a competent ambulance service to be provided and health personnel to be well trained. Non-availability of a bed is not to be used as an excuse to deny admission.

Treatment may be denied by individual doctors on grounds of non-competence or lack of equipment but certainly not on financial grounds. Every person is entitled to emergency first aid, and payment cannot be insisted upon. The “Baby Doe” case, when the parents refused surgery on a Mongol Child with esophageal atresia, raised a storm in the USA. The Department of Health and Human Resources ruled that no child can be refused treatment, because of a handicap. In our country where children are considered family wealth, level of education is poor, and most people have strong belief in religion and miracles, telling the truth may not be easy. The Consumer Protection Act of 1986, advises the medical practitioner to take “informed” consent from both parents before any surgical procedure. It should be done preferably in the presence of a witness. The total implications of surgery must be explained as well as risks of operation. All records must be maintained and patient must have access to them. Medical negligence will be punished.

Of late, the US Congress has taken a pragmatic view of some of the situations a pediatric specialist can face. In 1985 it amended the Child Abuse and Neglect Preventive Act and excluded from its purview, medical negligence in the following situations:  
  a. Child is chronically and irreversibly comatose.
  b. When the condition is such that prolonging life might mean prolonging death.
  c. Treatment is worse than disease. The “right to die with dignity”. Society of India is also seized of this matter. Hopefully there will be similar legislation in our country soon.

PRENATAL DIAGNOSIS

Advances in renal time ultrasonography have made it possible to diagnose several congenital defects prenatally. Although several interventional techniques are available like amniocentesis, cord blood sampling, chorionic villus biopsy and fetoscopy, most structural defects show up in the early middle trimester on a good sonography machine. Those of interest to the Surgeons are: Neural tube defects, PU valves, PUJ obstruction, diaphragmatic hernia, sacrococcygeal teratoma, lung defects and intestinal atresia.

The Indian society for prenatal diagnosis (ISPAT) has done commendable work to improve the standard of prenatal diagnosis and laid down guidelines regarding treatment. They advise formation of a core group consisting of sonologist, a perinatalogist, pediatric surgeon, geneticist, ethicist, psychologist and social worker. Because, fetal intervention carries some risk to both baby and mother, it is desirable that all matters concerning fetal intervention be referred to them. Let the core group consider the pros and cons and take a decision in their collective wisdom.

Four Options are Available

1. Fetal abortion, e.g. Spina bifida, multiple defects, trisomy.
2. Fetal intervention because of increasing organic damage for, e.g. PU valves, diaphragmatic hernia
3. Early cesarian section, e.g. PUJ obstruction with E/o increasing renal cortical thinning.
4. Await delivery: Early operation on the newborn, e.g. Intestinal atresia.

Option two carries a risk of death of fetus, maternal infection, evisceration and injury.

Guidelines on ethical problems involved in fetal therapy have been clearly laid down in the International Conference on Fetal Medicine (1987) and are as follows:

1. Most defects are best treated at birth.
2. Select the fetus most likely to benefit.
3. Adhere to selection criteria.
In cases of doubt whether fetal intervention will help or not, the benefit should be given to fetus and the pregnancy continued. No cesarian section must be done unless 34 weeks or unless the baby is 2 kgs.

After informed consent, if the mother refuses any intervention it is her prerogative. The courts can intervene, in case the mother is biased, e.g. divorced couple in which case fetal rights become paramount, so long as there is no risk to the mother.

It must be admitted that most fetal surgery in India at present is experimental. In cases where the fetus clearly stands to benefit for, e.g. PU valves and intervention is minor; it should be carried out after fully explaining the risks to the mother.

One looks forward to the day when endoscopic and minimal invasive surgery will come, carrying lesser risk to mother and fetus.

**NEONATES**

The availability of surfactants ventilators and other technology, made it possible for physicians to save very small babies, asphyxiated babies and newborn with multiple congenital defects. Many of them would not have survived a few years back. After survival some of them may end up with cerebral palsy, blindness and deafness.

An informed consent from the parents may be difficult because of the short time lag between birth and decision making. Most of the time, therefore, one is apt to over treat these babies. In 1993, Jobe put forth a disturbing finding that although surfactant treatment increased the survival of small infants, the morbidity between treated and untreated infants was the same.\(^4\) Strong suggests a multidisciplinary approach in such cases to include the physician, parents and relative; ethicist, and/or a religious person.\(^5\)

To resuscitate or not in the delivery room can be another problem. CPR (cardiopulmonary resuscitation) must be available to all babies if clear guide lines are not available. Jones has suggested DNR (Do not resuscitate) to children with easily recognisable diseases, incompatible with life or poor quality survival, e.g. hydrocephalus, holoprosencephaly, anencephaly, trisomy 13, 18. Renal agenesis, short limb dwarfism, Meckel-Gruber syndrome, triploidy and sirenomelia.

All these cases are obvious or diagnosis can be confirmed soon after birth. Additionally the severely asphyxiated neonate or the very low birth weight child also may be not resuscitated if parental consent is available.

**MULTIPLE DEFORMITIES**

A child with multiple defects is not an unusual problem for the Pediatric Surgeon. Request for treatment throws up four options: Full cure, life with acceptable handicap, life with unacceptable handicap and death. Acceptable handicap will depend on the cerebral function of the survivor and the socio-economic status and mental attitude of the parents.

Infants with multiple malformations can be divided into six groups:

1. Malformations are curable. Only one is life threatening (e.g. imperforate anus with hypospadias). Obviously threat to life must be removed and other problem sorted out later.
2. Both malformations are life-threatening and curable. (e.g. Esophageal atresia and imperforate anus). Treatment must be staged and cost factor discussed with the parents.
3. Both malformations are life-threatening. Only one is curable (e.g. imperforate anus and neural tube defects). Threat to life must be removed. Long-term implication of the other defect must be discussed.
4. One life threatening and one non-life threatening but not curable (e.g. Duodenal atresia + trisomy). Removal of life threatening defect, results in a permanent handicap. Options must be given to parents.
5. Neither malformation is life-threatening. One can be cured (e.g. Cleft palate; Down’s syndrome). Treat the treatable.
6. Both malformation are life-threatening and incurable (e.g. Neural defect and gross cardiac malformation).

This is basically a situation for euthanasia. Parents must be helped to take a decision. In this situation the words of Willis Potts, in his book “The Surgeon and the Child” are worth recalling.\(^6\)

“An infallible answer to the question of performing or with holding life saving operations for extensively deformed infants is not always available. Each case is different. Religious belief, philosophy of life and economic consideration alter decisions. Life is the most precious thing in the world. Is it so to the individual born without a brain capable that make social seclusion
necessary, and marital live impossible? Our duty as
doctor is crystal clear to preserve life. And yet when
looking at a hopeless little mass of deformed humanity,
compassion wrestles with duty”.

Should such infants be encouraged to live or die
with dignity? Euthanasia may be practised passively
by withholding treatment or actively (rarely) by
administering lethal doses of drugs. The second will
need state sanction and legislation. Also whether such
drugs should be given surreptitiously or openly is a
matter of debate. Abandonment of defected babies by
parents is not uncommon. Sometimes even
orphanages refuse to take them because they are unfit
for adoption.

NEURAL TUBE DEFECTS

Neural tube defects, myelomeningocele is one of the
most common and tragic congenital abnormality. Not
only is the child paralysed below the waist, he is also
incontinent of urine and faeces. Because of Arnold-
Chiari malformation, there is also hydrocephalus.
Associated defects like club foot and heart disease are
not uncommon. Treatment is life-long beginning with
repairing the meningocoele and putting in a shunt. Later
an orthopedic operations to enable the patient to walk.
Lastly urinary diversion may be required to control
incontinence. It is perfectly possible that some of these
operations may have to be repeated. Mental status is
unpredictable. Under these circumstances we have to
fit in this disease with parental thinking, Hippocratic
principles, child rights and quality of life. The Baby
Doe case in America brought in legislation of rights of
the handicapped. So even the courts may be involved
in decision making.

Because of widespread public awareness, two
groups have emerged, right to life versus death with
dignity. ‘Baby Doe’ regulations versus quality of life
judgement. Individual approach versus socialistic
approach. Some even question whether doctor,
parents and nurse should decide the future of the child
or social worker, courts and ethics board should
decide. Dr John Lorber was the first who advocated
diagnostic indicators and selection of cases. Today
prenatal diagnosis is available and if the sonography
is convincing about the presence of myelomeningocele
with hydrocephalus, these cases are best aborted.
Recent work has shown that folic acid given in
adequate doses to married women before and in the
first trimester pregnancy can prevent neural tube
defects. After birth if the patient has no associated
anomalies and good power in the hip joints, the
chances of walking with support are high. These
children must be given the benefit of operation after
speaking clearly with the parents regarding the nature
and duration of disease. Expensive investigations
should be kept at a minimum and parental education
must continue parapassu with treatment so that
parents can take on increasing responsibility of
nursing care. Gross deformities associated with
myelomeningocele, minimum earning capacity of
parents and social ostracization is a tragedy that many
will face unless clear guidelines come regarding
euthanasia.

INTERSEX

Ethical issues in intersex are complicated by medical,
social and even emotional factors.
1. Diagnosis can be difficult even for an experienced
clinician, e.g. congenital adrenal hyperplasia with
labial fusion.
2. Some patients may present at prepuberty for, e.g.
Androgen insensitivity, 5-Alpha reductase
deficiency.
3. Some children may present late, and the parents
may already have assigned gender to them.
Conversion to another gender may be non-
acceptable.
4. Registration of birth.
5. The fixation of Indian families to have a male child.
6. Even after treatment many of these patients will
end up being reared as females.
7. Fertility, menstruations and procreation may not
be achievable.
8. Lastly, counseling parents and the patients.

Types of Intersex are as Follows

• Female pseudohermaphrodite
• Male pseudohermaphrodite
• True hermaphrodite.

Female Pseudohermaphrodite

This is the commonest type of intersex and they are
all genetic females (46 XX) born with hypertrophic
clitoris, virilization due to 21- hydroxylase deficiency.
Additionally there may be labial fusion and poorly
developed vagina. Diagnosis is easy and is possible at
birth by estimating 17-alpha ketosteroids and
karyotyping. Properly treated with corticosteroids
they have a good fertility potential and can function
as normal females. Reduction clitoroplasty with or
without vaginoplasty can be done in early infancy.
Should the parents have already assigned sex, they
should be persuaded to reverse it because to convert
them to a functional male is very difficult.

**Male Pseudohermaphrodite**

These are genetic males (46\(\times\)xy) and raise serious ethical
as well as surgical problems. They are basically of two
types: Complete androgen insensitivity and in-
complete androgen insensitivity and 5-alpha reductase
deficiency.

a. **Complete androgen insensitivity:** As the external
genitalia are completely feminine, babies are not
bought to the doctor at birth. They may present later
for inguinal hernia with a palpable gonad or for
primary amenorrhea. Family history of sterility and
scanty hair in the patient and mother may be
suspicious. Karyotyping would confirm the diagnosis.
These patients have male gonad that produces
estrogens. These children require gonadectomy after
the breast has developed. Also vaginoplasty. These
children look like females but do not have the internal
organs of females. Vaginoplasty will give them ability
for coitus but they are unable to reproduce or
mensturate. It is difficult for parents to understand
and accept this situation so a multidisciplinary
approach with a gynecologist and psychologist will
be required.

b. **Incomplete androgen insensitivity and 5-alpha reductase
deficiency:** These children are incompletely Masculi-
nized and have small genitals. It is necessary to
distinguish between the two conditions. Androgen
insensitivity will produce female sexual characters
where as alpha reductase deficiency may get virilized
after puberty. Decision to rear them as male and female
will depend on the size of phallus and response to
testosterone therapy. In case of a good phallus and
good response to testosterone, the hypospadias should
be corrected and the boy brought up as a male. In
incomplete androgen insensitivity, it is better to rear
up the child as a female. Corrective surgery can be
done in infancy. Parents find it very difficult to accept
that although the patient is a genetic male how and
why should it be reared up as female. This is the hard
core of the intersex problem.

**True Hermaphrodites**

These children have ambiguous genitals; complicated
genetic picture and are often brought late. Assigning
gender takes time and a full coterie of tests with or
without laparatomy. If they have prominent male
external genitals, (which is rare) they must be reared
as males. Otherwise females. Fertility potential either
way is poor. These are tragic situations and will tax
the patience of both, parents and surgeon. Transsexuality is being slowly accepted in this country.

Two other questions need to be addressed.
Registration of birth, normally required within 40 days
of birth can always be extended by giving a suitable
medical certificate. Secondly the possibility of
malignancy must be explained in case of androgen
insensitivity and gonadal dysgenesis.

Telling the child patient is the most difficult of all.
Help of a child conseller is in order.

**PEDIATRIC MALIGNANCY**

Most liquid and embryonic tumors in the pediatric age
group are curable with multimodal therapy. Ethical
problems that may arise in the treatment of
malignancy are:

1. Should costly investigations be ordered?
CT/MRI have become the gold standard of diagnosis
and staging of the disease. In view of the radiation
and the cost involved only minimal cuts must be
ordered. Repeat investigations in the course of
treatment must be kept to a minimum.

2. Financial involvement:
Cancer being a chronic ailment, treatment is apt to be
prolonged. As it is a disease of the under five, parents
are usually young. Financial resources may be limited.
As and when need to they should have access to the
poor fund and the social service department. There is
a tendency in some parents to become martyrs and
sell property and other assets in the hope of a cure for
the child. They must be clearly advised as to what to
expect from treatment.
Chemotherapy

Because of advances in chemotherapy patients are living longer. Most chemotherapy has side effects which cannot be avoided. So beneficence and malefice may coexist. Similarly, no advance is possible without drug trials which may involve animals or human volunteers. Elements of risk and malefice are always there in newer drugs, needless to say the child cannot take his own decision and the parents have to be led into believing that chemotherapy will help. So even autonomy is questionable. In advanced cancer, recurrent cancer and terminal cases the choice of euthanasia must lie with the parents.

Euthanasia

For patients with advanced malignancy, multiple organ failure, bed sores and incontinence, euthanasia is a clear option. It is mostly of a passive nature and involves with holding treatment. Only symptomatic and pain relieving treatment need be given. Because of emotional bonding and religious taboo permission for active euthanasia practically never comes from the parents. In fact their belief in supernatural miracles, saints and seers is so high that the message of terminal disease is often lost on them. In such cases the doctor can only be a passive observer of the event.

Euthanasia for other cases

Deliberately causing death in an easy manner is called Euthanasia. It is usually meant for terminal patients who have incurable diseases involving a lot of suffering. It may be voluntary, if requested by the patient or involuntary when decided by others, usually the dear and near ones. It can be active, e.g. injection of lethal drug or passive, by withdrawing of life saving systems.

Euthanasia has always been debated by ethicists, but has received a fresh impetus after the Supreme Court of India ruled, that attempted suicide is not punishable by law.

Advances in technology have made it possible to prolong life although it may have lost its meaning. Sometimes by prolonging life we are prolonging death. Life must be meaningful and pain free and the patient must be capable of responding to the demands of living. Once cerebral function is lost (brain death) the other organs follow suit. In such cases drugs, drips dialysis and artificial ventilation should not be used to prolong life. In this debate on euthanasia two groups have emerged: One which believes in terminating life if its purposeless, handicapped and painful. The other believes in leaving it to God.

In the pediatric context when autonomy is not the principle involved but decision has to be taken by others, there is room for euthanasia in special situations, e.g.
1. Prenatal: Multiple defects, poor brain function and likelihood of a dependant life.
2. Child having some correctable and some uncorrectable defects leading to handicapped life. Parents unable to cope.
3. Advanced malignancy.

In such cases it is difficult to decide whether saving the life is beneficence or malefice!!

Ethics in Research

Nowhere are the principles of Hippocratic Oath so stretched as in conducting research. This include development of new techniques, not all of them may be successful. Research is the bass of progress in science. It involves:
1. Animal experiment: Here the rights of animals must be kept in mind. Animal to be used as last resort and suffering kept to a minimum.
2. Embryo research: The unresolved question is what makes an embryo? Is embryo a person? As most of these questions are unresolved only removing cells from the embryo for research purpose is justified. Transfer of animal embryos into human or vice versa is not justified. Cloning is not justified. Development of newer techniques like tissue cultures and computer developed models will reduce the need for experimental animal. One looks forward to a future which will be animal free and pain free. At present only research on aborted embryos is justified.

Hospital Ethics Committee

Now that high technology has made inroads into the practice of medicine, doctors are getting more and more technical and less and less humane. The art of bed side manner is a thing of the past and communicating with the patients is left to the junior most echelons of the medical pyramid. This often
results in frustration, bitterness and sometimes litigation.

Most hospitals in the West have an ethics committee which goes into quality patient care, medical research, publication and even ethical dilemmas that may arise in dying patients. This committee should include physicians, surgeons, departmental heads, matron, social worker and ideally should be presided by a person with a religious background.

Our own ethical norms in this country are confused. We have codified or tried to codify, principles of ethical behavior based, on Judaeo Christian thought that was imbibed by Indians educated by Western minds and exposed to Western literature. The time has come for our Medical Councils to face this issue head on and formulate ethical norm as that will encourage practice in keeping with our traditional and modern Indian values.

The committee should concern itself with improved patient care. How to cut down out patient procedures, the location and design of various departments by easily understood symbols. Improve the paging system of doctors. Over see medical audit and reduce beaurocratic obstacles in issuing certificates specially death certificates.

Publish or perish should not be the motto. Publication must be quality controlled and be relevant to the local problems. Meager resources that we have should not be dissipated in duplicating work done abroad. Even if the committee meets once a month it will have a lot to do specially as time goes on.

REFERENCES
Esophagoscopy

B Othersen Jr, HS Hassan

The ability to visualize the lumen of the gastrointestinal tract added an extra dimension to the diagnosis and management of various pathological conditions affecting it. Rarely in the history of medicine has a new technology so influenced a major specialty, as has gastrointestinal endoscopy influenced gastroenterology. Within less than 50 years, endoscopy has reoriented diagnostic approaches to numerous clinical problems, facilitated ingenious therapeutic development, permitted new physiological studies and modified long held concepts of gastrointestinal disease events. The refinement of the endoscope and ancillary diagnostic techniques has led to an increased ability to diagnose and treat patients with diseases of the esophagus. The addition of biopsy and brush cytology techniques further augments its abilities. The use of absorptive stains that are sprayed on the mucosa during endoscopy has been described by several groups and can assist in the detection and definition of abnormalities. Endoscopic ultrasonography has expanded the diagnostic capabilities of endoscopists by imaging the wall layers of the esophagus as well as the surrounding structures. Additional techniques that appear to have endoscopic applications include molecular biologic investigation of specimens obtained at endoscopy, tissue autofluorescence, and magnetic resonance imaging during endoscopy.

INDICATIONS OF ESOPHAGOSCOPY

Diagnostic

Esophagitis

Endoscopic findings of esophagitis include erythema, loss of the superficial vascular pattern that can be seen just below the mucosal surface, erosions, ulceration or nodularity, mucosal bleeding on contact, white plaques of various configurations surrounded by an erythematous border and cobblestone appearance of the mucosa. However, histologic changes of esophagitis may be found in a grossly normal mucosa, and conversely, subjective gross endoscopic findings including erythema, edema, increased vascularity and friability do not predict abnormal histology. Diagnosis of esophagitis is based on histologic criteria in biopsies obtained during endoscopy in infants and children. The sine qua non of histologic esophagitis is intraepithelial neutrophils. The finding of only one neutrophil per high power field in a section of a punch biopsy is reported to be pathologic and sufficient to make a diagnosis of histologic esophagitis. Intraepithelial neutrophils are regarded as less specific than eosinophils. Boyle JT suggested a grading of esophagitis that incorporates both gross and histological findings.

Gupta et al found that vertical linear indentations in distal esophageal mucosa might be a highly specific
endoscopic feature of esophagitis in children. Isaac et al found that endoscopy also help in treatment of esophagitis by specifying a specific etiology.

**Corrosive Ingestion**

Endoscopic examination is necessary to determine whether or not there has been an esophageal burn. Studies have shown that signs and symptoms are unreliable guides to the presence or severity of an esophageal injury. It should be performed the next day (12-24 hours after ingestion) not immediately because the extent of injury may be difficult to determine, and because if the patient has a full stomach, regurgitation of caustic may produce further injury. As many as 75% of patients will be found to have no esophageal injury. The most likely sites of injury are at points of natural narrowing of the lumen: the cricopharyngeus, the aortic arch, the left main stem bronchus, and the diaphragm. It is not possible to accurately evaluate the depth of the burn at esophagoscopy. Although ulceration is usually associated with full thickness damage, apparently mild mucosal changes may conceal a transmural injury. The risk of perforation is minimal if the examination is stopped when evidence of mucosal burn is seen.

Endoscopic grading of corrosive esophageal and gastric burns:

- **Grade 1** = Mucosal hyperemia and edema
- **Grade 2** = Limited hemorrhage, exudate, ulceration and pseudomembrane formation
- **Grade 3** = Sloughing of mucosa, deep ulcers, massive hemorrhage, complete obstruction of lumen by edema, charring, and perforation

There are several limitations to esophagoscopy. At times it may be difficult to evaluate the depth of any burn with absolute certainty by observing superficial epithelial necrosis. When a severe burn is encountered in the upper-third of the esophagus, the esophagoscope is not passed beyond this area and the involvement of the middle and lower thirds cannot be ascertained. The area of burn may not be visualized, thus delaying the diagnosis. The areas of ulceration may be more easily visualized if a dilute solution of methylene blue is instilled into the esophagus at the time of esophagoscopy. The normal epithelium will be stained blue, whereas the areas of ulceration will not.

**Diagnosis of Tracheoesophageal Fistula (TEF) and Other Anomalies**

The symptoms of choking and coughing with feedings, excessive tracheal secretions, and recurrent atelectasis or pneumonitis should direct attention to the possibility of an H- or N-type tracheoesophageal fistula, or a recurrent fistula in a patient with a previous repair. TEF is one of the rare congenital anomalies of the trachea and esophagus. It constitutes 4-5% of these anomalies. Seventy percent of H-type TEF occurs at or above the level of the second thoracic vertebra and extends in an oblique course like the letter N, from the posterior membranous wall of the trachea to the anterior wall of the esophagus. Although congenital, the condition may present late; this may be explained by various theories; an occlusive valve like mucosal flap, which may close during swallowing because of the oblique direction of the tract, or spasm of the muscular layer occluding the lumen during swallowing. The key to repair of isolated (H-type) and recurrent TEF is identification of the level of the fistula. This is important both before operating, so that the correct exposure can be planned, and intraoperatively, so that the fistula can be localized and repaired.

TEF can be diagnosed by endoscopy either directly or by using some techniques. Although better seen by a bronchoscope, an esophagoscope can also be used to visualize the esophageal opening of the fistula.

Other anomalies as congenital stenosis, leiomyomas, cystic duplication, esophageal diaphragm and epiphrenic diverticulae can also be confirmed by esophagoscopy.

**Upper GIT Bleeding**

A variety of etiologic factors may be responsible for an upper GIT bleeding. Commonly esophageal varices, severe peptic esophagitis, peptic ulcer or Mallory-Weiss syndrom. Esophagoscopy can determine the etiology and, in certain instances as esophageal varices, may be used in management.

**Esophageal Perforation**

Esophageal perforation may be intraluminal, as occurs during instrumentation: Endoscopy, dilatation, intubation (nasogastric or Sengstaken tubes, or sclerotherapy, or due to foreign body impaction, or
caustic ingestion; or may be extraluminal as in cases of penetrating wounds, blunt trauma, operative injuries, and fracture spine. Spontaneous perforation (Boerhaave’s syndrome) may also occurs in newborn and older children.

Although diagnosed by plain X-ray, contrast study or even CT scanning, esophagoscopy can identify major tears or complete disruption.

Dysphagia

Esophageal causes of dysphagia include esophageal strictures (Figs 18.1A and B) and webs; vascular anomalies as aberrant right subclavian artery, double aortic arch and right aortic arch with left ligamentum; trauma: either external or trauma during intubation and endoscopy; neurologic defects: as occurs in head trauma and hypoxic brain damage or peripheral nervous system congenital or traumatic diseases; neuromuscular diseases as myasthenia gravis or miscellaneous causes as achalasia and esophageal spasm.

Esophagoscopy is an aid to diagnosis of many of these causes. Some lesions of the esophagus are sometimes amenable to endoscopic treatment. Endoscopy may be a useful adjunct in the diagnosis of vascular anomalies, because pressure with the tip of the scope on the vessel indenting the esophagus may abolish one or more distal pulses, thereby helping to identify the offending vessel.

Miscellaneous

Esophagoscopy is an aid to diagnosis of many other conditions as hiatus hernia, achalasia, stenosis, and Barrett’s esophagus (Fig. 18.2).

Therapeutic

Esophageal Dilatation

For patients with narrow esophageal lumen for whatever etiology, esophageal dilatation is an important therapeutic modality. There is no perfect

Esophagoscopy

225

dilator or dilating procedure for the management of peptic esophageal strictures. Successful dilatation requires versatility in technique and instrumentation. Until recently, a common means of dilatation was the passage of dilators via the rigid esophagoscope under general anesthesia, modern equipment has made the routine use of this technique obsolete, and it is reserved for special situations such as uncooperative patients, high cervical esophageal strictures, or dilatations that have been unsuccessful under local anesthesia and sedation.37

Several types of dilators are available: Gum elastic dilators (Jackson), mercury filled dilators (Maloney), Eder-Puestow dilators, Savary-Gilliard dilators or balloon dilators. All these dilators require esophagoscopy for pre-evaluation, insertion of the dilator and examination after the dilatation setting.

Esophageal Foreign Body Removal

Ingestion of foreign bodies is a common problem in pediatric patients, and the majority of these objects are coins (Fig. 18.3). Because the esophagus is the narrowest portion of the pediatric alimentary tract, a significant number of ingested coins will lodge here. Esophageal perforation and aspiration are well-documented complications of retained esophageal foreign bodies, and this risk, although of low incidence (9.1 %) mandates immediate extraction.38,39

Foreign body ingestion is a relatively common problem in the United States, with an estimated incidence of 120 per 1 million population, resulting in approximately 1500 deaths each year.40 Swallowed objects may be true foreign bodies) such as coins, plastic toys, bones, pins, or disc batteries.41-43

Prior to the 1960s, esophagoscopy was the accepted method of managing esophageal foreign bodies. In 1966, however, Bigler reported a method of extracting smooth esophageal foreign bodies using a Foley balloon catheter.44 Subsequently, several authors have reported the technique of esophageal bougienage to dislodge coins into the stomach.45,46 Each of these methods has its proponents, and all of them are effective.

Those advocating balloon catheter or bougienage techniques cite the following advantages over esophagoscopy: (1) avoidance of the use of an operating suite, (2) avoidance of hospitalization, (3) avoidance of the risks of general anesthesia and endotracheal intubation, and (4) avoidance of the risks of esophagoscopy. At a glance, these may seem to be worthwhile arguments, but on closer examination their foundation is not strong. For instance, the alternative methods are recommended only for blunt foreign bodies, usually coins, of short duration without pre-existing esophageal disease or other factors that make complications more likely. These are precisely the foreign bodies that are the easiest and safest to remove by esophagoscopy. Any foreign body that can be removed by a Foley catheter or a bougie can be removed just as easily and perhaps more safely under direct vision with esophagoscopy. Foreign bodies with any suggestion of complications are not considered candidates for the alternative blind methods of extraction. It seems logical that the safest technique for removal of complicated foreign bodies should also be the safest technique for removal of uncomplicated foreign bodies.47

Kelly et al, however, noticed a striking difference in cost between esophagoscopy and the use of Foley catheter or bougienage.48 He developed a protocol for management for esophageal coins utilizing either Foley catheter (for proximal 1/3 of the esophagus) or bougienage (for distal 2/3), and reverting to esophagoscopy only on failure of those techniques. He applied the protocol selectively, adopting the criteria developed by Jona et al; thus excluding from this protocol all cases seen after 24 hours form impaction, those patients with respiratory distress or history of esophageal pathology, and in the presence of more than one coin.48,49

Fig. 18.3: Chest X-ray showing radio opaque battery in esophagus
Finally, pharmacological methods to manipulate the muscular tone of the esophagus, allowing passage of an impacted foreign body, have been attempted. Glucagon and nifedipine have been used with varying degrees of success. Gas-forming agents have been tried; the idea being that increased pressure from the gas would force the object into the stomach. Magnets were used to pull metals as pins, rings and batteries. Enzymatic digestion of a meat bolus with papain has largely been abandoned because of an unacceptable complication rate.

**Sclerotherapy for Bleeding Esophageal Varices**

Bleeding from esophageal varices is the most common cause of serious gastrointestinal bleeding in children. It is associated with a considerable morbidity and a reported mortality of 12-21% even in the absence of liver disease.

The first report of the injection of sclerosant into esophageal varices for the control of bleeding came in 1939 from the two Swedish surgeons Crafoord and Frenckner, who used this technique in a 19 years old female to control bleeding esophageal varies, utilizing a rigid esophagoscope and a specially deviced needle.

Techniques of injection sclerotherapy presently in use can be divided into those aiming to inject sclerosant into the varix to obliterate the lumen, and those injecting into the submucosa alongside the varix (paravariceal) to produce a layer of fibrosis to cover the vessel. With both methods the flexible fiberoptic endoscope and injection needle has largely replaced the rigid esophagoscope, although the latter instrument is still favored by some, especially in the presence of active bleeding when the field of vision and the control of the bleeding point by the tip of the esophagoscope are superior. More elaborate methods of injection sclerotherapy have included a means of balloon tamponade in order to maintain a blood-free field during the procedure. This has been achieved in two ways. Firstly, by applying traction to the large gastric balloon of the Linton’s tube and then injecting the varices immediately above the gastroesophageal junction by means of the fiberoptic endoscope and, secondly, by incorporating a balloon onto the distal end of a fiberoptic endoscope which is inflated against the injection site to prevent any post-injection bleeding.

A verity of sclerosants might be used, including: 5% sodium morrhuate, 5% ethanolamine, 1.5% sodium tetradecyl, and 50% dextrose. Complications include retrosternal pain and burning at the time of injection, fever, esophagodynia, superficial ulcers and pleural effusion.

Recently, endoscopic variceal ligation has been shown to be just as efficacious and is associated with fewer complications. Endoscopic variceal clipping is also a promising; Ohnuma et al successfully used a clipping apparatus to stop bleeding in 99.3% of cases of his series.

**Miscellaneous**

Other miscellaneous authors report successful endoscopic management of some diseases. Hoelzer and Luft reported successful occlusion of a recurrent tracheoesophageal fistula using fibrin glue, applied endoscopically in a 6 years old child. Kim et al successfully used chemocauterization to occlude the opening of a pyriform sinus fistula by endoscopically applied trichloroacetic acid, and suggests this technique as a reasonable alternative in the management of pyriform sinus fistula.

**INSTRUMENTATION**

**Flexible Esophagogastroscope**

The use of the flexible esophagogastroscope is indicated in most instances. The apparatus have a working channel through which graspers, biopsy cups, scissors, etc. can be passed through. It is also prepared with air insufflation, suction and irrigation capabilities. The tip of the scope can be moved in four directions controlled from the handle. Operator may use the eyepiece or a video camera may be mounted on the eyepiece to deliver the picture to a monitor. Illumination is provided by an external light source with a xenon arc or halogen -filled tungsten filament lamps. A pediatric size is now available by many manufacturers.

**Rigid Esophagogastroscope**

Since the first flexible fiberoptic endoscope was constructed by Basil Hirschowitz in 1957, the technique of flexible endoscopy has been the primary method employed by gastroenterologists for
investigating patients with complaints involving the upper digestive tract. With the technical advances that followed the original design gastroenterologists abandoned the rigid endoscope for the flexible version. It has proven easier to use, with fewer complications. However, rigid esophagoscope still have a place in clinical practice, particularly for foreign body removal.

Complications
Complications include esophageal perforation, impaction in the esophagus, aspiration pneumonia and infection.17,69-71

Contraindications
Strict contraindications include agitated patient, shock, inexperienced endoscopist, defective instruments and absent CPR equipment. The relative contraindications include neck deformities, large pharyngeal pouch, aortic arch aneurysm, recent surgery and perforated esophagus.

3. Johnson DG. Esophagoscopy and other diagnostic techniques in O’neill JA, Rowe MI.
The development of the Hopkins rod lens has revolutionized the field of bronchoscopy. The reduction in the size of the fiberoptic bronchosopes has expanded its utility from the diagnostic to its use in operation theatres, casualty, neonatal/pediatric intensive care units, assisting endotracheal intubations and diagnostic procedures such as bronchoalveolar lavage and transbronchial biopsy. Pediatric bronchoscopy is now being performed even while on high-frequency oscillatory ventilation the development of narrow-caliber flexible fibreoptic bronchoscope has enabled diagnostic bronchoscopy in premature and newborns in the neonatal Intensive Care Unit. The rigid bronchoscope however can not be replaced and is of immense use for removal of foreign bodies. While rigid bronchoscopy is performed by only Pediatric Surgeons, a flexible bronchoscopy is performed by Pediatric Surgeons, Otorhinolaryngologists, Pneumologists, Anesthetists and Pediatricians.

**PEDIATRIC AIRWAY ANATOMY**

The infant larynx is placed more anteriorly in the neck compared to the adult. The epiglottis has a U shaped curvature and the arytenoid cartilages may be very prominent in the infant. The subglottic space is the narrow portion of the airway in infants and young children as compared to the glottis in the adults. This should be taken into consideration during selection of bronchoscope. In children the trachea is nearly round, with the cartilages extending visibly through an arc of approximately 320 degrees. Some inward protrusion of the membranous portion of the trachea and main bronchi may be seen. The main carina is keel shaped and oriented in an anteroposterior plain. In the adult the main carina is sharp and a widened carina in adults may indicate subcarinal lymphadenopathy. In the child the main carina is often quite blunted. The right mainstem bronchus is immediately visible on passing the scope down the trachea (Fig. 19.1).

The right upper lobe division takes off just beyond the carina at an angle of approximately 100 degrees. The right upper lobe bronchus itself may have a small length before dividing into the anterior, posterior and apical segmental bronchi. Beyond the origin of the right upper lobe bronchus, the right mainstem bronchus continues as the bronchus intermedius, after which it gives rise to the middle lobe bronchus anteriorly, the superior segment of the right lower lobe posteriorly and right lower lobe bronchus that divides into basilar segments. It is however not possible to negotiate the bronchoscope into the terminal bronchioles in children.

The left main bronchus can be visualized in its entirety from the carina, after turning toward the left, and even then it takes a curving course so that its bifurcation may not be seen from the carina.

The left mainstem bronchus terminates into the upper lobe and lower lobe bronchi. As the left upper lobe bronchus ascends superiorly, the lingular bronchus arises and extends slightly downward in an inferior-lateral direction. The upper division bronchus of the upper lobe passes beyond the orifice of the lingula and gives rise to the apicoposterior and the anterior segments. Immediately on entering the left lower lobe bronchus arises the superior segment of the left lower lobe that descends posteriorly and then the basal bronchi.
INDICATIONS FOR BRONCHOSCOPY

Although pediatric bronchoscopy has become a well-accepted routine procedure with a high diagnostic yield, it is important that the most appropriate means of access to the airways is chosen according to the indications and the age of the child.5

Diagnostic
1. Tracheobronchial foreign body.
2. Stridor, wheezing and persistent cough.
3. Persistent pneumonia, persistent atelectasis.
4. Persistent opacity on the chest radiograph.
5. Use in the intensive care unit.
6. Suspected mucus plug blocking the bronchus.
8. Diagnose H-type tracheoesophageal fistula.
10. Respiratory symptoms in immunocompromised child.

Confirm Suspected Diagnosis
1. Recurrent laryngeal nerve injury—Vocal cord palsy.
2. Laryngomalacia.
3. Tracheomalacia.
4. Subglottic stenosis.
5. Tracheoesophageal fistula.

Therapeutic
1. Removal of foreign body.
2. Removal of mucous plugs.
5. Treat H-type tracheoesophageal fistula—fibrin glue/laser/coagulation, deflux.
6. Interventional —Balloon dilatation.
7. Tracheobronchial prosthesis—stents.
8. Tracheostomy care.
9. Aid in intubation.

Stridor forms one of the most common indications for bronchoscopy in children.6 Bronchoscopy is indicated when stridor is severe, persistent or worrisome. The common causes of stridor are laryngomalacia, tracheomalacia, vocal cord paresis, subglottic cysts or stenosis and extrinsic compression of the trachea (vascular ring or innominate artery compression.7 The common causes of acute stridor in children are croup, epiglottitis or a laryngeal foreign body. In a series of 90 infants, the causes of stridor diagnosed with fiberoptic bronchoscopy were subglottic stenosis in 21, tracheobronchomalacia in 20, laryngomalacia in 20, tracheal stenosis in 17, cervical hemolymphangiomas in 5, vocal cord palsies in 4, and glottic edema in 3.8 More than half of these patients
(51%) required surgery. The severity of stridor does not always correlate with the severity of the lesion.

In presence of persistent cough, bronchoscopy may reveal unsuspected foreign bodies, tracheomalacia, bronchomalacia, extrinsic compression in the tracheobronchial tree or gastroesophageal reflux. Unilateral or a localized wheeze is a definite indication for bronchoscopy. In case of bilateral wheezing, bronchoscopy is indicated if it were persistent or poorly responsive to optimal bronchodilator therapy. The common findings in these situations are unsuspected foreign bodies, tracheomalacia, bronchomalacia or airway stenosis.

In cases of tracheostomy, the trachea may be examined for the presence of granulation tissue or stenosis at the site of tracheostomy. Retrograde laryngoscopy may be performed through the tracheostomy stoma to evaluate the subglottic area and larynx. Flexible bronchoscopy may be used for endotracheal intubations for patients with a difficult airway.

Bronchoscopy may also be used in confirming the diagnosis and identifying a tracheoesophageal fistula.

**BRONCHOALVEOLAR LAVAGE**

Bronchoalveolar lavage (BAL) is a safe and sensitive technique for investigating infectious causes of respiratory disease. Bronchoalveolar lavage allows the recovery of both cellular and noncellular components from the epithelial surface of the lower respiratory tract and differs from bronchial washings, which refer to aspiration of either secretions or small amounts of instilled saline from the large airway. When the pulmonary pathology is diffuse, BAL is performed from the lingula and right middle lobe due to their favorable anatomical location, ease of obtaining a good wedge, and a higher volume of returning fluid as compared to other lobes. When the pathology is localized, BAL is obtained from the affected segment.

In children over 3 kg of weight, 1-3 aliquotes of 5-10 ml each are used up to a maximum of 3 ml/kg. Some authors restrict the amount of lavage fluid to no more than 5-15% of the functional residual capacity (FRC). The FRC may be measured by spirometry or estimated from the patient's height using the following equation: FRC = 1.3 to 1.5 ml × height or length in centimeters.

In the immunocompromized child BAL is used to obtain samples for microbiology and cytology studies. The most common indications for BAL in immunocompromised children are fever, hypoxia, and abnormality on chest auscultation. The safety and diagnostic yield of BAL in this set of patients has been reported to be relatively high with a rate of > 60% positivity. In immunosuppressed patients with diffuse lung infiltrates, *P. carinii* can be identified in BAL with a sensitivity of up to 85%

**DISINFECTION OF BRONCHOSCOPE**

High level of disinfection, defined as a procedure that inactivates all fungi, viruses, and vegetative microorganisms, bacteria but not necessarily all bacterial spores, can be achieved with 2% glutaraldehyde. Immersion in glutaraldehyde for 10 minutes will destroy bacteria, viruses, and 99.8% of mycobacterial organisms. Immersion in glutaraldehyde for 45 minutes at 25 °C will destroy all mycobacterial organisms.

**CARE OF HOPKINS ROD LENS TELESCOPE**

Prior to use, the Hopkins rod lens telescope must be carefully and meticulously cleaned and sterilized or disinfected. For machine cleaning, only special procedures may be used which have been tested and approved (maximum temperature 93 °C). Use a cleanser with a neutral pH (e.g. enzymatic cleanser). After a program is completed, remove the telescopes from the machine immediately if possible. All Hopkins rod lens telescopes should be routinely gas sterilized or chemically disinfected (soaked). Following routine gas sterilization, no aeration is required. The telescopes must be positioned securely. Any careless and slight bending of the rigid telescope may damage the rod lens system making it foggy or even unusable. The telescope should not remain for more than 60 minutes in any solution, including sterile water. Otherwise there is a risk of making it foggy. Similarly, the body and the tip of the telescope should not be touched with a heat source like laser fiber, diathermy coagulation, etc.

Due to foreign matter in the steam, stubborn films of deposit may in time develop on the cover glasses of the optical end faces after autoclaving. These deposits can be removed with the special cleaning paste.
enclosed with scopes. Polishing may be done to remove even stubborn films of deposits. Cleaning with special cleaning paste should only be performed if the image as viewed is clouded and not as a matter routine after every cleaning.

Hopkins telescopes that are marked "Autoclave" can be steam autoclaved at 134 °C (272 °F) for 5-8 min at three atmospheric pressure. When the autoclave cycle is complete, remove the container from autoclave and allow telescopes to cool to room temperature before removing top container.

During the steam autoclaving, the telescopes should not come into direct contact with metal instruments, trays, etc. Sudden changes in temperature may fracture the glass components of telescopes. The telescope should not be immediately exposed to air after removal from the autoclave. Never attempt to cool telescopes by pouring cool, sterile liquid over them. Forced cooling will cause severe damage to the telescope.

**FLEXIBLE FIBEROPTIC BRONCHOSCOPY**

The flexible fiberoptic bronchoscope is relatively atraumatic as compared to rigid bronchoscope. It is of immense utility for diagnostic purposes especially in the intubated child in the intensive care unit. It allows visualization of the natural dynamics of the palate and larynx. The upper lobes can be easily visualized. The limitations include partial occlusion of the airways and limited instrumentation.

The various sizes of flexible bronchoscopes available for pediatric flexible bronchoscope range from 2.2 mm - 4.9 mm (outer diameter). Bronchoscopes that are 3.2 mm or more in diameter usually have a working channel, which facilitates suction and also allows passage of biopsy forceps. Bronchoscopes that are 2.2 mm or less in diameter do not have a working channel and are particularly useful in the intensive care units, for neonates, in assessing nasal space and laryngeal/vocal cord pathology.7

The different parts of the flexible bronchoscope are: (i) the eye piece; (ii) angulation control lever; (iii) angulation lock; (iv) working channel; (v) suction connector; (vi) insertion tube: at the distal end has objective lens, light guides and instrument channel (which is also the suction channel) and has a bending section at the tip of the endoscope; and (vii) universal cord which connects to the light guide connector section.

A laryngeal mask airway has been used as an alternative to endotracheal intubation for flexible fiberoptic bronchoscopy in children.14 The major complications reported with its use have include airway obstruction and failure to place the laryngeal mask airway in the appropriate position, laryngospasm, bronchospasm, and oxygen desaturations have been reported.15,16

The advantages to the use of a laryngeal mask airway include secured airway, accommodation of a larger bronchoscope with a suction channel and less resistance to gas flow compared to a conventional endotracheal tube and greater visibility of the glottis and supraglottic structures.17 Also, with a larger bronchoscope, transbronchial biopsies can be performed in younger children.

The disadvantages of the laryngeal mask airway include increased work of breathing when compared to endotracheal intubation.18 However, these effects may be lessened once the bronchoscope is inserted into the artificial airway. The laryngeal mask airway is relatively contraindicated in presence of severe respiratory.17

**RIGID BRONCHOSCOPY**

The rigid bronchoscope will remain the gold standard treatment for removal of foreign bodies. The system offers a large lumen, removable telescope, adjustments for various types and sizes of the foreign body forceps and enough space for ventilation. The posterior commissure of the larynx is better visualized with the rigid bronchoscope as it approaches the larynx from an anterior angle. There is an excellent control of the airway. Figures 19.2 and 19.3 show the parts of a rigid bronchoscope.

![Fig. 19.2: Rigid bronchoscope set — different sized sheaths, telescope and an optical foreign body removal forceps fitting well with the scope](image-url)
All therapeutic interventions can be done with ease as there is facility to pass instruments through the bronchoscope sheaths. There is however a risk of trauma to the airway and inability to pass the scope into the distal airways. It is also difficult to visualize the right upper lobe bronchus with the rigid system as it opens at a right angle in the trachea.

**THERAPEUTIC BRONCHOSCOPY**

Bronchoscopy has been the time tested modality to confirm the diagnosis of tracheoesophageal fistula. Bronchoscopy is a useful adjunct to guide the surgical treatment of H-type tracheoesophageal fistula by identification and passing a catheter for easy identification of the fistula peroperatively. Recently, various therapeutic attempts have been made at the time of bronchoscopy to treat the tracheoesophageal fistula. These have included fibrin glue, Laser and diathermy coagulation. The authors have recently used deflux injections in 4 cases, tracheoesophageal fistulas, (three of them complicated with prematurity, serious ongoing chest infections making him unfit for major surgery, and a recurrent TEF). The outcome had been satisfactory and none required surgery during the followup ranging from 8 months to 2 years.

Tracheoscopy and bronchoscopy has also been used to guide the extent of surgical manipulations intraoperatively for aortopexy/tracheopexy procedures.

Peroperative fiberoptic tracheoscopy assisted repair of tracheoesophageal fistula has been reported to be useful for the surgeon with regards to identification of the fistula and proper fistula ligation. Fiberoptic bronchoscopes with an outer diameter of 2.0, 2.4 and 2.8 mm were passed through the lumen of the endotracheal tube into the fistula that helped the surgeon to rapidly identify and dissect the fistula. Bronchoscopy-assisted neonatal tracheostomy as been described as a new technique that restricts dissection strictly to the midline and ensures accurate placement of the tracheostomy below the first tracheal ring.
preventing potential for damage to adjacent neurovascular structures. Preliminary experience with the use of balloon dilatation and expandable metallic airway stents for tracheobronchial stenosis in the pediatric population has been reported to be encouraging.

**Foreign Body**

Children are more prone to aspirate foreign bodies due to the decreased ability to chew the food sufficiently. Also the propensity to talk, laugh, and play around while chewing and the habit of putting objects in the mouth, make them highly vulnerable to aspirate despite of the defense mechanisms operating against the lodgment of a foreign body (motility of the epiglottis and arytenoid cartilages in closing the airway, intense spasm of the vocal cords and cough reflex) in the respiratory tract. However, none of these mechanisms is full proof and foreign bodies do lodge frequently in the pediatric airways. The peak ages for aspiration of foreign bodies are 2-4 years, though accidental aspiration may occur at all ages. Even relatively younger immobile infants have been victims of foreign body aspiration while playing with small objects or due to the acts of their siblings, who may put the wrong objects/foods in the baby's mouth in an attempt to help feed them. The authors have even seen infants aspirate jewellery items of the mother like pendants and earrings and even the nails, beads, nuts and safety pins while playing with them (Fig. 19.4). The uncommon foreign bodies removed by the authors include screws, torch bulbs and pieces of whistles (Fig. 19.5).

**Fig. 19.4:** Skiagram chest showing a radiopaque broken safety pin in the left main bronchus lying for more than 6 months. Foreign body could be removed after clearing the bronchus from granulation tissue.

**Figs 19.5A and B:** A. Skiagram chest showing a radiopaque nail in the left bronchus left for many months inviting local reaction and partial blockage of the lumen and recurrent chest infection. The "head" of the nail projecting proximally was in an unfavorable position and could not be grasped bronchoscopically. A thoracotomy and bronchotomy incision was made "over the head" of the nail and the rusted nail was removed successfully. Distal bronchus was suction cleaned. B. Skiagram showing a metallic nut in the right main bronchus, with the head facing proximally and making the grasping impossible with the foreign body forceps. A thoracotomy and the bronchotomy incision over the head of the nut successfully delivered the foreign body.
The most common aspirated materials are small food items such as groundnuts and seeds. Food items that are small, round, smooth, or both, such as grapes and balloons, are more likely to cause tracheal obstruction. Dried foods may cause progressive obstruction as they absorb water. Free floating foreign bodies in the trachea are more dangerous than the ones lodged in one of the bronchi. Old foreign bodies, vegetable or metallic, invite local reaction, inflammation and granuloma formation with the blockade of the lumen resulting in collapse consolidation, abscess formation or even the bronchiectetic changes in the corresponding lobe or the lung.

In a child in the upright and supine position, the right main bronchus is wider and has a more direct entry from the trachea, thus is a more common site for housing the foreign bodies and aspiration. There may be a definite history of observation of accidental aspiration or sudden episode of coughing or choking while eating with subsequent wheezing, coughing, or stridor. However, in most cases, the episode is not witnessed or recalled and the diagnosis depends on a high index of suspicion. In delayed cases the child may present with persistent wheezing, persistent or recurrent pneumonia, lung abscess, focal bronchiectasis, or hemoptysis. A foreign body in the subglottic space may present with stridor, recurrent or persistent croup, and voice changes.

On auscultation, adventitial sounds like wheezes may be heard. There may be stridor or decreased breath sounds. The coarse wheeze is often unilateral, but not as a rule. The sounds are inspiratory if the foreign body is in the extrathoracic trachea. If the lesion is in the intrathoracic trachea, noises are symmetric expiratory stridor, more prominent in the central airways. Once the foreign body passes the carina, the breath sounds are usually asymmetric. It should however be remembered that a lack of findings on physical or radiological examination does not preclude the possibility of an airway foreign body.

If the child has respiratory distress and is unable to speak or cry, complete airway obstruction is likely present, and the likelihood of morbidity or mortality is high. In those cases, a Heimlich maneuver may be tried. If the child is able to speak, the Heimlich maneuver would be contraindicated, as it might dislodge the material to an area where it could cause complete airway obstruction.

Most aspirated foreign bodies are radiolucent. Thus, indirect signs of the foreign body aspiration have to be looked for. These include an area of focal overinflation or an area of atelectasis, depending on the degree of obstruction. If the airway is completely occluded, the radiograph should show opacification of the distal lung because the residual air is absorbed and there is no air entry. If the obstruction is partial with progressive ball valve obstruction, there is focal overinflation in the area of the lung directly connected to the affected airway.

An anteroposterior expiratory radiograph, lateral decubitus or fluoroscopy of the chest may be helpful in showing focal air trapping.

A chest CT scan may demonstrate the material in the airway, focal airway edema, or focal overinflation not detected in the plain radiographs. However, if the degree of suspicion is high one may straight away proceed with bronchoscopy, without wasting time. No routine investigations are required for this life saving procedure.

The differential diagnosis includes gastroesophageal reflux, asthma, bronchitis and pneumonia. Rigid bronchoscopy is the therapy of choice for diagnosis and removal of foreign bodies. Flexible bronchoscopy should not be encouraged for dealing with the foreign bodies. However, the flexible bronchoscopy may have a theoretical advantage that it can be used to detect the foreign bodies in moribund patients in the emergency room without the need for general anesthesia. Once, the foreign body has been confirmed at flexible bronchoscopy, the rigid bronchoscopy is warranted to remove the firm, large and solid foreign bodies. The fact that the rigid system has a wider lumen, the instruments of appropriate size and length can be adapted to suit the removal of the foreign body. On the contrary, the flexible bronchoscopes have a narrow side channel and at the best can accommodate only a thin sized instrument (foreign body removal and biopsy forceps) suitable, if at all, only to remove the thin peels or the covers of whistle or the ground nut.

Predictive signs of a bronchial foreign body have been reported as a radiopaque foreign body, and associated unilaterally decreased breath sounds and obstructive emphysema (positive predictive value = 0.94). Some authors prefer to perform a rigid bronchoscopy first, in all cases presenting with asphyxia, localized wheezing or atelectasis. This
algorithm has been thought to decrease the negative first rigid bronchoscopy rate to 4%. However, flexible bronchoscopy can also be performed first for diagnostic purposes. Fiberoptic bronchoscopy has a diagnostic accuracy rate of 100% but played a poor therapeutic role with 10.7% complete resolution of cases.

Rigid bronchoscopy has been successful in the removal of the tracheobronchial foreign body in 97.2% of patients. The authors’ preference has been to use the rigid system for the removal of all types of foreign bodies. It requires combination of skill and innovations to grasp the foreign body and take it out without slipping or harming the child. A Fogarty catheter may be employed to remove a rounded bead with a central hole large enough to permit the deflated catheter to negotiate through it. Vegetable nuts impacted in the respiratory tract swell up and become large enough to be retrieved in one piece. These may be first broken or divided in pieces before removal. Also a larger section of the same may be retrieved en block with the bronchoscope system holding the foreign body firmly all through. Authors resorted to open bronchotomy in many cases presenting late with sharp and dangerously impacted foreign bodies with presence of lot of granulation tissue in the bronchi, which bled to touch with the scope. A decision for thoracotomy and open bronchotomy exactly over the head of the impacted nail (directed upwards) is much better and safer procedure to the repeated attempts on rigid bronchoscopy. It may be extremely difficult to grasp the head of the nail as its sharp edges would get lodged in the wall of the bronchus. Similarly, a ragged long wire or a broken safety pin impacted in the bronchus may have to be divided first with a wire cutter before the same could be retrieved safely, holding the same on either side with artery forceps to avoid its dislodgement.

VIRTUAL BRONCHOSCOPY

This is a new noninvasive diagnostic modality that has enabled to view tracheobronchial anomalies in fair detail and accuracy. This has been found useful in cases of tracheal atresia and tracheoesophageal atresia to see the exact opening of the fistula in the trachea.

Three-dimensional computed tomography bronchoscopy has been reported to demonstrate accurate anatomical structures in 2 cases of prenatally diagnosed congenital lobar emphysema caused by bronchial atresia at the left upper lobar bronchus.

REFERENCES

A child is a gift from God - a promise for the future. Irrespective of the geographic or socioeconomic milieu, the child remains the focus of a family. A sick child is even more vulnerable and deserves the full support of the family and society to make a recovery. If recovery is not possible, death in dignity is his right. It is an erroneous and callous thought that children are neglected in the poorer societies; the apparent neglect is the result of poverty and not the lack of concern. Society associates children with growth, activity and hope and in the natural order of things children are not supposed to die. Hence, it is difficult to accept terminal illness and death in childhood. Further, the hospital setting for preterminal and terminal care reduces the inbuilt support from family and society.

Despite the advances in neonatal and pediatric care, a sizeable number of children with complex anomalies, chronic disease cancer and HIV infection eventually succumb to their illness. With life sustaining critical care, a number of such children remain on pre-terminal support for varying periods, particularly in the developed world. Many undergo various operative procedures on routine or emergency basis for effective palliation.

Since the causes (trauma, lethal congenital anomalies, extreme prematurity, heritable disorders and acquired disease) and patterns of death are different from the adult, adult palliative care guidelines are not suitable for the child and specific approaches are still being developed. Given its socioeconomic, linguistic and cultural diversity, the complex emotions of the grieving process is very different in the Indian context. Grief counseling guidelines adopted in the western world are not entirely appropriate for the child in a developing country.

Empathy, pain relief and optimal palliation of the terminally sick child have a dramatic effect on the psychosocial recovery of the family.

NEED FOR FORMAL TRAINING

Parents of terminally ill children have a right to know about the diagnosis, treatment and prognosis of their child’s illness.

Studies of medical school curricula, textbooks and residency programs showed absence of an integrated approach to systematically address the complexities of terminal care and death. A study on practices of pediatric oncologists regarding terminal care revealed a lack of confidence in dealing with various core issues. In the absence of formal training, they relied on a trial and error learning method with inputs from senior role models. The acknowledgement of impending death was considered a daunting task and many were unsure of the meaning of euthanasia. Hence they chose to maintain a distance so as to be able to discharge their duties in a detached manner. An equal proportions of health personnel report terminal cares as the ‘best’ or ‘worst’ parts of the job.

Similarly, well-designed studies reflect the dissatisfaction of parents with the overall management of such cases. A striking difference was noted between the physician’s perception of the child’s pain and that of the child/parent. Physicians often communicated in vague and confusing language, particularly during the transition from curative to palliative care.
Identified obstacles in terminal care are communication difficulties, unrealistic expectations of parents/family regarding outcome, extreme emotional burden on family for decision making, difficulties in pain assessment and control and impact on care providers. This is further impacted by the prevalent financial and sociocultural influences. There is evidence that many bedside manners (communication and psychological skills) for terminal care can be taught. It is recommended that palliative care be integrated into curative care as early as the prognosis becomes clear. It is not advisable to set it aside till all curative options are exhausted since by such time an opportunity to enhance the quality of life (QoL) is lost.

**CHARACTERISTICS OF TERMINAL ILLNESS**

Terminal illnesses in Pediatric surgical practice may be due to congenital conditions complicated benign illnesses and malignant diseases. The following is a brief characterization of its peculiarities.

**Classification**

Terminal illness in children has been classified into the following broad categories depending on the nature of medicosurgical care required.

*Palliative Care from Time of Diagnosis*

Congenital anomalies and advanced metastatic malignancies that carry a very poor prognosis and a predictably short life expectancy (months/years) are included here. They involve major systemic afflictions that need support for survival like nutrition. For example, in Trisomy 18 (Edward’s syndrome), neonates have considerable feeding and respiratory difficulties and a gastrostomy tube may be placed for feeding.

*Treatment Available, Uncertain Prognosis*

This comprises pediatric malignancies where treatment has reached the stage of trial therapeutic protocols and HIV infections. The life expectancy is not predictable and depends on various factors. Vascular access for chemotherapy/parenteral nutrition and minor procedures for complications of the disease warrant surgical intervention, e.g. abscess drainage in HIV infection.

**Chronic Course with Short Life Expectancy**

Neuromuscular degenerative disorders and congenital metabolic disorders typify the prototype of this group. They exhibit a variable progression of disease to a terminal crippling event resulting in premature death, e.g. meconium ileus with cystic fibrosis. Even if these children survive the neonatal intestinal obstruction and are maintained with pancreatic enzyme supplementation and respiratory care, they succumb to pulmonary compromise by the third decade of life. In their lifetime, they may require surgical attention for intussusception, bronchiectasis, cholecystitis, etc.

**CAMPBELL AND DUFF’S SCHEMA—COST BENEFIT ANALYSIS**

The dilemma to continue or forgo life-sustaining measures in managing critically ill children has ethical, psychosocial and financial implications. Campbell and Duff have proposed a schema, which defines three groups according to prognosis of the illness (Fig. 20.1). With prognosis changing from good to poor, the benefits of treatment decline while the costs increase.

![Fig. 20.1: Scheme defining three groups on the basis of prognosis (abscissa), benefits (horizontal bars) and costs of treatment (vertical bars).](https://mebooksfree.com)
In Group II and III circumstances where the prognosis is poor, benefits of treatment are uncertain, and life sustaining measures personally and economically burdensome, active family involvement is desirable in deciding to provide/limit/forgo further treatment. Decisions are most difficult to make in Group II. Though originally described for neonatal critical care, this scheme exemplifies the problem of cost-benefit in critical care of the terminally ill child.

ETHICAL ISSUES

Numerous moral and ethical dilemmas confront the caretaker and the physician caring for the terminally ill child. Advances in medical technology, increasing cost of health care and free access to medical literature has moved the conventional patient-physician toward a consumerist focus. Despite this development, the following ethical principles are to be adhered to in resolving issues concerning disclosure, informed consent, shift of treatment to palliative care, etc.

- Autonomy – right to self-determination
- Beneficence – duty to do good and avoid harm
- Nonmaleficence – duty not to harm
- Fidelity – making and keeping promises
- Justice – fairness
- Veracity – truth telling and integrity.

The child rights need to be remembered at every stage. These include the right not to endure ineffective therapy, not to have a poor quality of life extended artificially, to have access to palliative interventions and to have the terminal goals met.

Another practical concern is the rationing of resources. Rationing is of two types. The first involves a greater efficiency in the delivery of care. The care that is less expensive, yet as effective as the more costly care is chosen. The second involves refusal of needed and wanted care because of unaffordable expense. All rationing decisions including those involving costly extraordinary measures to preserve life in the face of significant risk of death or severe debility are governed by the ethical principles outlined earlier.

Despite the primary obligation to sustain life, situations arise where medical interventions no longer prove to be in the patient’s best interests. In such cases, the decision to shift the goal of management from curative to palliative intent is reached after repeated consultations with the family and inputs from ancillary-quarters, e.g. ethical committee, religious personnel, etc. This does not mean withdrawal of care or decrease in concern and is distinct from euthanasia or intentional termination of life.

The fine balance between physician responsibility to inflict no harm (non-maleficence), do good (beneficence) and respect for the patient’s wishes (autonomy) may occasionally be impossible, e.g. the decision to withdraw life support systems. When the physician is not satisfied with the decision, he may withdraw from the case/handover the case to an alternative physician or seek medicolegal assistance.

The birth of a child is the beginning of life and modern society expects children to outlive their parents. The death of a child is met with resistance and the impact ripples across generations. It is important that events surrounding death are dealt with diligently, lovingly and humanely with utmost consideration for the overall well being of the dying child, the parents, siblings, extended family, community and care providers. The terminal phase is remembered and choices made are reviewed many a times in the minds of bereaved parents.

HASTENING DEATH

Euthanasia is the intentional termination of life and is commonly referred to as ‘physician assisted suicide’. Much of the available literature refers to the adult population; the dynamics in pediatric practice could be more complex. When a child/adolescent requests euthanasia, the health care team should respond with a renewed focus on holistic palliative care. With the provision of adequate analgesia and sedation for the treatment of rapidly progressive symptoms, requests to hasten death are generally abandoned. Although the topic lends itself to personal interpretation, national regulatory bodies such as the AAP do not support the practice of Physician assisted suicide or euthanasia in children.

Sometimes, medications provided for the relief of suffering may through a foreseeable, unintended consequence hasten death. This ‘rule of double effect’ has been generally accepted. This rule justifies the liberal use of opioids and sedatives to alleviate symptoms and suffering in terminal illness and is distinct from euthanasia.
PATTERNS OF DEATH

The pattern of death in terminally sick child may be broadly characterized as –

a. Brain death – where clinical and investigative tests confirm brain death and the patient is ‘alive’ on life support systems such as ventilation/ ionotropes.

b. Failed cardiopulmonary resuscitation – where death occurs after failure of the normal resuscitative attempts in the face of a cardiopulmonary arrest consequent to the primary disease.

c. Death following a Do Not resuscitate order – as in ‘b’, but no resuscitation is attempted in the presence of the order.

d. Death following a withholding/withdrawal of therapy – death follows partial/complete restriction of life sustaining measures.

The proportion of cases in each category depends on various factors.

PALLIATIVE CARE

‘Palliative care’ is defined as comprehensive, interdisciplinary care of patients and families facing a terminal illness, focussing primarily on comfort and support. It affirms life and seeks to enhance the quality of life (QoL) in the face of an ultimately terminal condition. Palliative care begins with the diagnosis of a life-threatening disease and continues regardless of whether the child is receiving curative treatment for the primary disease.

It implies active total care of the child’s body, mind and spirit as well as support for the child’s family. The family get time and space to begin the process of anticipatory grieving. The goal is to add life to the child’s years and not simply years to the child’s life.

The key principles of palliative care are –

1. Respect for the wishes, preferences and dignity of the patient and family.
2. Compassionate, coordinated competent health care at the hospital/home/extended care facilities/daycare centers, etc.
3. Personalized care aiming at maximizing patient determined quality of life.
4. Family centered care that extends through bereavement time to ensure that the family unit remains functionally intact.
5. Meticulous symptom control.
6. Improved professional and social support-regulatory, educational, insurance, etc.
7. Psychosocial and spiritual care.
8. Caregiver support.
9. Continuing research and education of involved personnel.

Hospice Care

This embodies a philosophy and attitude that aims at maximizing the quality of life of the child, family and caregivers. It is a holistic approach incorporating inputs from psychological, social and spiritual angles. The personnel involved include the primary physician/surgeon, child psychiatrist, child psychologist, social worker, nutritionist, religious personnel and volunteers. Palliative care is not reserved for hospices, but can be provided in hospitals, community health centers and in the child’s home.

Home Care

The home is the most appropriate place for the child and least disrupts the family life. Considerations include the child’s desire to be at home, parental commitment to have the child at home, sibling perspectives and the health care team’s willingness to participate in home care. Besides lower costs and individualized parental attention, it is a source of pride and accomplishment for the family.

The medical team (nurse, doctor, psychologist, etc) act as facilitators and assure the family of advice and support at all times. Even trial drugs and experimental therapies may continue in the home setting. The facilitators help in the procurement of drugs not available over the counter, particularly narcotics. They provide instructions on the procedures to be followed in the event of death. Families are encouraged to care at home till the time of death though the option to return to hospital always exists.

However, home care cannot be adopted in all families. Some parents and children feel safer in the hospital or the family circumstances may not be conducive to optimal home care. Many misconceptions (belief that hospitalization for terminal illness is the best, confusion about the appropriate time for home/hospice care) and logistic difficulties (lack of physician support/resource personnel for this care,
family conditions such as single parent, poverty, unstable family structure) restrict the adoption of home/hospice care.

**Respite Care**

This is the provision of care to an ill child by qualified caregivers other than the family members to allow the family time to rest and renew. It may be offered at anytime in the course of the illness for varying time periods.

**COMPONENTS OF PALLIATIVE CARE**

**Procedural Aspects**

These attain enhanced significance in the light of delicate ethical and psychosocial issues involved. Some of these routine *formalities* which pose practical problems in care of the terminally ill are discussed.

**Disclosure**

A suitable time and place is chosen to make an honest attempt at disclosure about the child’s condition to the family and, if appropriate, the child. Compassionate communication, sensitive discussion and thorough attempts to support the family facilitates acceptance. Miscommunication and misinterpretation can foster anger, isolation and abandonment in the family. Delicate issues such as termination of treatment, resuscitation, Do Not resuscitate orders and autopsy should not be designated to junior personnel. Active participation of the family is sought on pain and comfort management.

**Talking to a Child about Death**

Adults, physician and parents alike, have preconceptions that children are incapable of understanding death. Although they may not overtly express it, awareness of death develops over time. Since there exists a general pervasiveness of death themes in children games, media exposures and daily experiences, the idea is certainly not alien to children. By the age of 3 years, a child is aware of death. At 5 years, they are increasingly curious and by 6-10 years they view death as irreversible, final and a personal experience. By 10-12 years their concept and comprehension of death is similar to adults, though variations occur. The adult concept of death is universal (happening to everyone), irreversible (impossible to change) and permanent (for all time). Children attain this concept through a process more dependent on developmental level rather than chronological age.

An assessment of the child’s developmental level and the family’s communication pattern is necessary before attempts at broaching the subject. Over-protection, lying, covering up or evading the issue does not make his life easier. It is useful to take clues from the child and respond accordingly. Guidelines in discussing death with children include physician conviction about the need to do so, involvement of the family member, and use of non-verbal/symbolic communication such as play, drama, art, stories and schoolwork. There has to be a willingness to respond to that occasional question ‘Am I dying?’ with such questions, children are only seeking emotional support and companionship; they are forgiving of faltering adults if they care to communicate.

**Decision Making**

This is crucial at every stage of management and must involve the entire treating team, the family and in select circumstances the sick child. The child should participate to the fullest extent possible depending on his illness experience, developmental status and level of consciousness.

The factors that are evaluated prior to any form of therapy include nature of the indication, cost-benefit analysis, surgical and anesthetic risks, overall prognosis and informed consent. Individually, each is a difficult assessment and all decisions are made after thorough discussions with the parents. A multidisciplinary approach with a significant time commitment by team members is needed. Such counseling time and place must be consciously scheduled amidst busy mainstream pediatric practice. Impromptu, fleeting conversations cannot address these issues comprehensively.

**Consent**

Conventionally, a child is not legally competent to decide on his/her medical care. The law of the land determines such competence. In a child who is legally not competent, the parent/legal guardian acts in the
Management of Terminal Illnesses

best interest of the child. This proxy decision maker is termed “surrogate”. However, the medical fraternity respects the involvement of the child in the decision making process (autonomy) depending on the child’s comprehension and maturity. Adolescents, who have decision-making capacity, are considered separately.

Informed consent implies respect for patient autonomy and right to decide where possible. There are two situations where a child can give informed consent. Firstly, when he/she is an emancipated minor (self-supporting, married, pregnant or a parent, member of military, declared by court) or secondly when the child is a mature minor, capable of making decisions for self or seeking treatment for specific health care concerns such as venereal diseases or drug abuse.

DNR (Do Not Resuscitate) Order

A DNR order is written by the primary physician in children with terminal conditions after extensive discussions with the surrogate decision-maker. This prevents resuscitation of the child in the event of a cardiopulmonary arrest. It is formulated in the best interests of the child on the assumption that a cardiopulmonary arrest will be a spontaneous event in the dying process and not of iatrogenic origin.

DNR orders are not empirically reversed as such a step disregards patient autonomy/surrogate decision making. In certain special situations such as anesthesia, DNR orders may need specific modifications or temporary suspension. These are based on cure and comfort care policies and are individualized. Such ‘required reconsideration’ of DNR orders are instituted after the family discuss the options preoperatively with the surgical team. Two such modified orders are ‘goal directed DNR orders’ and ‘procedure specific DNR orders’. A goal directed DNR order is based on the physician’s intimate knowledge of the patient and allows for resuscitative measures to achieve the child’s/family’s goal. It honors the child’s/family’s wishes but also provides the medical staff with management flexibility. The major limitation of this order is the reliance on physician’s intimate knowledge of the patient and interference of his personal feelings. In contrast, procedure specific DNR orders provide clear and strict guidelines for the performance of specific resuscitative measures (e.g. ionotropic support) as per the child’s/family’s wishes. It limits the scope of resuscitative measures irrespective of the cause of arrest or potential for reversal.

PAIN RELIEF

Pain (Greek-‘poine’) means punishment and the immature mind may wrongly blame himself for the pain. Mc Caffney writes-‘Pain is whatever the experiencing person says it is and exist wherever he says it does’. Children do experience and remember pain.

The pain may be from the disease or from diagnostic/monitoring procedures or therapy. Psychological variables should not be blamed where physical causes have not been exhaustively addressed. Individual perceptual variation, lower verbal fluency and changing development add to the complexities of pain assessment. Insufficient knowledge of pharmacology of analgesics, irrational fear of overmedication, difficulties in pain assessment and evaluation has resulted in undermedication.

“The quality of mercy is essential to the practice of medicine”— Angell. The vulnerability, powerlessness and dehumanization that accompany pain must be controlled. The goal of pain management is to keep the patient pain free and as alert as possible to enjoy precious time. There is no one way of pain management and frequent evaluation of drug choice, dosage and frequency is warranted till the child is pain free.

Effective pain relief facilitates earlier mobilization, shortened hospitalized stay and reduced costs.

Pain Assessment

Three primary components of pain assessment are cognitive (self-report), behavioral manifestations and psychological responses.

Cognition and evaluation of pain is influenced by multiple factors such as the meaning of pain to the individual, prior experience with pain, expectation of the painful experience and cultural attitudes. The expression of pain may take on several forms—vocalization, verbal statements, facial expressions and body posture and the manner in which the child interacts with the environment. All children do not overtly express their pain and unlike adults, self-report
can vary greatly in children. Depending on the age and developmental level, various formal assessment tools are used to quantify the cognitive component of pain. Self-report for the 4-7 years group and Wong and Becker’s Faces Pain Rating Scale (WBPRS) for > 7 years children are illustrative examples. The POPMP (postoperative pain measure for parents) is a simple pain assessment tool for parents in home care.

Behavioral responses like ‘projecting’ the pain onto dolls/drawings, restlessness, sleeping, irritability and poor quality/destructive activity/play in the young child signify unrelieved pain and pain coping mechanisms. FLACC scale the Toddler-Preschooler Postoperative Pain Scale (TPPPS) for the preverbal/nonverbal children are behavioral assessment tools. However, one must be cautioned to interpret behaviors cautiously. Behaviors such as playing, sleeping or even watching television may be strategies that the child uses for coping with pain. Pain behaviors are also obscured in the child with continued severe pain or in situations such as depression, fatigue, extreme illness, and the use of sedatives or hypnotics.

Physiological signs such as sweating palms, tachypnea and tachycardia can be used as adjuncts to self-reports and behavioral observation measure but they are neither sensitive nor specific as indicators of pain. Despite all these measures when one is unsure and there is reason to suspect pain, a diagnostic trial of analgesics is strongly recommended.

**Treatment Modalities**

**Cognitive behavioral techniques:** These are taught during the pain free interval and guide the child to a better sense of control. For example, passive relaxation with mental imagery, cognitive distraction/focussing, music therapy, hypnosis, deep breathing, progressive muscle relaxation. Cognitive behavioral techniques are used in conjunction with pharmacotherapy for optimal pain relief.

**Physical methods:** Like holding, rocking, massaging, position change and TENS (transcutaneous electrical nerve stimulation) all increase the child’s comfort. Activities like playing/watching TV may distract from pain. Parents are a source of help in the event of pain. They are termed as extremely powerful analgesic agents.

- Pethidine is not recommended for chronic use because of its long half-life and cumulative toxicity of metabolite.
- For > 50 kg children, normal adult doses are advised.

**Pharmacologic methods:** The World Health Organization’s three-step ladder of analgesia is applicable to children. Non-opioid analgesic for mild pain (e.g. Paracetamol), weak opioids for moderate pain (e.g. Codeine) and strong opioids for severe pain (e.g. Morphine sulfate) forms the standard steps. NSAIDs and opioids are commonly employed. They are administered around the clock (ATC) based on the duration of action and are supplemented by additional breakthrough/rescue dose in between. An “as needed basis” is often suboptimal and associated with under medication. Analgesics are administered prophylactically before chest physiotherapy, suctioning and other potentially painful procedures. Additional local anesthesia decreases the dose of analgesics during invasive procedures. It is useful to consult the pain clinic personnel when needed. Table 20.1 summarizes dosages and routes of administration of analgesics in common use.

Paracetamol has been conventionally used in subtherapeutic doses (10 mg/kg). An initial loading dose of 30 mg/kg and a ceiling dose of 90 mg/kg/
day is currently accepted. Doses above 150 mg/kg/day cause liver toxicity. Paracetamol-codeine combination is superior to paracetamol alone. Bleeding is of particular concern in the cancer patient on NSAIDs. Non-opioid analgesics have a ‘ceiling effect’ whereby increasing the dose beyond the recommended therapeutic level has little additional analgesia but a significant increase in side effects and toxicity.

Opioids are used in severe pain. Dosages are calculated using 0.1 mg/kg dose of morphine sulfate as standard. These are dosages to begin with and except codeine, increasing doses of opioids provide increased analgesia. There is no ceiling effect with opioid analgesics. Therefore, unless adverse drug reactions are observed, the opioid dose may be increased till adequate pain relief is obtained.

Drug administration should be by the simplest, most effective and the least painful route. If oral intake is not preferred, intermittent parenteral route is used. An indwelling central venous line is useful and precludes patient discomfort and fear of needles. A continuous infusion gives consistent therapeutic blood levels. Bolus or as needed infusions may be used. Multimodal analgesic regimens, long acting oral formulations, transdermal delivery systems and patient controlled analgesia are newer patient and physician friendly management options. Such medication can be instituted in home care too.

The physician and family must note the difference between dependence/tolerance and addiction. Physical dependence is the physiological need for a substance in order to function; characterized by signs and symptoms of withdrawal if the body is suddenly deprived of the narcotic. Tolerance is habituation to a substance such that larger doses of the narcotic are required to attain the original level of effectiveness. Addiction is a psychological and/or physiological dependence on a narcotic, characterized by an intense craving for the drug and an overwhelming involvement in obtaining it and using it for purposes other than pain relief. Addiction never occurs unless drug abuse was present prior to the onset of disease. Paradoxical fears of addiction (opiophobia) lead to under medication. It must be clarified to parents that increasing dosages of narcotics to achieve pain control does not necessarily mean worsening disease.

Side effects of opioids need careful control. Constipation is managed with dietary changes, laxatives and enemas. Vomiting and itching are occasionally seen and rarely need specific therapy. Respiratory depression with standard opioid doses is a problem in the infant. In mild depression, doses are to be withheld/reduced and the child stimulated to breathe. In severe depression, airway support, oxygen and reversal with carefully titrated opioid antagonist (Naloxone) are required.

The analgesics may be combined with adjuvants in pain management. These include:

- Tricyclic antidepressants (e.g. imipramine), anticonvulsants (e.g. carbamazepine, gabapentin) and systemically administered local anesthetics (oral mexiletine, parenteral lignocaine) in refractory neuropathic pain.
- Psychostimulants to counteract the sedative effects of opioids (e.g. dexamphetamine, methylphenidate)
- Biphosphonates and radioisotopes (e.g. strontium-89) in pain associated with bony metastases.
- Medications to relieve muscle spasm (e.g. benzodiazepines and baclofen) in neuro-degenerative disorders.
- Local anesthetics-topical local anesthetic, e.g. Emla cream(lignocaine and prilocaine) to reduce pain from peripheral venous cannulation, etc.
- Other pain relieving procedures such as nerve blocks and spinal(epidural, intrathecal) analgesia
- Corticosteroids are useful initially but the long-term side effects outweigh it’s benefits.

**SYMPTOM CONTROL**

Assessing symptoms involves discussion with the child, review of parental reports and formal assessment tools. This is relatively difficult for preverbal and developmentally challenged children.

Dealing with symptoms is challenging, more so if home care is instituted. A delicate balance is struck between preparing a family to recognize problems and arousing unfounded fears. Keeping calm, initiating specific first aid measures and contacting the hospital staff for advice is stressed. In certain instances, the patient may need to be shifted to hospital for therapy.

Children find it difficult to take large number/amounts of drugs and complicated regimens are not feasible to implement. A careful choice between the various routes (oral/rectal/transdermal/subcutaneous/intramuscular/intravenous) and formulations (tablet/capsules/crushed tablets/liquid mixtures/
long acting formulations) is made to suit patient and physician acceptability. Constipation, diarrhea, fatigue, pain, dyspnea and poor appetite are commonly reported problems. Symptoms of treatment related complications cause more suffering and are less alleviated than those did attributable to progressive disease.

Anxiety and Delirium

This is commonly seen and gets exacerbated with events such as external bleeding, seizures and dyspnea. It reflects the child’s needs to express his/her fears and distress. Benzodiazepines and haloperidol provide relief in the final stages of life. Neuroleptics such as haloperidol and chlorpromazine improve the thinking in both agitated/delirious and confused/tranquil patients.

Depression

Common in terminal illness, it is under recognized and under treated. Physicians must assess patients for depressive signs (e.g. late night sleeplessness that is not due to pain) that cannot be attributed to the primary illness. It has a biological basis and is treated with psychostimulants such as dexamphetamine or methylphenidate which have a rapid onset of action.

Fatigue

A common symptom in cancer patients, physicians often pay little attention to this. Causes include progression of disease, anemia, poor nutritional status and depression.

Feeding

Sucking and eating are part of the normal development of a child and provide comfort, pleasure and stimulation. Children with brain tumors or neurodegenerative disorders will require assisted feeding with a nasogastric tube or gastrostomy.

Anorexia

Since appetite is equated with good health, anorexia is disturbing. The anxiety during eating is eased by helping the family accept the child’s natural loss of appetite. Small frequent feeding of the child’s favorite food with modifications to increase their nutritional and caloric value yields better results. Progestational agents, such as megestrol acetate, and glucocorticoids improve anorexia.

Nausea and Vomiting

They are often exhausting. Anti-emetics (prokinetics, serotonin antagonists) are selected according to their site of action and probable cause of nausea (Table 20.2). Oral/parenteral/rectal routes are used as appropriate. Careful hydration is essential with frequent emesis.

Constipation

Inactivity and high doses of narcotics lead to constipation. Increasing fiber and bulk in the diet and use of stool softeners are useful. An oral, poorly absorbed opioid antagonist, such as naloxone, is useful in opioid associated constipation when the above measures fail.

Fever

In neutropenic patients, fever heralds potentially life threatening complications. Besides sponging with tepid water and antipyretics, sensitivity based antibiotics are indicated. The desire to treat vigorously is dictated by the family’s wishes.

Dyspnea

Nebulization/steam inhalation, provision of humidification/O₂ can reduce the distress. Benzodiazepines are used in extreme anxiety. Oropharyngeal suctioning must be ‘gentle’ especially inpatients with thrombocytopenia.

Bleeding

Visible external bleeding is most frightening to the family. External bleeds are managed with packs, topical agents (thrombin, gelatin sponge) and blood product transfusion as indicated.

Convulsions

Protection of the child’s body and head during a convulsion is essential. Rectal diazepam and subcutaneous midazolam are useful at home in emergencies. Readjustment of anti-convulsant dosage as the disease progresses and relief of increased intracranial pressure (brain tumors) with medication/shunts may be required.

SURGICAL CARE

A number of surgical procedures, minor and major, are likely to be performed on terminally ill children. The procedure may be palliative/elective or both.7 Palliative procedures aim at patient comfort and improved quality of life, e.g. gastrostomy and tracheostomy in a neurologically impaired child. Elective procedures aim at limiting/curing an unrelated associated condition (not considered to be a usual terminal event) with the aim of prolonging life, e.g. surgery for an obstructed inguinal hernia in a child with Stage 4 neuroblastoma. The distinction is often blurred and different members of the treating team may disagree on the scope of each. This is more so when the prognosis is unknown or questionable.

ANESTHETIC CARE

Anesthetic care is as demanding as surgical care for the terminally ill. A compromise between hemodynamic stability and optimal anesthesia is often elusive. Generally low risk strategies such as regional anesthesia or monitored anesthesia care (MAC) is preferred where possible. However, general anesthesia may be required in certain circumstances. Anesthetic care may be individualized according to the underlying disease, pathophysiologic state and risk-benefit analysis. A compromised pulmonary status and consequent risk of pulmonary failure is the prime concern.

Existing DNR orders will need reconsideration. During anesthesia, hemodynamic instability may lead to cardiopulmonary arrest and measures to reverse the same should not be withheld in the presence of a DNR order. In fact a blanket DNR order encourages the use of anesthetic options with inferior patient comfort.

PSYCHOSOCIAL SUPPORT

The commonly heard statement ‘There’s nothing more we can do for the child’ is out of place and much can be done even for a dying child. Hope needs to be fostered in the child and the family. The hope for happy times with the family— an important conversation, a good meal, a game while the family could see the child comfortable and free of pain is the essence of palliative care.8

The process of preparing a child/parents for survivorship/death begins when they learn the diagnosis. A degree of emotional distancing is needed to facilitate anticipatory grieving. Early introduction of intervention programs positively affects later adjustment. Liaisons with schools and community resources and certain flexibility in professional approach ease the work. Knowledge of the child and the family’s beliefs about life and death and sources of emotional support helps in providing psychological support. Such an approach is central to the concept of palliative care.

Bereavement is a state of loss of a significant other through death or as a process that individuals must work through or recover from. Grieving is the emotional response to bereavement. Grief is a dynamic process; a continuum that begins at the point of diagnosis of the terminal illness. The situation elicits stressful behavior from all quarters—the patient, the siblings, parents and physicians. The responsibility of the bereaved families should not be overlooked after the death of the child. The family will often feel the need to discuss/clarify thoughts and notions during the process of bereavement. Providing compassionate knowledgeable information during this period is crucial. An introduction to bereavement intervention programs involving self-help groups, religious establishments, etc. is useful.

Patient

The responses are primarily dependent on the developmental level with the adolescent reacting quite
differently from the toddler. The infant and preschooler are entirely dependent on the parents and the immediate family and have not established a relationship beyond this insular environment. The majority have little/no fun, are sad, afraid and not calm or restful. One needs to decipher symbolic communication in many instances. At every step, an effort is made to involve personal artifacts of the child/family and personalize the care.

Adolescence is a transition from childhood to adulthood and the dying adolescent is acutely aware of the reality of losing everything suddenly. Marked physical deterioration imparts a wasted child like appearance; however, intellectual maturity and adult like insight leads to significant depression in the terminally ill. Signs of depression (e.g. sadness, irritability, multiple aches, deranged sleep patterns) may overlap with symptoms of the illness and are easily missed. Frequent hospitalization, school absenteeism, social isolation from peers, parental overprotection and parental dependence throttles the emerging independence of adolescence. Most adolescents are aware of the impending death and raise issues that are realistic and not existential. Their queries are directed to members of the healing team they perceive as ‘competent’ to answer. Inappropriate efforts to hide the knowledge from them are counterproductive. The young have less tolerance to pain and identify deficiencies in pain control.

These issues can be managed by encouraging normal adolescent activities (school participation, education, peer interaction), frank communication (expression of fear/anxiety, essential information about care and prognosis, encouraging questions), ‘permission giving atmosphere’, ensure patient confidentiality and adequate pain control (patient controlled analgesia), desires and wishes. Sick children need the opportunity to pursue their interests and have short-term goals for as long as possible.

**Parental Grief**

When a child is diagnosed to have a terminal condition, the family undergoes a myriad of changes. Parents initially react with disbelief, anguish, and despair and feel loss of control not only over their lives but also of their child’s life. Anxiety, fright and a sense of uncertainty loom large. Parental grief is severe, long lasting and manifests itself with a multitude of psychological (e.g. shock, numbness, apathy, anger, etc) and physical reactions (e.g. lethargy, weight loss or gain, crying spells, etc.). The degree of parental grief varies with the age of the child at the time of death and the attachment bonds between the deceased and the bereaved. A change in parental relationships is inevitable with the death of an offspring. Interparental relationship, change in family structure and concerns about surviving children influence parental grief.

Intervention for bereaved parents include helping them to accept the reality of their loss, facilitate the expression and interpretation of feelings and assistance in finding resources for continuing support. Providing parents with complete and honest information about the child’s condition is essential to anticipatory grieving. Clarity and accuracy should substitute for euphemisms. Dysfunctional and persistent denial states may be challenged. Silent presence, empathy and personal use of the self are the need. Parents should be assisted in dealing with sibling concerns. The families of children with an inherited condition have additional problems of guilt and blame; they need genetic counseling and information regarding prenatal diagnosis in the future.

**Sibling Grief**

The sibling may feel confused, ignored, betrayed or isolated. Other behaviors observed include acting like the deceased, psychosomatic illness, regression and depression. An adolescent sibling is developmentally more unstable and vulnerable. Factors influencing sibling grief are sudden death, developmental age, pre-existing psychological difficulties, family-community support systems and disruption of routine.

Facilitating anticipatory grieving with parental support, sibling participation in care of the sick child and receiving consistent information all along can alleviate sibling grief. Home care is more suited to these tasks.

**Caregiver Grief**

Attending physicians tend to perceive the terminal illness and death of their patient as a personal failure and an affront to one’s abilities to preserve life. It reminds us of our limitations and vulnerability.
Physicians and nurses may blame themselves overtly or covertly for the death. Each caregiver has to introspect and come to term with his/her personal pain and sentiments. They may experience a grief similar to that with the death of a loved one; the extent of such a reaction is proportional to the degree of their involvement in the care of the patient.

This is often ignored and needs to be tackled. Taking personal care is an obligation to oneself and the patients. The physician should know his limitations and reach for help when needed. This is influenced by an individual’s stage of personal and professional development. Overinvolvement/underinvolvement are defined with years of experience and introspection and a continuing review of one’s personal philosophy.

INTERVENTIONS AROUND A CHILD’S DEATH

This is a sensitive phase and is of critical importance. It must be ensured that the child dies with the parents/loved ones in attendance. At this moment it is necessary to guard against protecting the parent and allow them to ‘parent their child’. If the child dies alone, the staff should take the family aside and relate the events surrounding the death.

Focus on Religious Beliefs of the Family

Health care professionals are faced with varied cultural and religious beliefs of families during the terminal phase of their child’s life. It is necessary to enquire about these beliefs and restrictions and prepare to offer whatever possible in the event of death. Illustrative examples are presented below.

Hinduism

- A devout Hindu receives solace from hymns/readings from the Bhagavad Gita
- A desire for performance of a holy rite such as sprinkling of sacred water from the Ganges over the person.

Islam

- The dying patient may wish to sit or face Mecca
- The body is considered a belonging of God; so postmortems/organ transplants are prohibited unless legally binding.

Sikhism

- Special regards should be given to the special K’s (Kesh- unshorn hair; Kara- iron wrist band; Kirpan-a short sword; Kanga- wooden comb). The hair is covered, the body is straightened and covered with a white shroud with a religious emblem.
- Newborns and still births are buried while others are cremated, preferably within 24 hours.

Catholicism

- Baptism of great significance before and even at death
- The sacraments are given great importance – sacraments of the sick is a symbol of Christ’s healing.

Free churches and other significant Protestant churches:

- Visit from leaders of community is an essentiality.

Zoroastrianism (Parsees)

- Last rites include thorough cleansing of the body, covering it with a cloth (sadra) and a sacred kusti, covering the head with a cap/scarf
- Burial/removal/disposal of body by water is considered inappropriate, instead they have bodies placed in the tower of silence.

Jehovah’s Witness

- Postmortem, body/organ donation is based on individual’s desire. They are strictly against blood transfusions.

Time should be provided for the family to grieve over the child’s body in private and as they wish. Allow the family to talk about their feelings and to cry. There is no right way to react—extreme shock; anger, withdrawal and denial are all ways of expressing grief. Denial is a form of emotional protection, which disappears once the individual is ready to accept.

It is necessary to acknowledge parental grief and say ‘I’m sorry’. It only exhibits the concern health professionals have for such families. Avoid unthinking comments or inadvertently blaming anything/anyone for the death. Recount the positive aspects of the child’s life and discuss sibling needs, participation and bereavement. The parents could be offered limited bereavement time with the health personnel who were...
intimately involved with the child during the follow-up.

**POSTDEATH INTERVENTIONS**

These are aimed at facilitating grieving and preventing dysfunctional consequences of bereavement. Areas of continuing misunderstandings are clarified, questions answered and preventive bereavement counseling provided. They include:

- Self-help programs
- Person to person contact with another bereaved individual/group
- Referral to a mental health professional

Most families do not need specialist counseling but general support and reassurance from those who know the family and the illness.

**REFERENCES**

Trauma is the principle cause of death in children aged 1-14 years in the developed world.\(^1\) Its management has improved considerably over the past 30 years; whilst there will always be some injuries incompatible with life, effective early institution of care can significantly reduce morbidity and mortality.\(^2\)

In 1979, Cowley defined the ‘Golden Hour’, the first hour following traumatic injury, as being critical for treatment to ensure optimal care for patients.\(^3\) Subsequently, common systematic approaches to injury assessment and management have been developed (Advanced Trauma Life Support/Advanced Pediatric Life Support) which begin treatment of life threatening injuries or problems as soon as they are detected.\(^4,5\) Knowledge, experience, rehearsal, and practical experience of the procedures involved makes for a smooth effective delivery of care in an otherwise stressful time for doctor, nurse and the patient.

Motor vehicle accidents, pedestrian accidents, falls, bicycle accidents and child abuse are the most common causes of injury in children. Non-accidental injury (NAI) is particularly important in children under 1 year of age.\(^1\) Transmitted energy during injury delivers more force per unit volume resulting in multisystem injuries in children.

We aim to give an informative background explanation of areas specific to pediatric trauma, followed by a revision of the treatment protocols.

Many aspects of the initial resuscitation of children depend on the child’s weight.\(^6,7\) This is not always easy to estimate or practical to measure in the emergency situation, hence the development of the Broselow Pediatric Resuscitation Measuring Tape (Fig. 21.1) which relates height to weight, and gives fluid and drug doses appropriate for the size of the child.\(^8,9\) In addition, if the age of the child is known, the following formula can be used to derive an estimate of weight:\(^5\)

\[
\text{Weight (kg)} = 2 \times (\text{Age} + 4)
\]

**ANATOMICAL AND PHYSIOLOGICAL DIFFERENCES IN CHILDREN**

The anatomy and physiology of children differs significantly from that of adults. It is vital to have a sound appreciation of these differences because they alter the types of injury sustained and permits prediction of outcome. Body proportions, structures and normal physiological parameters change with age.

**Head**

Children have a large head to body size ratio, which needs to be considered, in relation to heat loss, and surface area of burns patients. The head is 19% of surface area at birth, reducing to 9% at the age of 16 years.

The size of the head also affects safe positioning of the unconscious child. If a child lies on a flat surface the large size of the occiput relative to the chest causes a flexion of the neck potentially compromising the airway.\(^10\) The airway is best protected with the midface moved anteriorly and superiorly (the ‘sniffing position’). A child’s trunk can also be supported on a raised pad to avoid this happening. However, the neck must not be over extended as the trachea is short and soft, and over-extension of the neck may result in tracheal compression. The relatively large size of the head also puts children at greater risk of head and high cervical spine injuries.
Upper Airway

Infants less than 6 months are obligate nasal breathers. The face and mandible are small leading to a small oral cavity, whilst the tongue is large tending to obstruct the airway in the unconscious child. The tongue may also obscure the glottis during intubation. The floor of the mouth is easily compressed by extrinsic pressure, so a mask being used on the face needs to be held carefully.

Narrow airways are often obstructed by mucus, loose teeth are at risk of being lost into the bronchial tree, and adenotonsillar hypertrophy is frequently present between 3-8 years, adding to the difficulties of securing the airway.

The epiglottis is more U-shaped in the child, projecting posteriorly at 45 degrees. The larynx is cephalad and anterior at the level C2-3 in the infant, as compared with C5-6 in the adult. It is therefore easier to intubate children younger than 12 months with a straight bladed laryngoscope. The narrowest point of the upper airway is the cricoid ring, which is lined with pseudostratified ciliated epithelium, which is prone to edema if cuffed tubes are used for intubation. Uncuffed tubes are used for all children who have yet to reach puberty, and the sizing of the tube should allow a small leak of gas past the tube during inflation of the lungs.

The trachea is short, in neonates 4-5 cm and in infants 7-8 cm; therefore tubes can easily become displaced accidentally or during transport, entering the relatively straight right main bronchus.

Neck

In children, the interspinous ligaments and joint capsules are more flexible; the vertebral bodies are wedged anteriorly, so tend to slide forward with flexion and the vertebral facet joints are flat. Cervical spine radiographs in children can cause some concern due to normal physiological appearances mimicking fracture or dislocation. It is important to correlate clinical examination and radiological findings. It is unusual to find a fracture without physical signs.
Pseudosubluxation (anterior displacement C2 on C3 or sometimes C3 on C4) is a common finding in approximately 40% of children less than 7 years old and up to 20% of children up to 16 years. There is normally more than 3 mm of movement when the joint is studied in flexion/extension. To differentiate pseudosubluxation from cervical spine injury, the flexion of the spine needs to be removed by positioning the head in a neutral position, bringing the head forward to a ‘sniffing position’.

Skeletal growth centers can also be confused with fractures. The basal odontoid synchondrosis has a radiolucent area at the base of the dens in children less than 5 years, whilst the tip of the odontoid epiphyses appears separate in children age 5-11 years. The growth center of the spinous process can itself be mistaken for a fracture.

Spinal injuries in children are rare but can occur; most affect the cervical spine. Spinal cord injury without radiological abnormality (SCIWORA) occurs almost exclusively in children < 8 years old. SCIWORA mainly affects the cervical spine and to a lesser extent the thoracic spine (the upper cervical spine is more susceptible due to its increased mobility). Seriously injured children should be immobilised until full neurological assessment is possible. Magnetic resonance imaging (MRI) may have to be used.

**Cardiovascular**

The young cardiovascular system has an increased physiological reserve compared to adults and able to tolerate significant blood loss without obvious outward distress. As a consequence, there may only be subtle signs of severe shock. Early assessment and recognition of shock is essential to the appropriate management of the injured child. Tachycardia and reduced capillary refill are frequently the only signs available. It is important to note that the normal physiological parameters vary with age (Table 21.1). Anxiety and pain in the injured child can confound tachycardia as a sign of shock.

The child’s heart has a limited capacity to increase stroke volume, so cardiac output is mostly dependant on heart rate. With a typical blood volume of 80 ml/kg, an amount of blood, which would otherwise be considered a minor blood loss in an adult could severely compromise a child.

The child initially responds to reductions in intravascular volume by increased heart rate and vasoconstriction, thereby maintaining cardiac output. Thus, shock in a child is difficult to recognise below 25% volume loss, but may be suggested by a weak thready pulse, increased heart rate, lethargy and irritability, and cool clammy skin. There would be a slight reduction in urine output if measured.

As volume loss approaches 25-45% the heart rate remains raised, but there is a definite reduction in consciousness and a dulled response to pain. The skin becomes cyanotic, with reduced capillary refill time (CRT) and the extremities become cold. If measured there would be minimal urine output.

Finally above 45% volume loss the child can no longer compensate and there is a point at which the child becomes hypotensive and bradycardiac, and the child is comatose. These are late signs and signify a grave situation.

An idea of a child’s normal parameters is required. As an approximate guide:

- Systolic Blood Pressure (mm Hg) = 80 + (Age in years × 2)
- Blood volume (ml) = 80 × Weight (kg)

**Thermoregulation**

With a large surface area to body mass ratio and a relative lack of adipose tissue children cool down rapidly in a cold environment. This may affect their conscious level, hemostasis through deranged clotting and reduce their response to treatment.

Every effort should be made to reduce exposure and keep the child warm and comfortable, without compromising safe resuscitation, primary and secondary surveys. The patient should be kept warm...
with heaters, thermal blankets as appropriate, and all intravenous fluids, and preferably, inhaled gases used in treatment should be warmed.

**Compliant Skeleton**

The child’s skeleton is more elastic and compliant compared to that of the adult. As a result, injuries to internal organs may be encountered without external signs of trauma or fracture (e.g. pulmonary contusions without rib fractures).

**Structured Approach to the Seriously Injured Child**

The accepted structured approach has been developed and refined by surgeons in recent decades and is one which all doctors ought to be familiar. Greater detail can be found in the manual of the Advanced Pediatric Life Support group.5

It consists of the following basic sequence:

1. Primary survey
2. Resuscitation
3. Secondary survey
4. Emergency treatment
5. Definitive care.

**HISTORY**

A brief description of the suggested mechanism of injury or the circumstances in which the child was found gives the trauma doctor an idea of what injuries to expect. Children are frequently too distressed to give a coherent story, and relatives are often extremely distressed. The ambulance crew who have been at the site of the accident can usually give a good account.

**PRIMARY SURVEY**

The aim of which is a rapid assessment to identify immediate life threatening problems and prevent secondary injury.

A Airway and cervical spine control
B Breathing
C Circulation and hemorrhage control
D Disability
E Exposure.

**Airway and Cervical Spine Control**

The airway should be assessed to ensure its patency. This is done by looking for chest and/or abdominal movement, listening for breath sounds and feeling for breath.

Cervical spine injury should be assumed present until excluded; the C-spine protected by immobilisation. The airway is optimised by correct positioning of the head relative to the neck using either a head tilt/chin lift or jaw thrust maneuver. The mouth and oropharynx are cleared and oxygen is supplied. If the child is unconscious then an oral airway is inserted under direct vision curving it over the tongue, to prevent trauma to the palate.

If the child is unable to maintain their own airway or has a Glasgow Coma Score (GCS) of 8 or less, or requires assisted ventilation, then the child needs to be intubated with rapid sequence induction. The child should be preoxygenated beforehand as children rapidly desaturate. Prolonged bag and mask ventilation may result in gastric distension which could splint the diaphragm and make abdominal examination difficult. Passage of an orogastric tube may be useful in this situation.

The endotracheal tube (ETT) should be close to the diameter of the little finger or the size of the nares. The following formula can also be utilised to calculate the approximate ETT size:

Endotracheal tube size (mm) = (Age / 4) + 4

An unuffed tube is used which sits in position at the cricoid ring. In children less than 8 - 12 years the glottis is cone shaped and the use of an unuffed tube prevents later subglottic stenosis secondary to intubation.10 Auscultation over the chest and stomach helps avoid selective endobronchial intubation or tube misplacement.

Cricothyroidotomy is unlikely to be required in a child, and if necessary, needle cricothyroidotomy is the preferred first step, using oxygen jet insufflation.10

**Breathing**

Once the airway is secured and the cervical spine controlled, breathing should be assessed. Its adequacy is established by looking at the effort, efficacy and effects of inadequate breathing on other systems.
Normal ventilatory rate varies and reduces with age. Tidal volume is of the order 7-10 ml/kg. Care should be taken when assisting ventilation to match these parameters without using excessive force, which may result in barotrauma or volutrauma. In an effort to avoid this, many bag-valve-mask devices have pressure-limiting valves to limit insufflation pressures. Hypoventilation is the most common cause of cardiac arrest in children, resulting from the ensuing respiratory acidosis.5,15

The chest needs to be assessed for the presence of pneumothorax/hemothorax and definite treatment planned.

Circulation and Hemorrhage Control

Circulatory assessment consists of a rapid assessment of the following parameters:

- Heart rate
- Systolic blood pressure
- Capillary refill time
- Skin color
- Temperature
- Respiratory rate
- Mental status.

Capillary refill time (CRT) is measured by squeezing and elevating an extremity, great toe or thumb, above heart level, for 5 seconds, then releasing it. A CRT > 2 seconds, skin mottling, and low peripheral temperature are signs of shock.

When shock is suspected, a 20 ml/kg bolus of warmed crystalloid solution is given. Failure to improve suggests either ongoing hemorrhage or gross fluid depletion. A 20 ml/kg bolus represents 25% of blood volume, but as this volume becomes distributed into other body fluid compartments up to three boluses of 20 ml/kg may be necessary to achieve 25% blood volume replacement. Blood replacement (whole blood or packed cells) should be considered if a third bolus is required.5

Venous access in a young child is often difficult at the best of times. In the emergency situation, two attempts at peripheral cannulation, lasting 90 seconds, should be made. If these are unsuccessful, then either placement of an intraosseous needle (Fig. 21.2) into the proximal tibia in children less than 6 years, or a venous cutdown should be used. Placement of an intraosseous needle is relatively safe, quick and effective, and allows marrow to be taken for blood grouping. Once alternative vascular access has been established it should be removed. The preferred site for cut down is the saphenous vein at the ankle. An experienced anesthetist may place a percutaneous central line or femoral line using the Seldinger technique.

Disability

A brief assessment of the child’s conscious level is undertaken and also to determine the pupil size and reactivity. The AVPU scale can be used to assess disability with ease:

- A Alert
- V Responds to voice
- P Response to pain
- U Unresponsive.

Exposure

All surfaces of the child need to be inspected during the course of the primary survey, but this can be done region by region to avoid distress and heat loss.

Resuscitation

Treatment of life-threatening injuries should be undertaken as they are identified during the primary survey.

Standard Investigations

Standard trauma bloods are taken during placement of intravenous access and the primary survey. Seriously injured children should undergo a series of radiological investigations (trauma series).

---

Fig.21.2: Intraosseous infusion needle
Blood:
- Full blood count (FBC), electrolytes (U and E), glucose (Glu), amylase (Amy)
- Blood for group and save (G and S) or urgent cross match (XM)
- Arterial blood gases (ABGs)

X-ray:
- Trauma series (Chest, lateral C-spine, pelvis)
  Additional investigations are taken once the patient is stabilized.

SECONDARY SURVEY

The secondary survey is a head to toe assessment, including reassessment of vital signs. A complete neurological exam including the Glasgow Coma Scale (GCS) should be carried out. A brief medical history needs to be recorded. A useful mnemonic being used is AMPLE:
A - Allergies
M - Medications
P - Past illnesses/pregnancy
L - Last meal/drink
E - Events related to the injury.

EMERGENCY TREATMENT

Emergency treatment is that required to stabilise the child prior to transfer to an appropriate referral centre, theatre for operative treatment or the ward for conservative expectant observation. These interventions are not as urgent as those provided during the resuscitation phase, but important nevertheless.

DEFINITIVE CARE

Definitive care is the final phase in the structured approach to trauma; others than the admitting trauma team may provide it. The patient may require transfer to receive definitive treatment in a tertiary center; consequently, it is essential that good written records are maintained throughout the admission process.

HEAD TRAUMA

Head injury is the most common reason for hospital admission in children, and the most common cause of death in children after the age of 1 year. Vomiting is frequently used as a justification for admission for observation in young children because of the association with raised intracranial pressure, but even very minor injuries may cause children to vomit. Children may sleep fairly heavily and not wake as promptly as adults, especially when subjected to hourly neurological observations, leading the less experienced to assume a reduced conscious level.

In infancy, the possibility of non-accidental injury (NAI) should be considered. Older children are more likely to suffer from falls either around the house or at play. Road traffic accidents are the commonest cause of fatal head injury. The use of cycle helmets has led to a significant reduction in the severity of head injuries.17,18

Unfortunately significant head injuries do occur. The standard trauma and resuscitation approach is used in the assessment and early treatment of these patients and the aims of emergency treatment are directed at preventing secondary brain injury, and referring early to a neurosurgical unit for definitive treatment.

PRIMARY AND SECONDARY BRAIN INJURY

Neurosurgical referral is indicated if there is a deteriorating conscious level, Glasgow Coma Score (GCS) < 12, focal neurological signs, depressed skull fracture, basal skull fracture or penetrating injury. Definitive treatment is directed at the cause of the raised intracranial pressure or injury. This may involve the evacuation of hematoma or elevation of depressed fracture in addition to other intensive care measures.

Any child with a GCS of 8 or less should be intubated and ventilated with rapid sequence anesthesia. If the conscious level deteriorates rapidly despite all other supportive measures then urgent referral is indicated and measures intended to increase cerebral perfusion in the short-term are used. These include the use of:
1. IV mannitol 0.5-1 g/kg.
2. Hyperventilation to a PaCO₂ of 3.5 - 4.0 KPa.
3. 20 degree head up position to promote venous drainage.
4. Plasma expanders to avoid cerebral hypotension.

A focal seizure is considered as a focal neurological sign. Generalised fits are of less concern but should be controlled if they have not stopped within 5 mins. IV diazepam is preferred.
In many cases, head injuries are restricted to minor scalp hematomas. Injuries are often associated with self-limiting vomiting and normal neurology. If the head injury appears stable, a period of close observation for 24 hours is appropriate.

The assessment of head injuries in children depends on the age of the child, their ability to describe the mechanism of injury, and the history obtained from reliable witnesses. Potentially serious injuries are suggested by significant energy transfer, e.g. RTA or fall from height > 2 m, loss of consciousness (LOC), an altered state of consciousness, obvious neurology, or penetrating injury. The conscious level should be documented using the appropriate scale for the age of the child.

THORACIC TRAUMA

Children have compliant, elastic ribs and the thorax can absorb significant amounts of energy without obvious external signs of injury. An apparently normal chest radiograph cannot exclude significant thoracic injury. Rib fractures suggest a significant transfer of energy and other associated organ injuries should be suspected.

The provision of high flow oxygen via a reservoir mask allows a FiO2 of greater than 60% to be achieved and should be used routinely in chest trauma. Chest injuries can be immediately life threatening or only become apparent at a later stage.

Clinical examination and assessment should be swift. Early identification of injuries and their treatment can maximise outcomes. We discuss the management of immediately life threatening injuries in this section.

Tension Pneumothorax

Air is drawn into the pleural space compressing the mediastinum and compromising venous return to the heart. Cardiac output reduces, such that the child becomes hypoxic and shocked, and the jugular veins become distended.

There will be hyper-resonance and reduced air entry on the side of the pneumothorax. As the mediastinum is pushed to the opposite side the trachea is said to deviate away from the side of the pneumothorax.

Treatment should be immediate needle thoracocentesis in the 2nd intercostals space mid clavicular line, relieving the tension and converting the injury into a simple pneumothorax. Definitive treatment is insertion of a chest drain.

Major Hemothorax

Bleeding into the pleural space from damage to the lung vessels or chest wall can be a source of a large volume of blood loss. In addition to the reduction in lung volume, shock and hypoxia may be evident if significant blood volume has been lost. There will be reduced chest movement, reduced air entry and reduced resonance to percussion on the side of a hemothorax. Treatment requires volume replacement and the insertion of a large bore chest drain.

Open Pneumothorax

The presence of penetrating wounds to the upper body, between the umbilicus and root of the neck should alert the clinician to the possibility of an open pneumothorax.

There will be reduced chest movement, reduced breath sounds and hyper-resonance on the side of the pneumothorax. Air may be heard to suck and blow through the wound. Treatment requires the creation of a flap valve using a air tight dressing secured on three of four sides, to allow air out but not in, thereby preventing a tension pneumothorax from developing. A chest drain is required, followed by surgical exploration, debridement and repair.

Flail Segment

In the child, a flail chest is a very significant injury due to the amount of energy required to create it and the degree of underlying lung injury. Abnormal chest movement may be seen over the flail segment and crepitus may be felt. Early involvement of an anesthetist is advised. Treatment should consist of endotracheal intubation and ventilation.

Cardiac Tamponade

Injury that results in bleeding into the pericardial sac reduces the volume available for cardiac filing. As the pericardial sac fills with blood, the cardiac output is reduced. Shock develops, the heart sounds become muffled and the neck veins may become distended. Treatment is emergency needle pericardiocentesis.
Pediatric Surgery—Diagnosis and Management

Even aspiration of a small volume of blood from within the pericardium can increase cardiac output.

**ABDOMINAL TRAUMA**

The abdomen is more exposed in children than in adults. The soft elastic rib cage offers less protection to the liver, kidneys and spleen. The pelvis is shallow and the bladder is intra-abdominal in the younger child. The most common organs to be damaged following blunt trauma are in order, spleen, liver, kidney, gastrointestinal tract, genitourinary tract and pancreas. Penetrating trauma most commonly affects the gastrointestinal tract, liver, kidneys and blood vessels. The significant morbidity and mortality following splenectomy has lead to a more conservative approach with regard splenic trauma. Experience has shown that the majority of abdominal injuries can be treated conservatively, provided they receive close observation, repeated assessment and monitoring. Attention should be paid to vital signs, fluid balance and blood factors. A pediatric surgeon should be available during this period if required.

Operative intervention is required if the child exhibits:

1. Hemodynamic instability after replacement of 40 ml/kg of fluid.
2. A penetrating abdominal injury
3. A non-functioning kidney on contrast study (warm ischemic time for a kidney is 60 mins)
4. Signs of bowel perforation

The abdomen is only considered in the primary survey under circulation if shock does not respond to volume replacement and no other obvious site of hemorrhage can be found. In children a nasogastric tube or orogastric tube should be passed, as air swallowing occurs during crying and can cause significant gastric distension. This may result in splinting of the diaphragm making breathing and/or ventilation difficult.

During the secondary survey the abdomen is inspected for bruising, laceration and penetrating injury. The external genitalia must also be examined and the external urethral meatus inspected for blood. If blood is seen, this is an indication for retrograde urography and passage of urethral catheter must not be attempted by anyone other than a Consultant Urologist. Rectal examination on children is carried out only if it is considered appropriate by the pediatric surgeon who would be operating.

**FRACTURES**

Skeletal injuries in young children are common; up to 42% of boys and 27% of girls will sustain a fracture during childhood. In the early stages of resuscitation, fractures should be thought of as a potential source of volume loss. Grossly displaced fracture/dislocations should be reduced. The blood loss from a long bone or pelvic fractures is proportionately greater in a child than adult and should be considered.

The majority of children’s fractures heal rapidly and well. Whilst the bones are still growing there is a good capacity for bone remodeling, so some angulation of a reduced fracture can be accepted. Fractures of the soft springy immature bones in children are often the classic greenstick fracture. In very young children small buckle fractures also known as torus fractures are seen as small defects in the cortical surface.

Some injuries such as crush injuries to the epiphysis are very difficult to diagnose radiologically, yet they can have serious consequences on the future growth and therefore symmetry of the limbs. Other fractures have well-established association with vascular and neurological injury, which should be sought once such a fracture is seen.

**PSYCHOLOGICAL ASPECTS OF TRAUMA**

Our aims are to try to establish useful communication to assess the mechanism of injury, extent of injury, and response to treatment, whilst calming and reassuring the child. Communication with an injured child in pain and distress, in an unfamiliar environment is a challenge to the most empathetic experienced doctor. A younger child has a limited ability to describe and localise pain, and is less able to give a clear history. They will become distressed at interventions required during the course of the resuscitation, investigation and treatment of injuries. The medical team should be sympathetic to the needs of the child, and co-operation may be better gained if one nurse is focused on communication and comforting the child.

Accompanying relatives are frequently distressed and need careful consideration. In appropriate circumstances, providing they are calm enough to be of comfort to the child they should be encouraged to stay in attendance and given as much explanation as is required so that they understand what is happening and why.
NON-ACCIDENTAL INJURY (NAI)

The abuse of children by their carers is a regrettable fact of life. It can take many forms, physical, sexual, emotional or neglect. It is important to have a high index of suspicion of the possibility of abuse and be aware of the patterns of presentation, explanations and injury seen.28

Factors which should alert the doctor to the possibility of NAI include, odd times of presentation for treatment, delayed presentation, presenting without the prime carer, inconsistent accounts and imprecise times for the mechanism of injury. The injury may not be compatible with the mechanism of injury, or the carer’s attitude or focus of concern does not seem right. Perhaps the child’s interaction with the adult is abnormal, or their behavior seems inhibited or withdrawn.

Injuries seen in NAI include head injuries, including occipital fractures and intracranial injury. Fractures of long bones and particularly multiple fractures at different stages of healing may be seen. Bruising and finger marks in a hand print distribution, burns, scalds, cigarette burns, belt and bite marks should all be carefully examined.

Sexual abuse may present as frank injury, genital infection, or may present with odd inappropriate behavioral or other emotional problems.

Assessment of any child with suspected child abuse needs great care and sympathy, and the involvement of seniors at the earliest point of concern.

TRAUMA SCORES

Trauma scores are used as a predictor of survival and for comparative purposes.29 They include the following:

**Pediatric Trauma Score**

<table>
<thead>

RTS = 0.94 GCS + 0.73 Systolic BP + 0.29 Respiratory Rate

The RTS can be in the range 0 - 7.84. When RTS is plotted against survival a sigmoid shaped curve is produced.

**Trauma Score – Injury Severity Score (TRISS)**

TRISS is used to estimate probability of survival of a patient obtained from multiple regression analysis of a large trauma outcome database. It uses weighted values of revised trauma score, injury severity score and age.

**IMMUNE DYSFUNCTION FOLLOWING TRAUMA**

Severe trauma can cause life-threatening complications after immediate survival and resuscitation due to the dysfunction of the immune system.30 The normal response to trauma is to restore homeostasis. This is achieved initially by hemostasis, followed by increased regional blood flow to allow removal of waste material and the repair of tissue (‘the classical ebb and flow phases of stress response’).

Following major trauma, the excessive immune activation in response to tissue damage, necrosis, hemorrhagic shock, and infection can have an adverse effect on otherwise healthy tissue and organs. This may result in Systemic Inflammatory Response Syndrome (SIRS), which may progress leading to Multiple Organ Failure (MOF). This may also be complicated by sepsis. Multiple organ failure typically occurs in a progressive sequence affecting the lungs (Adult Respiratory Distress Syndrome ARDS), gastrointestinal tract, kidneys, heart and liver.

The immune system is a complex inter-related defence system that is influenced by a multitude of...
molecular messengers, released in response to a variety of stimuli. Multiple feedback loops are involved in the system. SIRS following massive trauma is thought to develop due to the excessive release of pro-inflammatory mediators in response to tissue damage, disrupting the existing balance between pro- and anti-inflammatory mediators.30

The initial response observed is macrophage activation leading to the release of cytokines and complement response to tissue damage.31 Endothelial cells are stimulated by complement breakdown products to release additional factors, which are chemotactic for leucocytes. Monocytes arrive and mature into tissue macrophages.

Cytokines are low molecular weight proteins effective at very low concentrations, which act by binding with cell surface receptors. Their effects may be multiple and overlapping - growth factors, modulators of leukocyte chemotaxis, modulators of lymphocyte function and modulators of inflammatory response (either pro or anti-inflammatory).

Cytokines such as TNF-α, IL-1, IL-6, and INF-γ are released in response to tissue damage and other, second messenger compounds, platelet activating factor (PAF), intercellular adhesion molecules (ICAMs) etc, are produced in response.30 This can lead to a massive uncontrolled activation of the complement and cellular based immune system. Cytokines cause rapid activation of non-specific monocytes and macrophages, alter production of cell surface adhesion molecules, induce enzyme production at distant sites (including nitric oxide) and depress cell-mediated specific immune systems. For example, TNF-α increases the phagocytic and respiratory burst activity of macrophages and increases neutrophil adhesion.52

Activation cascades result in the production of acute phase reaction proteins, which have systemic effects on thermoregulation, metabolism, catabolism, and liver protein synthesis. There is reduced production of albumin and coagulant proteins.

Nitric oxide synthase activity is increased due to proinflammatory activation; levels of nitric oxide increase as a result. Nitric oxide (NO) is a transmitter molecule of multiple cell types including vascular endothelium, smooth muscle cells, fibroblasts, and macrophages. It is also involved in regulating platelet aggregation, platelet adhesion, and neutrophil adhesion to endothelial cells, and can produce highly reactive molecules when combined with superoxide radicals.

An understanding of the basis of SIRS and the need for prompt treatment to avoid hemorrhage, hypoxic tissue damage, and the stimulus of necrotic tissue may reduce its occurrence. Ultimately the development of drugs and antibody therapy to control or limit the immune activation may be possible in the form of immunomodulation, but is still under evaluation.33

The treatment of SIRS remains supportive; this may include nutritional support in the form total parental nutrition (TPN), mechanical ventilation, renal support, hemo-correction of coagulopathy, and antibiotic treatment of infection.

REFERENCES

Head injuries in children differ from adults on account of age related differences in its etiological mechanisms, clinicopathological responses, type, management, prognosis and sequelae.¹

**ETIOLOGY**

Head injuries in children can occur due to accident, fall or abuse. Most common cause of head injury in children is a fall from height. The commonest cause of severe head injury in children is motor vehicle related trauma. The peak incidence under the age of 1 year largely due to non-accidental trauma – birth trauma and “battered child” being the major causes. At 1-4 years of age, falls from lap, cot, windows and stairways and injury by siblings are common. Recreational, automobile and other vehicular injuries are commoner after the age of 4 years.¹

**MECHANISMS**

Motor vehicle accidents with acceleration/deceleration forces results in a diffuse injury, whereas trauma produced by low velocity focal contact injuries produce local injury. The pliability of skull and compressibility of brain in infants allows focal absorption of energy rather than causing acceleration of fluid wave across the intracranial cavity producing a contrecoup injury, which is relatively uncommon in young children. Most injuries in the perinatal period result from low momentum deforming forces that lead to tears of structures such as falx, tentorium, venous sinuses or the bridging veins. This static loading allows surface injuries and makes contracoup lesions rare.²

**PATHOPHYSIOLOGY**

Structural differences in a thin, flexible and elastic skull capable of undergoing much deformation, open fontanelles and sutures, a large subarachnoid and extracellular space immature developing brain, more water content of brain, incomplete myelination, low ratio of brain to CSF, low cerebral blood flow and cerebral metabolic rate for oxygen in young children result in special physiological response to trauma. Children tolerate a rapidly expanding intracranial mass lesion better and the onset of features heralding impending disaster are delayed. The elastic skull can withstand a considerable amount of distortion without fracture and the degree of deformation is sufficient to produce local brain damage. Cerebral trauma in the linear growth period from 1-4 years after birth may disrupt brain development and functional maturation, resulting in defects of behavior, intellect and seizures. The child’s brain is more susceptible to edema formation and physiological reactions are more rapid and intense but of a shorter duration.¹³

Great majority (86%) of head injuries are mild. Severe head injuries in children are less likely to involve surgical mass lesions compared to adults.⁴

**TYPES OF INJURIES**

**Birth Injuries**

These are of two types:

i. Injuries produced by normal forces of labor and delivery, e.g. ping-pong fracture, subarachnoid hemorrhage, subdural hemorrhage and caput succedaneum.
ii. Injuries produced by obstetrical instrumentation, i.e. misapplication of forceps, e.g. linear and depressed fractures with or without dural laceration and hemorrhage.

Common birth injuries are:\(^1\)

a. *Caput succedaneum* is localized swelling of scalp due to edema rather than a hematoma. It is typically seen in midline posterior parietal area. No therapy is required.

b. *Cephalohematoma* is collection of blood between periosteum and skull and is limited by sutures. It usually resolves spontaneously. If it doesn’t resolve by 6 weeks and plain X-ray skull shows calcification, surgical removal may be indicated.

c. *Subgaleal hematoma* is bleeding into loose connecting tissue layer between galea aponeurotica and pericranium. It shouldn’t be aspirated unless there is impending compromise of scalp circulation.

d. *Ping-pong fracture* is produced by steady pressure of ischial tuberosity against skull. Lesions larger than 3 cm. require corrective surgery. After 2-3 cm. scalp incision, periosteum elevator is inserted between dura and bone beyond deepest part of depression to get adequate leverage to pop the fracture out.

**Skull Fractures**

i. *Linear*: These fractures may be single, multiple, branched, circumferential (blow-out type) or stellate.

ii. *Growing skull fracture*: Also called the cranio-cerebral erosion or traumatic leptomeningeal cyst, is progressive diastatic enlargement of fracture line (Fig. 22.1).\(^5\)\(^8\) Dural laceration conciding with diastatic skull fracture of 4 mm or more, under the age of 3 years are essential factors for its production. Growth of fracture line is due to resorption of adjacent bone as a result of continuous pulsatile wedge pressure from tissues herniating through the fracture line. Arachnoid prolapses out through dural tear and is trapped. A ball valve mechanism with easy ingress than egress of CSF and arachnoid adhesions form a cyst. When arachnoid is also torn, brain herniates. Repair of growing fracture requires removal of bony edge circumferentially until normal dura is defined all around. Cyst is drained and gliosed brain scar is excised. Dura is separated from brain and duraplasty is done with pericranium or faci- lata followed by cranioplasty with split clavarial or rib graft.

iii. *Basal fracture and CSF liquorrhea*: CSF otorrhea and early onset CSF rhinorrhea generally subside spontaneously within 2-3 weeks. Episode of pyogenic meningitis, persistent or recurrence of liquorrhea and late onset rhinorrhea would require surgical repair.\(^2\)

iv. *Depressed fracture* (Fig. 22.2): Closed depressed skull fractures require surgery when the depression is more than 5 mm located over motor or sensory cortex, compound or there is an associated foreign body. Depressed fracture is
Pediatric Surgery—Diagnosis and Management

Elevated and bone fragments are replaced back after duraplasty and thorough wound toilet.

Hematomas

Intraventricular and subarachnoid hemorrhage is more common in younger children, as compared to intracerebral, acute epidural and subdural hematomas.

i. Acute epidural hematoma (Fig. 22.3): It is less common in children because harp edged fractures are unusual, dura is tightly adherent to the suture lines and middle meningeal vessel grooves in the inner table of skull are not yet formed. The location of such a hematoma in a child is higher in the parietal region than in adults and a typical low temporal burr hole may miss it. Fall from < 3 feet is most common mechanism in children below 2 years. It occurs following multiple blows to the head, such as a fall down the stairs. Tachycardia may occur as clot expands because of acute anemia associated with blood loss in epidural space.

ii. Acute subdural hematoma (Fig. 22.4): These are usually seen with traumatic breech delivery. The hallmark is a rapid clinical deterioration. A neonate with acute subdural hematoma in an acute neurological distress should have diagnostic bilateral subdural aspirations.

iii. Shaken baby syndrome or “Child Abuse:” These children have bulging fontanelles and retinal hemorrhages. They may develop apnea, deacrebration or fixed dilated pupils requiring immediate fontanelle tap. CT scan shows acute subarachnoid hemorrhage and convexity or posterior interhemispheric triangular shaped subdural hematoma produced by tearing of parasagittal bridging veins by violent shaking of the child. Diffuse or focal hypoattenuation of brain suggest poor outcome and survivors later develop infarcts.

iv. Chronic subdural hematoma: It is common in infants of 3-6 months of age. Lethargy, vomiting, failure to thrive, delayed milestones, chronic anemia, increasing cephalofacial disproportion, large square shaped head, tense fontanelle with distended scalp veins and setting sun eyes, or subhyaloid hemorrhages are suggestive of chronic subdural hematoma. Respiratory embarrassment is an early sign of posterior fossa subdural hematoma.

v. Intracranial hematoma: An intracerebral hematoma in children may cause mass effect, seizures or progressive deterioration in alertness/neurological deficits.

Diffuse Axonal Injury

Under the age of 5 months, stress to the head sufficient to cause damage to cerebral tissue results in tears of the white matter rather than contusions or hemorrhages, which are most often found beyond this
age. This response is probably due to different elastic properties of the immature brain, compliance of skull and smoothness of the intracranial fossae. This is most common post-traumatic entity in children with severe head injury. Motor vehicle accident is the exclusive cause. Immediate unresponsiveness and minute to minute fluctuation in neurological examination are common. Emergence from coma waxes and wanes. CT scan may reveal small hemorrhages in the head of caudate nucleus, corpus callosum, superior cerebellar preduncle or around the aqueduct.

**Diffuse Brain Swelling (Fig. 22.5)**

This syndrome of malignant brain edema may occur after trivial trauma or delayed deterioration may occur due to seizures, SIADH, hypoxia or fluid overload. History of apnea or shock is often present and neurological examination has been impaired from the outset. It is exacerbated by hypoxia or ischemia from hypovolemic shock due to scalp laceration or subgaleal hematoma. Ischemia and hypoxia in infants with non-accidental injuries show hypodensity in CT scan, so called “big black brain”. Children with diffuse axonal injury develop severe brain swelling as a result of vascular engorgement due to paralysis of resistance vessels or increased cerebral blood flow and vasodilatation. Within hours of head injury 20-40% children who are comatose show cerebral swelling cisterns, and non-visualization of Sylvian fissures, gyri and perimesencephalic cistern. It is associated with primary subarachnoid hemorrhage or acute subdural hematoma. Brain swelling appears within 2-4 hours and subsides in 3-5 days, while brain edema appears about 24 hours following injury reaching its peak in 3-10 days. Brain swelling, on CT appears as low or isodense and diffusely spread, whereas brain edema appears as low density spread from contusions into surrounding white matter as finger-like projections. Brain swelling with low density brain suggests injury and poor prognosis. Normal or increased density of brain carries good prognosis.2,13-16

**Brain Contusion or Laceration (Fig. 22.6)**

Due to smooth intracranial fossae and rarity of centracoup injury. Contusion or laceration of brain is less common in children. They are usually treated conservatively. When the contusion is large in size producing, altered sensorium, mass effect and midline shift, surgery is indicated.

**Pediatric Concussion Syndrome**

It occurs following injury sufficient to produce loss of consciousness or amnesia. Child appears well shortly after trauma but sow clinical worsening during subsequent hours, child may appear in sleep, waking briefly and reluctantly to noxious stimuli then falling promptly back to sleep. This may be punctuated by vomiting, intermittent agitation and confusion. Impact seizures may occur in 12% cases which are not predictive of early or late post-traumatic epilepsy. No treatment is required unless recurs. Transient post-concussion blindness may occur from impact to back...
of head, vision usually returns within minutes or hours with no long-term sequela. Asymmetry of basal-cisterns in CT scan is predictive of subsequent swelling and deterioration.²

MANAGEMENT

Objectives

1. Reduction of risk of exacerbation of existing brain damage by prevention or control of hypoxia or ischemia.
2. Recognition of intracranial hematoma/contusion as early as possible.
3. Control of intracranial hypertension.
4. Reduction of complications like epilepsy, infection, etc.

A General: The ‘ABC’ system : A – airway; B – breathing; C – circulation, is aimed at rapidly assessing and initiating the life supports urgently needed followed by detailed diagnosis and adjustment of treatment. Respiratory evaluation, support and maintenance of free airway and paO₂ above 100 torr is the aim.

B. Control of scalp bleeding and correction of hypovolemic shock. Anemia if present is corrected by blood transfusion. Intubation is indicated in presence or hypoventilation maxillofacial injuries severe head injury with raised intracranial pressure. During intubation neck movement is minimized even if lateral cervical spine. X-ray is normal because of high incidence of ligamentious injury in children.¹⁷

C. Circulator support with intravenous fluid should never involve the use of 5% dextrose in water, because inappropriate antidiuretic hormone secretion is common in children with severe head injury, and dextrose adds to osmotic load, causes dehydration and hyperglycemic nonketotic coma which may confuse neurological signs and also cause massive cerebrial edema.

Fluid overload should be avoided. The preferred intravenous solution is 5% dextrose in one-half normal saline or ringer lactate maintained at half the normal daily amount of 1500 ml per square meter per day. ICP monitoring is required to detect large swings in ICP when both shock and coma are present.

D. Quick and careful examination for associated chest, abdominal and spinal injury or fracture of long bones.

E. Neurological Examination:

1. History and progress of neurological condition
2. Level of consciousness.
3. Seizures, hyperpyrexia, bleeding from orifices.
5. Pupils, size, shape and reaction subhyaloid hemorrhages.
6. Palpation of fontanelles and suture.
7. Examination of postural changes in tone and primitive reflexes.
8. Any evidence of weakness of any limb, cranial nerve palsy and meningeal signs.

9. Local scalp examination – subgaleal hematoma, depressed fracture, palpation of scalp laceration with gloved finger, ecchymosis over mastoid region (Battle’s sign) or periorbital discoloration (raccoon sign).

10. Glasgow coma scale (GCS) is applicable in older children. It is of limited value in infants and young children as it relies on fully developed language skills and patient’s cooperation. However, modified pediatric Glasgow coma scale grade more limited responses with maximum score of less than 15. Pediatric GCS or Adelaide pediatric coma scale are useful for assessment of initial depth of coma and its progress.

Modified Glasgow Coma Scale²,18,19

Eye Opening

- 4 – Spontaneous
- 3 – Speech
- 3 – To pain
- 1 – None.

Motor Response

- 6 – Obey commands (reaches)
- 5 – Localizes
- 4 – Withdraws
- 3 – Abnormal flexion
- 2 – Abnormal extension
- 1 – Flaccid.
Verbal Response

- 5 – Babble/gestures
- 4 – Cries for needs
- 3 – Cries – nonspecific
- 2 – Sounds
- 1 – None.

There is no reliable method to discover the occasional child who will develop intracranial hematoma, other than careful repeated observations of evolution of specific neurological signs. The mother’s opinion that the child is not well should never be dismissed. One major clinical indication of an intracranial mass lesion is the occurrence of seizures in the first 24 hours after a traumatic delivery. Any trauma to the head involving moderate momentum, i.e. automobile accidents or falls from several feet has the potential to produce rapid deterioration in a child who is initially alert and ambulatory. Acute deterioration in consciousness may occur due to seizure, acute brain swelling or expanding clot. Progressive agitation appearance or strange behavior, persistent vomiting and intermittent lethargy must be considered as a harboring of intracranial hematoma. The classical signs suggestive of coning and raised ICP seen in adults are rarely seen in children. The Cushing reflex or hypertension and bradycardia seen in adults may be not clear cut in children, in whom tachycardia and increasingly shallow respirations may be the first sign of cerebral compression. A child who deteriorates or fails to show steady improvement in neurological condition should be suspected to have intracranial hematoma unless proved otherwise.

**Indications of Hospitalization for Children with Head Injury**

1. More than momentary unconsciousness
2. Trauma of moderate momentum
3. Change in level of sensorium
4. Abnormal vital signs
5. Skull fracture – particularly traversing the middle meningeal vessel groove or sinus
6. Suspicion of child abuse
7. Neurological deficit–drowsy, irritable, hemiparesis
8. Persistent vomiting, increasing headache, fever
9. Seizures
10. A pale or anemic looking child
11. CSF liquorrhea
12. Unreliable parents to monitor child at home
13. Depressed fracture skull

Spontaneous bicycling movements of lower limbs may be seen in association with major head injury and should not be interpreted as normal. Hyperpyrexia is common in children with cerebral concussion and temperature above 40°C need vigorous therapy. Pallor, vomiting and tachycardia are extremely common following concussion injury in the child.

**Indications of CT Scan**

1. All unconscious children
2. All children with deteriorating level of consciousness/fail to show expected recovery/ deterioration of consciousness after initial movement
3. All children with depressed fracture – to know about underlying parenchymal injury
4. Persistent or increasing headache or vomiting
5. Seizure within 24 hours of traumatic delivery or head injury
6. Letharginess
7. Full anterior fontenelle
8. Split fracture on plain X-ray
9. Low hematocrit
10. Focal neurological deficit.

Standard lines with Glasgow Coma Score of 8 or less are intravenous line, arterial line, endotracheal tube and Foley’s urinary catheter. If GCS is 5 or less, ICP monitor should be inserted. Repeat CT scan is indicated in presence of new focal findings or change in alertness.

**Treatment of Raised ICP**

**Conservative or Non-surgical**

The aim is to keep the ICP below 20 torr in children with diffuse swelling.

1. Elevation of head to 30 degree
2. Controlled ventilation –PaCO2 around 30-35 torr.

If still there is no change in ICP and CT scan shows diffuse brain swelling:

1. Furosemide 1 mg/kg
2. Pentobarbital
3. Mannitol 1 gm/kg
4. In children with diffuse swelling mannitol is avoided except in presence of midline shift. Hyperventilation and dehydration are avoided because they exacerbate ischemia.

If CT shows brain edema, then elevation of head, megadose steroids, mannitol, furosemide, hyperventilation and barbiturates are used stepwise, if the ICP is not responding.

All unconscious children require proper nursing care. The position should be changed frequently and pressure at bony points should be avoided to prevent bed sores. Anticonvulsant therapy should be given in patients who have history or high risk of seizures. Unconscious children on prolonged ventilation or intubation may require tracheostomy for tracheal toilet, chest infection and reduction of dead space. Nasogastric tube may be required for feeding. Glycerol by mouth or nasogastric tube is given to children with chronic or persisting cerebral edema.

**Surgical Treatment**

1. Evacuation of acute EDH, SDH large ICH or contusion.
2. Decompressive craniotomy or lobectomy in cases refractory to medical treatment.

**PROGNOSIS**

The initial low Glasgow come score may be due to reversible causes and in children with scores above 5 with no associated injury or shock the mortality rate should be very low. Outcome after severe head injury is more favorable in children as compared to adults. Children do better than adults for the same type and severity of head injury. Reported mortality rate in children varies from 10-40%. Common cause of death is secondary brain edema. Primary are flexia denotes poor outcome. Brain contusion and subdural hematoma increase mortality rate by producing secondary brain edema. Mortality is highest in infants, decline until 12 years, then rises again in teenager and probably reflects mechanism of injury. Other factors associated with poor outcome include – low GCS at 72 hours, appearance of big black brain in CT, associated extracranial trauma, hypoxia, shock or ischemia, raised ICP and long duration of coma. Intellectual memory, attention behavioral and emotional defects may occur but are less permanent than in adults. Children below 2 years of age have a better potential for functional recovery.

**SEQUELAE**

1. *Epilepsy*: Children below 2 years of age with severe head injury and low GCS who are unconscious for more than 12 hours have higher risks of developing post-traumatic seizure. Incidence of post-traumatic epilepsy is < 5%. Psychogenic seizures can also occur.  
26,27

2. *Attention deficit hyperactivity disorder*: It may develop in children with moderate or severe closed head injury particularly, with thalamic and basal ganglion injury.  
28

3. *Persisting headache, dizziness and fatigue*: These are more common in children with pre-existing learning difficulties, previous head injury, psychiatric or family problem.  
29

4. *Intellectual, cognitive and behavioural disturbances*: It may occur.  
30-32

**Rehabilitation** – Post-injury motor, cognitive, memory, deficit, learning difficulties behavioral problems and poor scholastic performance require neuropsychological assessment and integrated rehabilitation services.

**Prevention** – Community programs of school children education like national SAFE KIDS campaign and THINK FIRST are efforts toward prevention of accidents. Improvement in suboptimal social or environmental factors, use of proper passenger restraints – seat belt, window lock, proper fit bicycle helmet may help in prevention.  
33,34

**REFERENCES**

MECHANISMS OF INJURY

The axiom “a child is not a small adult” is nowhere more pertinent than in relation to abdominal injuries, which account for approximately 10% of deaths from injury in childhood. In a child the kinetic energy from an external force is absorbed by a body mass that is considerably smaller than that of an adult, and there is a higher risk of multiple organ injury. Knowledge of the mechanism of injury as well as the anatomical site of impact is important for predicting the pattern of injury in an individual patient. Thus, when a car hits a child, it is very likely that the abdomen will be injured as well as other body regions (Fig. 23.1). In a child the relatively large, superficial liver, the spleen and the kidneys are not well protected from blunt trauma by the pliable ribs and thin abdominal wall muscles, and organ injury may occur without fracture of the overlying ribs. The kidney, being surrounded by less fat and connective tissue, is more mobile and therefore, susceptible to deceleration injury with traction on the renal pedicle, while the bladder lies in the lower abdomen and is vulnerable to direct trauma. In addition, an understanding of how children differ from adults physiologically and psychologically is essential for anticipating the effects of the injuries and their potential complications.

It is not surprising, therefore, that road traffic accidents (RTA) account for most of the deaths from injury. More than 50% of fatal RTA victims are pedestrians or cyclists struck by a vehicle and sustaining multiple injuries, most commonly of the head, neck, and limbs, but also of the abdomen. Within the vehicle, abdominal injuries may be caused by seatbelts that often are not correctly used and are not suitable for a small child. Cyclists may sustain abdominal injuries from direct contact with the bicycle handlebars. It is important to bear in mind that as many as 10% of abdominal injuries in children result from non-accidental (intentional) injury.

ASSESSING THE CHILD WITH ABDOMINAL INJURY

Clinical Assessment

This begins with the Advanced Trauma Life Support (ATLS) and Advanced Pediatric Life Support (APLS) Primary Survey ABCD sequence and concurrent resuscitation. When the Primary Survey reveals evidence of bleeding without an obvious injury to account for this, an intra-abdominal or pelvic injury must be suspected. In children, who are able to compensate for blood loss better than adults and maintain a normal blood pressure, early signs of
bleeding are tachycardia and peripheral vasoconstriction (indicated by cold peripheries, and prolonged capillary refill time > 2 seconds).

In the Secondary Survey the child is methodically examined for injuries. The abdominal examination begins by looking for any external evidence of injury, including the marks of tyres or seatbelts, the circular bruising of a cycle handlebar, or a penetrating wound. In an infant, bruises and abrasions of the abdominal wall or perineum may be an evidence of non-accidental injury and must be recorded. Abdominal distension may be due to acute gastric distension (which is common in the injured child), pneumoperitoneum or fluid (such as blood or bowel content); these may be distinguished by abdominal percussion for evidence of free air or fluid and by passage of a nasogastric tube to decompress the stomach. Tenderness and guarding are an evidence of intra-abdominal pathology, including hemoperitoneum or intestinal contusion or perforation. The presence or absence of bowel sounds is of no practical significance in the acute situation. Worsening abdominal signs suggest progressive peritonitis from bleeding or intestinal or bladder injury. Blood in the perineum may be due to a superficial straddle injury but could also be from the urethra, vagina or anus, indicating injury of the relevant organ system. We do not advise routine rectal or vaginal examination during the Secondary Survey in a conscious child, because this is traumatic for the child and often is inadequate; if indicated this examination should be done under general anesthesia. Finally, the child is logrolled to examine the spine.

Intentional/Non-accidental Injury (NAI)
The possibility of NAI must always be borne in mind, in particular for infants less than one year of age. All abdominal organs are at risk of injury. Common mechanisms of abdominal organ injury include tightly squeezing the abdomen while shaking or sexually abusing the infant (the marks of fingers may be visible), or punching, kicking or dropping the child. Suspicion must be aroused when the child is brought to hospital after an unreasonable delay, when inconsistent explanations are given for the cause of the injury or delay in presentation, when there are suspicious associated injuries and when there is evidence of previous injuries. If there is suspicion of NAI the child must be admitted to hospital regardless of the severity of the injuries, so that a full investigation can be undertaken by social workers and pediatricians trained in managing NAI. Referral to these experts must be made urgently so that appropriate investigations can be done before possible evidence is lost. This applies particularly to sexual abuse, when examination under anesthesia may be required to detect injuries, to take swabs for evidence of spermatic fluid, and to obtain photographs of the injuries.

LABORATORY INVESTIGATIONS
Laboratory investigations provide useful supportive information, but in a previously healthy child may be relatively normal on admission and serial measurements are necessary to detect evolving pathology. A falling haemoglobin level and hematocrit may be an evidence of continuing hemorrhage, but it must be interpreted in the clinical context, for example a large volume of intravenous crystalloids may lead to hemodilution. Serum amylase levels that rise progressively suggest pancreatic duct injury, while persistent metabolic acidosis may indicate hypovolemia or tissue ischemia as with intestinal injury.

IMAGING
With the reduced use of exploratory laparotomy, which provides an opportunity to rapidly examine the organs within the abdominal cavity and pelvis, there is increasing reliance on imaging to identify intra-abdominal injuries. While modern imaging techniques have become increasingly sensitive, their limitations must be appreciated, and there is no substitute for careful and repeated clinical evaluation for recognising intra-abdominal injury and the need for operation. The initial clinical examination may not reveal the true extent of visceral injury, particularly of the intestine, and repeated abdominal examination on several occasions is essential to detect evolving signs of peritonitis.

According to ATLS guidelines, the initial emergency X-rays must include an AP view of the pelvis for evidence of a fracture, which may be the source of hidden bleeding. In children the abdomen can be included on the same film and this is useful for identifying pneumoperitoneum or acute gastric dilatation, a common occurrence in the injured child.
Computed tomography (CT) with intravenous contrast enhancement is the preferred method for identifying abdominal and retroperitoneal injuries. This single non-invasive investigation shows the distribution and degree of solid organ injuries, presence of intraperitoneal fluid, and the status of retroperitoneal structures. CT is indicated in a stable patient with suspicion of abdominal trauma based on clinical signs or on the mechanism of injury. This includes patients who are hypotensive on admission and respond to fluid replacement or who have signs of slow continuing bleeding but are hemodynamically stable. CT is also indicated in patients in whom there is a risk of abdominal injury who either cannot be assessed clinically because of their depressed level of consciousness, or who require urgent operation for extra-abdominal injuries. CT is contraindicated when there is respiratory or hemodynamic instability or if there is an extra-abdominal injury (usually a head injury) requiring immediate intervention. Intravenous contrast enhancement highlights the major blood vessels and the blood supply to specific organs (Fig. 23.2). CT is superior to other methods for identifying intra-abdominal injuries provided it is of high quality and is interpreted by an experienced radiologist. However, it is noteworthy that if the CT is done in immediate post-injury period, it may not identify pancreatic injuries, even with contrast enhancement.

The routine use of oral contrast has been recommended in emergency CT to identify duodenal injuries. In our experience oral contrast has not been useful, largely because of delayed gastric emptying. The presence of free intraperitoneal fluid in the absence of an injury to the solid organs must raise suspicion of a hollow organ injury.

Ultrasound scanning (USS) has the advantage of speed and ease of execution and in adults is used to screen patients for abdominal organ injury. USS demonstrates intraperitoneal free fluid, an indicator of intra-abdominal injury, and may show injuries of the kidney, liver, spleen and pancreas. But in children the specificity and sensitivity of USS are inferior to CT. USS is useful for the follow up of solid organ injuries.

Intravenous pyelography and angiography are useful in selected situations.

Tc99 radioisotope scanning is rarely used but may have a value if CT is not available.

DIAGNOSTIC PERITONEAL LAVAGE (DPL)

DPL will demonstrate the presence of blood or bowel contents, but is not recommended in children for the following reasons: firstly, hemoperitoneum in pediatric trauma is not in itself an indication for operation; secondly, DPL is painful and makes further clinical assessment of the child’s abdomen impossible, and thirdly, the presence of residual lavage fluid in the peritoneal cavity may cause confusion in the interpretation of subsequent CT or USS. DPL may be useful for evaluating the abdomen of a child who is unconscious and is not sufficiently stable for CT to be done, or in situations where imaging is not available.

MANAGEMENT (FIG. 23.3)

Resuscitation

The general principles of emergency management of the injured child should follow ATLS and APLS guidelines. Vital signs are monitored, bearing in mind age-related normal values, especially blood pressure. In seriously injured children with evidence of abdominal injury, two large bore intravenous lines are inserted so that fluids can be infused rapidly; one of these must be above the level of heart in case of inferior vena cava injury. A nasogastric tube is introduced to empty the stomach and a urethral catheter is inserted to measure the urine output accurately. If there is blood at the urethral meatus, a suprapubic catheter

Fig. 23.2: CT scan with intravenous contrast showing absence of arterial perfusion of the left kidney due to an intimal tear, seen as a filling defect in the left renal artery
Pediatric Abdominal Trauma

275

may be required (see ‘urethral injuries’, p.26). The normal urine output for infants is 2 ml/kg/hr, for children 1.5 ml/kg/hr and for adolescents 1 ml/kg/hr. Early surgical consultation is important.

For hypovolemic shock, an initial bolus of 20 ml/kg of crystalloid is given, using normal saline or Ringer lactate; the latter is preferred in infants because of its lower sodium load. If the response is not satisfactory, a second bolus of either crystalloid or blood (whole blood or packed cells) is infused depending on the rate of hemorrhage and the degree of shock; this equates to replacement of 50% of the circulating blood volume (approximately 80 ml/kg). If hypovolemia still persists, a further bolus of 20 ml/kg whole blood or packed cells is given and urgent laparotomy must be considered. A severely shocked child would require intubation and mechanical ventilation.

Nonoperative Management

Most children with blunt abdominal injury do not require an operation. The child must be admitted for repeated clinical assessments, continuous monitoring of vital signs and urine output, serial estimations of the hemoglobin, hematocrit and serum amylase levels. Intravenous fluids are given as indicated. If there is slow grade continuous bleeding from solid organ injury, blood is transfused to maintain the hematocrit above 25%; (some centres accept a minimum hematocrit as low as 20%). Cross-matched blood should be kept available in anticipation of sudden deterioration. In patients with solid organ injury, the risk of hollow viscus injury is 3-4%, and increases with the number of injured solid organs therefore, serial clinical examination of the abdomen is essential as this is the most sensitive indicator of a hollow visceral or mesenteric injury that may require laparotomy.

Indications for Operation

Following initial stabilisation, operation is indicated for continuing hemorrhage requiring blood transfusion exceeding 40 ml/kg or when there is evidence of intestinal, mesenteric or a major pancreatic injury. Immediate laparotomy is indicated in major intra-abdominal bleeding or penetrating injuries.

Emergency Laparotomy

The skin preparation extends from the clavicles to the groins to allow thoracic extension without delay if needed. A vertical midline incision is used; this provides rapid access to the whole abdominal cavity, and can be extended easily into the mediastinum or pleural cavity. In the newborn infant, a wide transverse supraumbilical incision is advised because the distance from umbilicus to pubis is relatively short and the bladder extends to the umbilicus. The abdomen of an infant is square and a transverse incision will allow access to the whole peritoneal cavity. On opening the abdomen the tamponade effect is released and the rate of bleeding may increase; it is essential to ensure that intravenous infusions are on flow before making the incision.

The first objective is to identify and control the source of bleeding. Since the liver and spleen are common sources of bleeding, the upper abdomen should be examined first, by retracting the costal margins and removing free blood using suction and large swabs. If a source of bleeding is discovered it is initially controlled by direct pressure. The intestine must be retracted or exteriorised to enable inspection...
of the retroperitoneum and pelvis, and both the intestine and the mesentery are examined. As a general rule a retroperitoneal hematoma should not be disturbed unless it is rapidly expanding. If there is suspicion of duodenal injury, the duodenum is kocherised and carefully inspected. The pancreas is exposed by entering the lesser sac through the gastrocolic ligament. The management of specific organ injuries is discussed below.

Finally the abdomen is closed with a strong continuous suture to the midline fascia. A tight closure carries the risk of abdominal compartment syndrome, in which case temporary closure of the skin only or with a synthetic patch to the fascial layer may be advisable.

**Damage Control Surgery (Abbreviated Laparotomy)**

Most patients undergoing operation for blunt abdominal trauma are relatively stable and the procedure is straightforward. On the other hand, the outcome following a prolonged, difficult operation associated with massive blood loss and hemodynamic instability is generally poor, mainly due to progressive intraoperative hypothermia, acidosis and coagulopathy, which in turn exacerbate bleeding. This has lead to the concept of damage control surgery or abbreviated laparotomy.18-20

Damage control surgery is a staged protocol in which the first operation is limited to life saving procedures, followed by transfer to the ICU for resuscitation and stabilisation for 24-48 hours, and then a second definitive operation. At the initial operation, bleeding is controlled by ligation and tamponade. For example, with hemorrhage from major liver lacerations, tamponade is achieved using perihepatic packing to “close the book” and compress the laceration (Fig. 23.4).21 Contamination from intestinal injury is controlled by ligation and stapling. It may not be possible to close the abdomen primarily. Experience in children with liver trauma shows an increase in survival from less than 40% to over 80% using this approach.20

**Laparoscopy**

The role of laparoscopy in evaluation of an injured child is yet to be defined. Chen and Schopp22 used laparoscopy to identify and treat children with hollow viscus injuries and to assess stable children with penetrating wounds of the abdominal wall.22 Others have recommended laparoscopy as an alternative to laparotomy in children and adults.23,24

**MANAGEMENT OF SPECIFIC ORGAN INJURIES**

**Liver**

The child’s relatively large and unprotected liver is vulnerable to blunt or penetrating injury to the right lower chest or upper abdomen. Adjacent organs may also be injured, notably the lung, kidney and spleen. Injury to the porta hepatis may be associated with damage to the duodenum and pancreas. The extent and pattern of liver injury may be graded according to CT or operative findings (Table 23.1) but management depends on the hemodynamic stability of the patient and not on anatomical grade of the injury.25-27

**Nonoperative Management**

In children, most injuries to the liver parenchyma (linear fractures as well as stellate fractures and hematomas) will stop bleeding spontaneously. In about 90% of children with liver injury a policy of selective nonoperative management is effective and safe, provided the child remains hemodynamically
Pediatric Abdominal Trauma

stable after resuscitation. Patients are monitored as described above; admission to an Intensive Care Unit is not necessary for stable patients. In a review of children with isolated liver or splenic trauma more than 97% of patients with Grade I to III injuries recovered without operation; of these between 2% and 10% required a blood transfusion. Follow-up imaging with CT or USS has been recommended to identify residual hematoma or other fluid collections in symptomatic patients but is not necessary in all patients. A minor bile leak from a parenchymal laceration usually will resolve with or without percutaneous drainage. A rare but significant delayed complication is late hemorrhage from the parenchymal injury. Shilyansky et al and Berman et al described three patients with severe hemorrhage 3 and 10 days after liver injuries initially treated non-operatively, of whom two died. Risk factors for this complication included a high Injury severity score, on-going requirement for blood transfusion, and persistence of right abdominal and shoulder tip pain. Hemobilia is diagnosed by selective angiography and controlled by embolization.

Operative Management

Intra-abdominal bleeding is the major cause of death from liver injury, and surgical efforts to control the bleeding may be associated with significant blood loss. Massive blood transfusion results in coagulopathy, which further aggravates bleeding. Gross et al reported that a transfusion requirement in excess of 25 ml/kg in the first 2 hours was a strong indicator of major hepatic vascular injury requiring operation; these patients had a mortality of up to 70%. At operation, hemostasis is the immediate priority. A thorough understanding of the anatomy of the liver is important. Major bleeding from liver injury usually is venous in origin from deep parenchymal lacerations of major intra-hepatic vessels, disruption of retro-hepatic hepatic veins and the inferior vena cava, or from the porta hepatis. Adequate exposure and mobilisation of both liver lobes by dividing the triangular ligaments are necessary. Direct ligation or coagulation of bleeding points is more effective and causes less tissue damage than mass sutures or hepatic artery ligation. Formal anatomical resection has a high mortality and non-anatomic resection is preferred with resection of non-viable tissue. Cross-clamping the portal triad by Pringle’s maneuver provides temporary hepatic inflow occlusion while bleeding points are controlled. Temporary occlusion of the vena cava may be necessary using vascular clamps or intraluminal balloon tamponade using a Foley catheter. a procedure that requires a degree of expertise. Median sternotomy may be required for access to the proximal inferior vena cava. In general, when bleeding cannot be controlled with straightforward methods, temporary perihepatic packing is advised (see Damage Control Surgery, p 11). This allows time for the patient

| Table 23.1: Grading of liver injuries25,26 |
|-----------------|-------------------------------|
| Surgical grade | Injury description             |
| I Hemoma       | Subcapsular, <10% surface area |
| Laceration     | Capsular tear, <1 cm deep     |
| II Hemoma      | Subcapsular, 10-50% surface area; intraparenchymal, < 10 cm in length |
| Laceration     | 1-3 cm parenchymal depth, < 10 cm length |
| III Hemoma     | Subcapsular, > 50% surface area or expanding; ruptured subcapsular or parenchymal hematoma |
| Laceration     | > 3 cm parenchymal depth |
| IV Laceration  | Parenchymal disruption involving 25-75% of hepatic lobe or 1-3 Couinaud’s segments within a single lobe |
| V Laceration   | Parenchymal disruption involving > 75% of hepatic lobe or > 3 Couinaud’s segments within a single lobe |
| Vascular       | Juxtahepatic venous injuries; i.e. retrohepatic vena cava/major hepatic veins |
| VI Vascular    | Hepatic avulsion |

Computed Tomography Grade

I Subcapsular hematoma

II Simple laceration 1-3 cm small, 1-3 cm hepatic confusion

III Simple or complex lacerations > 3 cm deep. Peripheral in location. Large intrahepatic hematoma.

IV Hepatic transection. Extensive laceration, stellate dome, or posterior segment right lobe.

V Not applicable
to be stabilized, and is followed by delayed secondary laparotomy for definitive treatment. This procedure also enables the patient to be transferred to a tertiary care unit if appropriate.¹⁸,²¹

**Extra-hepatic Biliary Tract**

Injuries to the extra-hepatic bile ducts are rare. Those, which are associated with blunt pancreato-duodenal injury, may be identified during initial investigations or at operation, or may present later with a biloma or biliary fistula. Biliary tract injuries may also be caused by penetrating trauma or iatrogenic trauma during open or laparoscopic operative procedures or endoscopy. If not recognized early, this may lead to the formation of a biliary stricture causing obstructive jaundice. The diagnostic methods include USS, CT, Tc⁹⁹ iminodiacetic acid (IDA scan), endoscopic retrograde cholangio pancreatography (ERCP) or magnetic resonance cholangio-pancreatography (MRCP). Injuries to the gallbladder may require cholecystectomy. For injuries to the bile ducts, primary repair with t-tube drainage or stenting, or Roux-en-Y choledocho-enterostomy may be required; these are easier and safer to perform if postponed until the patient is stable. Endoscopic insertion of a nasobiliary drain has been reported.³⁵

**Spleen**

In children the spleen is not well protected by the overlying ribs and is frequently injured as a result of blunt trauma (Table 23.2). More than 50% of children with splenic trauma have multiple solid organ injuries, mainly to the liver and left kidney, and up to 85% have extra-abdominal injuries.³⁰

The clinical features of splenic injury include left upper quadrant pain and tenderness, and pain referred to the left shoulder. With hemoperitoneum, the tenderness becomes generalised. Chest X-ray may show contusion in the lower lobe of left lung, often without overlying rib fracture. CT confirms the diagnosis of splenic injury. USS or radio-isotope scan may also identify a splenic fracture but are less sensitive than CT.

The immediate consequence of splenic trauma is hemorrhage. Routine splenectomy is not recommended because of the risk of postsplenectomy sepsis and it is now established that in about 90% of childhood splenic injuries the bleeding will stop spontaneously within hours of injury.³⁶,³⁷ Management of splenic trauma is nonoperative in patients who remain stable following initial resuscitation.

**Nonoperative Management**

Patients are admitted for bed rest and monitoring, until the abdominal signs have resolved and normal gastrointestinal function has returned. Most patients can be discharged within a week after injury. Gandhi et al. formulated a clinical pathway for nonoperative management of splenic injury.³⁸ Use of this pathway showed that in hemodynamically stable children, isolated blunt splenic injuries could be treated safely with a 4 day hospital stay, followed by 3 weeks of quiet activities at home and then 3 months of light activity (including avoidance of contact sport) before returning to a full, normal lifestyle. Similar guidelines stratified according to grade of injury on a CT have been proposed by the American Pediatric Surgical Association.²⁸

 Concerns that nonoperative management would increase the need for blood transfusion have not been
confirmed and the studies suggest nonoperative management is associated with a reduced need for blood transfusion compared to patients who undergo splenectomy.39,40 Fewer than 10% of patients with isolated splenic injury require a blood transfusion.38

Delayed complications of nonoperative management of splenic injuries are rare. Acute hemorrhage due to secondary bleeding or rupture of a subcapsular hematoma may necessitate blood transfusion and splenectomy; fatal delayed hemorrhage is a very rare but a devastating complication. Splenic abscesses can be drained percutaneously.41 Routine follow-up CT or USS may not be necessary for stable uncomplicated injuries,28 but may be required in selected patients based on clinical assessment, in particular to exclude residual hematoma, which if present, needs a close follow-up.28 Shafi et al reviewed the use of follow-up CT scanning in 72 children with splenic injuries.42 In five, the CT showed a worsening radiological picture; however, only one of these children required operation, and the decision to operate was made on clinical grounds and not the imaging appearances. The authors concluded that routine CT follow-up of all patients was not beneficial.

Operative Management

Operation is indicated for continuing hemorrhage requiring blood transfusion exceeding 35-40 ml/kg (50% of the circulating blood volume). Patients with pre-existing disease predisposing to continuing hemorrhage, for example coagulation disorders or infective mononucleosis, are at particular risk but Cosentino et al reported successful nonoperative management of splenic injury in a child with Factor VIII deficiency and another with Factor XII deficiency.43 The goal at operation is to control the bleeding while conserving as much splenic tissue as possible; attempts to preserve the spleen are justified providing the patient is stable. The impact of the splenic injury on associated injuries must be taken into consideration, but in spite of the theoretical risk that a head injury might be aggravated by hypotension if bleeding is not rapidly controlled, nonoperative management of splenic and liver injuries is not contraindicated in this situation.44 The techniques for splenic preservation include topical hemostatic agents such as fibrin glue, splenic wrapping using synthetic mesh to tamponade the splenic fragments, partial splenectomy, splenorrhaphy, splenic artery ligation and selective splenic artery embolization.45-46 Partial splenectomy is done along anatomical planes, and an understanding of the anatomy of the spleen and its segmental blood supply is necessary. Operative salvage rates of 20% and higher have been reported, and in Toronto the overall rate of splenic preservation was 96%.30,36 Splenic remnants transplanted into the omentum will survive with reduced but demonstrable reticuloendothelial function.47

Post-splenectomy Prophylaxis

The spleen provides defence against infection, by production of antibodies and opsonising peptides, and clearance of circulating bacteria by the reticuloendothelial cells. The latter is particularly important in young children, who have a limited ability to mount a humoral response to infection. Overwhelming post-splenectomy sepsis (OPS), an important complication of splenectomy occurs in only 0.05 - 3% of patients but has a mortality of approximately 50%.48,49 In a 25-year retrospective review the incidence of OPS following splenectomy for trauma in 883 patients less than 16 years of age was 2% and the mortality 1%.50 OPS did not occur in 395 older patients. While young children are at greater risk than adults, the risk is lowest when a previously normal spleen is removed, as in trauma, compared to splenectomy for hematological or malignant disease.

Strep. pneumoniae accounts for more than 50% of post-splenectomy infections, but various other bacteria have been associated with OPSI, including H. influenzae and N. meningitidis. Holdsworth et al.50 suggest that the pattern and possibly the incidence of post-splenectomy Strep. pneumoniae infection reflects the natural history of these infections in the general population. Following splenectomy, prophylactic antimicrobial therapy is recommended using an antibiotic effective against capsulated bacteria, for example amoxycillin, in a single daily dose until the age of at least 5 years. Compliance is variable and it is important to ensure that the parents fully understand the risks to their child. In particular, acute pyrexial episodes should be treated promptly with therapeutic doses of the antibiotic, which should be readily available.
Polyvalent pneumococcal vaccine is recommended, but all serotypes are not covered.51 H. influenzae type 6 vaccine and meningococcal vaccine are also available.

**Pancreas**

Pancreatic injuries occur in 2-10% of children with blunt abdominal trauma. The pancreas is well protected in the retroperitoneum but may be crushed against the vertebral column by an external force, typically a fall onto the handlebar of a bicycle or a deliberate blow or kick.52 The injuries range from minor contusion to severe crush injury with complete transection of the pancreatic duct (Table 23.3). Injuries to the head of the pancreas may be associated with duodenal and bile duct injury, while injury to the tail of the pancreas may be associated with splenic injury.

There may be bruising of the skin in the epigastrium and the mark of a bicycle handlebar may be visible. Initially there may be little if any clinical evidence of injury to the pancreas and it is not unusual for a patient to be sent home, only to return a few hours later with vomiting and abdominal pain. Deep epigastric tenderness due to retroperitoneal injury must be distinguished from abdominal wall tenderness and guarding. Trauma to the tail of the pancreas is associated with tenderness in the left costovertebral angle. Serum amylase levels measured within 3 hours of injury may not be elevated, a progressive rise in serum amylase levels during the first 24-48 hours strongly suggests major pancreatic duct injury; however the correlation is not consistent, and a moderate elevation of the serum amylase does not exclude a major duct disruption.5,54 Injury to the parotid gland may also cause elevation of the serum amylase level; when head and abdominal injuries co-exist. In such cases serum or urinary lipase level, which is specific for pancreatic injury, should be measured.

As with other abdominal solid organs, CT with contrast is the preferred method for identifying pancreatic injury. CT and USS may give false negative findings in the early post-injury period, even with complete transection of the pancreas, possibly because the pancreatic capsule maintains the alignment of the pancreatic fragments, which cannot be distinguished until inflammatory changes have occurred.5 Associated duodenal injury may be detected by the presence of retroperitoneal free air or fluid on abdominal imaging. The key to managing pancreatic injuries is maintenance of integrity of the main pancreatic duct. This is best visualised by ERCP or MRCP. With ERCP there is a risk of pancreatitis or perforation.55,56 MRCP has the advantages of being non-invasive, sensitive, and safer.57 Most contusions and lacerations of the pancreas with an intact main pancreatic duct will heal without complications, and hyperamylasemia will resolve. The majority of patients therefore can be treated non-operatively, with bowel rest and intravenous feeding. Urgent operation is our treatment of choice when the main pancreatic duct has been transected, with or without associated duodenal injury. At operation, retroperitoneal edema may be the only evidence of pancreatic injury and pancreatic transection may be overlooked unless the pancreas is carefully palpated for the transverse groove at the site of the fracture. If pancreatic transection is confirmed, we perform distal pancreatectomy with preservation of the spleen.5,58 The proximal pancreatic stump is oversewn; with a previously healthy pancreas, it is not necessary to ligate the pancreatic duct or anastomose it to the small bowel.58 If a less severe pancreatic injury is found at operation the pancreas should not be disturbed. A suction catheter is placed in the lesser sac to reduce the risk of pseudocyst formation. ERCP with stenting of the main pancreatic duct is an alternative.56 An associated duodenal injury must be treated on its own merits. Non-operative management of pancreatic duct transection is recommended by some.59-61 Pseudocyst may be drained percutaneously or by open operation (see below). The disadvantages of percutaneous

Pediatric Abdominal Trauma

drainage are the need for prolonged intravenous feeding and considerably longer hospital stay of 44-161 days as compared to 10-17 days after distal pancreatectomy.52,58-60

Other complications of pancreatic injury include pancreatic abscess, fistula, duct stricture and chronic pancreatitis. Patients are followed with serial serum amylase estimations and USS or CT scanning to monitor resolution of the pancreatic injury and to detect pseudocyst formation. A pseudocyst may present after a previously unrecognised pancreatic injury with loss of appetite, vomiting, epigastric pain and an epigastic mass. The serum amylase is elevated and imaging studies show the typical lesser sac mass (Fig. 23.5). More than 50% of pseudocysts will resolve with nonoperative management.52 Those that persist beyond 3-4 weeks or become symptomatic may be drained by ultrasound guided percutaneous drainage.63 Operative management includes cystogastrostomy or distal pancreatectomy.64 Endoscopic cystogastrostomy is a less invasive mode of treatment.65 A persistent pancreatic fistula may require excision. Duct stricture is treated by endoscopic dilatation and stenting, or by operation.

Gastrointestinal Tract

Blunt injuries to the gastrointestinal tract in children are commonly due to a localised blunt force such as a seat belt, cycle handlebar or deliberate blow or kick). GIT injuries occur in 1-5% of injured children often in association with injuries to other intra-and extra-abdominal injuries.17,66,67 In a report by Canty et al, 19% of GIT injuries were non-accidental.66 With the trend toward the non-operative management of injuries to the solid organs in retroperitoneum there is a risk that injuries to the intestine may not be recognised early. In patients with multiple solid organ injuries, the chance of missing intestinal injuries is high17 because signs and symptoms of gastrointestinal injury may be masked by abdominal wall tenderness or by the effects of other injuries. Also, there is no specific imaging modality, which could reliably identify intestinal or mesenteric injuries. CT and USS may show thickening of the bowel or mesentery or fluid filled loops of bowel, but their sensitivity is low.68,69 CT with oral contrast may show extravasation from a perforation of the stomach or duodenum, but this is not a reliable test and we no longer use oral contrast.10 The presence of free fluid in the abdominal cavity on a CT without evidence of injury to the solid organs must raise suspicion of intestinal or mesenteric injury and may be an indication for laparoscopy or laparotomy.22,23,66,67,70 The most important and sensitive method for diagnosing intestinal or mesenteric injury is by serial abdominal examination.

Intestinal contusion or intramural hematoma may cause temporary intestinal obstruction but usually heal without complication. Immediate operation is required for intestinal perforation. Severe bowel contusion or avulsion of the mesentery may lead to ischemia and delayed perforation, in which case signs of peritonitis may appear after admission. This emphasises the importance of repeated clinical assessment. Fortunately, delayed diagnosis of intestinal injury does not appear to increase the risk of complications.66 Complex pancreatic-duodenal injuries are particularly difficult to recognise clinically and a high index of suspicion is needed. CT and MR scans may be useful in these cases, but exploratory laparotomy is the only certain way to clarify the situation.71

Operation usually involves repair of perforations with or without intestinal resection, depending on the degree of contusion. Defunctioning stomas are seldom required except for distal colonic and rectal injuries, when proximal colostomy is recommended. For duodenal injuries simple repair may be adequate, but

Fig. 23.5: Abdominal CT scan with contrast demonstrating a large pancreatic pseudocyst three weeks after transection of the body of the pancreas from a bicycle handle bar injury. The defect in the pancreas is clearly visible.
more complex injuries will require more complex treatment, including duodenal diversion.\textsuperscript{71}

**Kidney**

Although apparently well protected by its retroperitoneal position, the kidney is susceptible to injury in children because of the compliance of the overlying ribs and the paucity of perinephric fat to absorb the energy of an impact. As a result, renal injuries are more common in children than in adults.\textsuperscript{72} Injuries range from contusion to parenchymal lacerations with fragmentation (Table 23.4). Disruption of the collecting system will lead to extravasation of urine. Further, the kidney is mobile in an anteroposterior plane and apparently trivial acceleration or deceleration forces may stretch the renal pedicle causing an intimal tear and sometimes completely avulsing the renal artery. A pre-existing anomaly such as a congenital obstruction, malformation or tumor may be present in the injured kidney.

Hematuria strongly suggests renal injury and should lead to further investigation of the urinary tract, but the degree of the hematuria does not correlate with the severity of the renal injury.\textsuperscript{73,74} Clinical examination may reveal loin tenderness, and a palpable renal lump consisting of hematoma or extravasated urine. USS will identify the anatomical injury and the presence of perinephric fluid. It is useful for screening patients with suspected renal injury but does not assess function. CT with intravenous contrast will demonstrate parenchymal lesions, a perinephric hematoma, urinoma, as well as renal perfusion defects and any separated fragments. (Fig. 23.2). Importantly, the presence of a normal, perfused contralateral kidney will be confirmed at the same time. Intravenous pyelography or radionuclide scan will also demonstrate lack of function, but ultrasound examination is then needed to confirm the presence of the kidney.

Most contusions or lacerations of the renal parenchyma, with or without extravasation, will heal with nonoperative management, Margenthaler et al\textsuperscript{74} reported successful non-operative management in 48 of 55 (87\%) children with grade I–V blunt renal injury. Patients should be admitted to hospital for assessment and monitoring until the gross hematuria resolves. Perinephric hematoma or urinoma should be monitored by USS. In patients with major hemorrhage, ongoing heavy hematuria or an expanding flank mass, angiography with selective embolisation is the treatment of choice. Surgical exploration for hemorrhage after results in nephrectomy and should be avoided if possible. A retroperitoneal perinephric hematoma identified at operation should not be explored unless there is a strong indication for this such as major bleeding. Injury to the renal vascular pedicle requires immediate repair if the kidney is to be salvaged. However, in our experience renal salvage is rarely achieved and even if the kidney does survive, renal function is significantly impaired and there is a risk of hypertension. Nonoperative management may therefore be justified in most cases. There is controversy over the management of a major parenchymal injury extending into the collecting system with urinary extravasation. Some recommend immediate exploration but there is the risk of intra-operative bleeding necessitating nephrectomy.\textsuperscript{75} Others prefer monitoring by USS, with delayed exploration after few days if the urinoma persists.\textsuperscript{73} By this time the patient would have stabilised, the bleeding ceased and devitalised tissue become clearly apparent and can be removed along with repair of the collecting system. An exception is pelvi-ureteric disconnection, for which urgent repair is advised. Hypotension is a possible late complication after renal trauma and long-term follow up is

advised. Other complications that may develop following nonoperative management include abscess formation, urethral obstruction, renal cyst and dystrophic calcification.

Ureter, Bladder and Urethra

The diagnosis and management of these injuries in children is similar to that in adults. In infants the bladder is an intra-abdominal organ and may be injured by a blunt or penetrating abdominal trauma, leading to intra- or extraperitoneal rupture. A cystogram may confirm the diagnosis, but the perforation may be very small and not easily visible on contrast X-ray.

Injury to the anterior urethra commonly occurs as a result of a straddle injury to the perineum that crushes the urethra against the symphysis pubis. The typical presentation is with a perineal or scrotal hematoma, which may need aspiration. In girls following a straddle injury there often is an associated bruise or laceration to the vaginal introitus and perineum; the possibility of non-accidental intentional injury must be borne in mind and examination under anesthesia for evidence of sexual abuse is advised. Injury to the posterior urethra associated with a pelvic fracture presents with blood at the urethral meatus and inability to void. In this situation a suprapubic catheter should be inserted and urethral catheterization must not be attempted till the investigations to assess the integrity of the urinary tract, like ascending urography, have been performed.

REFERENCES

44. Keller M, Sartorelli K, Vane D. Associated Head injury should not prevent non-operative management of spleen or liver injury in children. Journal of Trauma 1996;41:471-75.

While assessing children with soft tissue trauma we must exclude relatively serious and sometimes occult injuries that will take precedence in management. Factors to be taken into consideration include history of the injury, child’s tetanus immunization status, whether the child has any medical problems or allergies, any medications that the child takes, what wound care was received prior to arrival in the hospital and any indication of child abuse—the “Ample” history

A: Allergies
M: Medications
P: Past medical history
L: Last meal
E: Environments and events.

MECHANISM OF TRAUMA

A. Blunt trauma, shearing forces are the most common mechanisms of injury.

However, compressive forces, such as contusions and crush injuries are more threatening for wound complications. The stellate wound resulting from compression should prompt more aggressive debridement and antibiotic prophylaxis because much of the tissue injury may be clinically occult.

B. Penetrating trauma may result from low-velocity or high-velocity wounds.

1. Low-velocity penetrating wounds are caused by stab wounds. Damage to the underlying structures, rather than the missile itself, is responsible for wound morbidity.
2. High-velocity gunshot wounds (> 2500 feet/sec) have the propensity to create enormous tissue damage, and only rarely should high-velocity wounds be closed primarily.

3. Distance is a key determinant of energy transfer in shotgun wounds. At < 2 inches, a single shotgun fire represents a high-velocity missile. Most shotgun missiles at < 20 feet distance will produce a single wound, whereas those at > 20 feet will produce multiple discrete wounds. In addition to the multiple or single projectiles delivered by a shotgun, hot gases and wadding can play a major role in the morbidity of the shotgun wound.

Soft tissue trauma can be considered in the following categories:

- Skin and subcutaneous tissue injury
- Vascular injury
- Nerve injury
- Muscle injury
- Tendon injury
- Ligament injury
- Synovial injury.

SKIN AND SUBCUTANEOUS TISSUE INJURY

Clinical Type

- Abrasions
- Contusions and hematomas
- Lacerations
- Penetrating injuries
- Crush injuries
- Foreign bodies
- Bites.
Mechanism of Wound
- Sharp versus blunt
- High energy versus low energy.

Condition of Wound
- Tidy versus untidy: Tidy wounds are created by sharp objects and do not contain devitalized tissue or debris. An untidy wound usually results from more forceful impact, crush, tearing or avulsion. As a result there is usually devitalized tissue, loss of tissue, and more frequently injury to deeper structures.
- Clean versus contaminated: Represents a general assessment of the number of bacteria in the wound and therefore the likelihood of a subsequent infection. The child will usually present clinically as pain in the injured area, bleeding and limited mobility of extremity in case of extensive soft tissue injuries. The child should be assessed systemically and locally. A history of injury (mechanism of injury, when it occurred, where it occurred, past medical history) and an initial examination (pre-anesthesia) should be carried out. The final evaluation of the injury should be done following anesthesia. The type of wound and extent of injury is noted. Injury to bone, joint, ligaments, tendons, nerves and muscles should be looked for and assessed.

Wound Assessment

A. Assessment of wound viability may be difficult in early stages of resuscitation. Repeat examination is essential. Physical examination of the wound must include assessment of the length and depth of the injury, circulatory status, motor and sensory function, the presence of foreign bodies and contaminants, and the involvement of underlying structures (nerves, tendons, muscles, ligaments, vessels, bones, joints and ducts).

B. Skin can be assessed by color, capillary refill, quality of bleeding, sensory and bleeding response to pin prick, and intravenous fluorescein injection using a Wood’s light.

C. Muscle is the most difficult tissue to assess for viability. Color, capillary bleeding, and contractile response to stimulation are not totally reliable. Muscle conservation is prudent during initial debridement. Tendons, muscles, and ligaments are tested distal to an injury, with special attention to hand and forearm injuries.

D. Fat is difficult to assess for viability, but it can be readily removed at the first debridement as long as care is taken not to devascularize skin.

E. Nerve viability can be ascertained by inspection and electrical stimulation.

If primary nerve repair is not indicated (e.g. in high-velocity wounds), nerve ends should be identified and tagged for later suture repair. Although the sensorimotor examination must precede the administration of anesthesia, the remainder of the examination should rarely be performed without adequate anesthesia. Sensation is tested by measurement of two-point discrimination distal to an injury. For children younger than 3 years of age, the use of a noxious stimulus, such as a pinprick, may be necessary to provide a sensory and partial motor assessment. Since normal autonomic tone produces a degree of normal sweating, denervated fingers do not sweat, which provides a clue to injury. The ophthalmoscope can assist in spotting sweat beads on the fingers.

F. Parotid or lacrimal duct continuity should be ascertained.

G. Circulation is evaluated by palpation of peripheral pulses and skin temperature, observation of skin color, and rapidity of capillary refill. Any clinical sign of vascular injury (minimal ooze or large hematoma, distal vascular skin insufficiency, absent distal pulse) should be followed up by diagnostic testing (Doppler flowmeter, arteriograms, CT scan, stabograms-contrast study through injury tract).

H. Adequate tetanus immunization must be assured for all wounds.

I. Extremities: All extremities are examined for deformity, contusions, abrasions, sensation, penetrating injuries, pulses, and perfusion. The presence of a pulse does not exclude a proximal vascular injury or a compartment syndrome. The long bones are palpated circumferentially, assessing for tenderness, crepitation, or abnormal movement. Open fractures and wounds should be covered with sterile dressings. Soft tissue injuries are inspected for foreign bodies and irrigated to...
minimize contamination, and devitalized tissues are debrided. Tendons, muscles, and ligaments are tested distal to an injury, with special attention to hand and forearm injuries. With cooperative older children, it is possible to test these structures functions individually; however, with younger, less cooperative children, one must rely on observation of posture, symmetry, and function and on exploration of the wound. A toy or penlight that requires manipulation by the child can be used to help in evaluating motor function.

J. Skin: The skin is examined for evidence of contusions, penetration sites, burns, petechiae, and signs of abuse. A traumatized child may have concomitant burn or inhalation injuries. The depth, location, and types of burns and the extent of body surface area involved need to be documented. The burns should be covered with sterile dressings and intravenous fluid resuscitation initiated appropriate for the extent of the burns.

K. Compartment syndrome: Increased pressure within enclosed soft-tissue compartments of the extremities can cause irreversible muscle and nerve injury. The incidence of compartment syndrome is related to the severity of the trauma. The lower leg and forearm are the commonest sites. Compartment syndrome can occur with open fractures, with pain that is either out of proportion to the injury and requires frequent strong analgesia, or is exaggerated by passive stretching of the distal joints, being the earliest indicator. Other important findings are swelling and tenseness of the compartment. Pallor, paralysis, paraesthesia and pulselessness are late findings, and the diagnosis should not be excluded if these are absent. Once the diagnosis is suspected, measurement of compartment pressures and/or fasciotomy should be performed.2-5

L. Photograph significant wounds, then apply a sterile dressing.

The priorities of managing a child with a soft tissue injury in sequence are:
1. Stabilization of the patient against life threatening conditions.
2. General history and physical examination.
3. Assessment of the tissue injury.
4. Treatment plan.
5. Institution of wound care.
6. Follow-up and reassessment.

**MANAGEMENT OF TRAUMATICALLY AMPUTATED PARTS**

Management of the amputated part is focused on reducing warm ischemia time.

Urgent transfer of the patient and the part must be organized unless the patient is already in a specialist center. The temperature of the part should be lowered as much as possible, without allowing it to freeze. This is best achieved by taking the following steps:

- Gross contamination is gently removed, but damage caused by rubbing is avoided
- The part is covered in a single layer of damp (not dripping-wet) gauze
- The covered part is placed in a plastic bag and the bag is sealed
- The sealed bag is placed in a container of water/ice mix

The amputated part should never be allowed to come into direct contact with ice, as this will cause frostbite.

The tissue priorities include

- Skin cover
- Skeletal stabilization
- Musculotendinous repairs
- Nerve and vessel repair.

**TREATMENT PLAN**

1. General measures
2. Wound closure.

**General Measures**

I. RICEM procedure for management of soft tissue injury for first 48-72 hours.

R: Rest—the child should stop moving the injured part.

I: Ice—cryotherapy (ice-packs, crushed-ice, ice-towels, ice-massage, gel-packs, refrigerant-gases and inflatable splints) for 10-20 minutes, 2-4 times a day for the first 2-3 days.
C: Compression of the injured area may squeeze some fluid and debris out of the injury site.

E: Elevation of the injured area in combination with ice and compression limits circulation to that area and therefore helps limit internal bleeding and minimizes the swelling.

M: Mobilization.

II. The use of NSAIDs for its analgesic and anti-inflammatory effects should be restricted to the first 3 days.

III. Prophylactic antibiotics

*Indications*
- Traumatic wounds with heavy contamination.
- Untidy wounds in which adequate debridement cannot be completed or must be delayed.
- Wounds entering joint spaces or compound fractures.
- Wounds in which treatment has been delayed (beyond 6-12 hrs).
- Most animal and all human bite wounds.
- The immunocompromised host.

*General Rule for Selecting a Prophylactic Antibiotic*6-8
- Use a bactericidal drug if possible
- Give in therapeutic doses for 3-5 days
- Use drugs based on wound culture reports. Gram-positive cocci are the most common organisms found in tissue wounds.

IV. Tetanus immunisation status must be checked.

V. Gas gangrene management.

VI. In case of animal bites vaccination for rabies must be considered.

VII. The detection and removal of foreign bodies like wood splinters, glass, metal and plastic can be done with the help of plain X-rays, image intensified fluoroscopy and ultrasound.

VIII. Physiotherapy/Rehabilitation.

Early mobilization, guided by the pain response, promotes a more rapid return to full functional recovery. Progressive resistance exercises (isotonic, isokinetic and isometric) are essential to restore full muscle and joint function.

**Analgesia/Anesthesia in Wound Management**

Open wounds are irrigated with large amounts of normal saline, RL or sterile water. The wound is covered with sterile dressing, moistened with saline or RLS. The extremity is splinted. Blood loss is reduced by application of manual pressure and pressure bandages. The hair around a wound should be trimmed closely with a pair of scissors, not shaved.

A. For the uncooperative child an effective combination of local analgesia is:
- Pethidine 2 mg/kg IM
- Promethazine 1 mg/kg IM
- Chlorpromazine 1 mg/kg IM.

It is important to wait for at least 30 minutes following IM injection before proceeding with care. Very young children or uncooperative children might require general anesthesia for wound closure.

Provision of local anesthesia is both a science and an art form. Lidocaine with epinephrine at 0.5-1.0% concentrations can be provided at a maximal dose of 7 mg/kg of body weight. Epinephrine is added to provoke vasoconstriction, thereby prolonging the effect of lidocaine.

1. Epinephrine should be avoided in the digits or in patients with severe arteriosclerotic vascular disease. The maximal dose of lidocaine without epinephrine is 4 mg/kg of body weight.
2. Warming the solution or adding bicarbonate and injecting slowly can significantly reduce the pain of injection.
3. Infiltrating the proximal portion of the wound can reduce discomfort of infiltrating the distal portion.
4. Allowing adequate time for local anesthetic to be effective can reduce discomfort and enhance vasoconstriction.

B. Regional nerve blocks are underutilized, but they can be helpful, especially on the distal extremities and face.

C. Judicious intravenous sedation or analgesia is useful.

**Wound Management**

**Debridement**

Sharp debridement is essential, removing obvious dead skin, muscle and fat. In wounds free of specialized tissue, early sharp resection of the wound edges and underlying tissues can be accomplished at the first debridement.

**Wound Cleansing**

Wounds containing specialized tissues such as nerves, tendons, and vessels may not lend themselves to
extensive sharp debridement. In these circumstances, high-pressure irrigation followed by open treatment with wet saline soaks and frequent Operating Room inspection is preferred.

Irrigation

High-pressure irrigation at a minimum of 8 pounds per square inch is useful. A variety of devices, including a large syringe with a small needle or catheter, pressurized fluid bag attached to an 18-gauge catheter, or commercially available pulse irrigators, have proved effective in wound management.

Packing

Aggressive, precise packing of external traumatic wounds can be effective in securing hemostasis in a traumatized patient with coagulopathy. Packing is primarily for hemostasis control and not for debridement. Subsequent wound care after packing removal is best done with either delayed closure or saline soaks. Most skin wounds do not need to be packed for hemostasis because they can be temporarily sutured or stapled closed.

Wound Closure

Traumatic wounds and surgical wounds in trauma patients are closed according to time from injury, amount of tissue available and degree of contamination.

1. Primary closure (primary intention) is appropriate for most superficial wounds. This implies that the wound is closed within the first 6-8 hours of incision or laceration.
2. Secondary closure (sometimes called secondary intention) implies that a wound is left open and allowed to close by subsequent granulation and contraction.
3. Tertiary closure (delayed primary closure) is used for class III (contaminated) or class IV (dirty or infected) wounds. Wound edges are left open for 4 - 5 days with application of wet saline dressings. The wound is then reapproximated with suture, tape, or staples.
4. Suture closure
   a. Wounds in cosmetic areas of the body usually undergo layered closure commonly incorporating subcuticular absorbable suture material with Steri-strips or fine skin sutures.
   b. In non-cosmetic areas of the body, simple closure of the skin is satisfactory, assuming underlying fascial layers have been reapproximated when appropriate.

Tissue Transfer

a. Split-thickness skin grafts are commonly used for traumatic wound closure. In general, full-thickness skin grafts are used for the face. Local flaps are most useful for the extremities and face, and myocutaneous flaps are designed primarily for the central part of the body.
b. Free-tissue transfer is most useful for defects in the distal extremities, although it can be used in many parts of the body.

Suture Removal

Varies with location of wound, size of wound, and pre-existing disease.

a. Face: 3-5 days
b. Abdominal wall: 5 - 7 days
c. Scalp: 10 days
d. Vertical torso wounds or wounds over movable joints: 2 weeks
e. Delay suture removal in patients with multiple organ dysfunction syndrome and immunocompromised patients.

Non-surgical modalities to enhance healing and care of soft tissue wounds.9-13

• Exogenous application of growth factors
• Cultured keratinocyte grafts
• Electrical stimulation
• Hyperbaric oxygen
• Vacuum Assisted Closure System (VAC).

VASCULAR INJURY

The incidence of pediatric vascular trauma is increasing as a result of more invasive diagnostic and therapeutic procedures on children and because children are more frequently the victims of domestic violence. Attempts at diagnosis should initially be made non-invasively, because arteriography has the potential of further injury. Arterial repair of major arteries should be undertaken to avoid growth retardation.
Mechanism of Injury Producing Vascular Injury

I. Trauma
   A. Penetrating trauma
      – Gunshot wounds
      – Stab wounds; including lacerations from sharp objects like broken glass windows.
   B. Blunt trauma

II. Iatrogenic
   – Cardiac catheterization and indwelling umbilical arterial catheters (and is most often seen in children under 2 years of age).

III. Long bone fractures involving the humerus and femur.

In the urban civilian experience, extremity vascular injuries comprise less than 50% of arterial trauma. Extremity arterial injuries predominate in the rural environment reflective of the higher incidence of blunt mechanisms and farming/industrial type injuries.

In the urban set-up, both upper and lower extremities have equal incidence of involvement. But in the rural set-up, the upper extremity is more commonly involved. The brachial artery is more commonly involved than the axillary artery in the upper extremity. The femoral artery is more commonly involved than the popliteal artery.

Trauma to blood vessels results in systemic, regional and local pathophysiologic imbalance. The systemic effects are produced by blood loss, which if not controlled will result in hypovolemic shock. The local and regional effects will be determined by the type of vessel injury, which is usually determined by the mechanism. A laceration is the most frequent type of injury to both arteries and veins.

Diagnosis

History

The work up should be expeditious with the goal being reperfusion of the ischemic limb within six hours or less. A history of pulsatile, bright red bleeding from the wound that ceased after a period of minutes suggests arterial injury; while the history of a steady flow of dark blood from the wound suggests a venous injury. Because peripheral pulses may be palpable in up to 33% of the patients with arterial injuries, a history suggesting vascular injury may be the most important diagnostic indicator at the time of initial evaluation. The most important differential diagnosis in pediatric vascular trauma is between thrombosis and spasm of the injured vessel. Spasm may be associated with adjacent injury to soft tissue, blunt trauma to the vessel wall, and hemorrhage into surrounding tissue. Nevertheless, spasm as the only cause of absent distal pulses is uncommon and will usually disappear within three hours. If the pulses remain absent beyond three hours, vascular occlusion is likely. When the pulses remain absent longer than six hours, thrombosis or transaction of the vessel is certain.

Physical Examination

The physical findings are extremely variable. The signs indicative of ischemia or ongoing hemorrhage, and which if present indicate the need for operative exploration are as follows:
   • Pulsatile bleeding
   • Expanding hematoma
   • Palpable thrill
   • Audible bruit
   • Evidence of regional ischemia
     – Pallor
     – Paresthesia
     – Paralysis
     – Pain
     – Pulselessness
   – Poikilothermia

The signs suggestive of vascular injury, but without definitive evidence of ischemia or hemorrhage and which, if present, indicates the need for further evaluation are as follows:
   • History of moderate hemorrhage
   • Injury (fracture, dislocation, or penetrating wound) in proximity to a major artery
   • Diminished but palpable pulse
   • Peripheral nerve deficit

Ultrasonic Flow Detection

The easily performed segmental pressure Doppler, combined with the flow velocity wave forms, is a useful instrument in determining peripheral vascular problems.

   Absence of palpable distal pulses and measurement of the ankle systolic pressure with a Doppler ultrasonic
flowmeter alone provide reliable and non-invasive, objective evidence of arterial insufficiency.

**Other Diagnostic Modalities**

- Duplex scanning
- Arteriography: In most series, the most common indication has been proximity of an injury to a major artery.
- Intra-arterial digital subtraction arteriography
- Digital venous angiography
- Magnetic resonance angiography
- Venography.

**Vessel Repair**

Figure 24.1 shows the incision of choice for exposure and gaining proximal and distal vascular control.

Before proceeding with a definitive arterial repair any thrombus that may have accumulated in either the proximal or distal artery during the period of ischemia is removed. Thrombectomy should be performed passing the smallest Fogarty catheter (2F or 3F) first proximally and then distally through the previous arteriotomy or puncture site. Systemic heparinization should be given unless it is absolutely contraindicated.

Vascular repair is indicated for pseudo-aneurysms and arteriovenous fistulae. Rupture of the pseudo-aneurysm is the most likely complication with resulting hemorrhage and compartment syndrome. Failure to repair an arteriovenous fistula in a growing child may result in marked hemihypertrophy of the affected leg from the increased growth of bones and soft tissue.

Arterial repair is accomplished by:

- Resection with end—end anastomosis
- Primary autogenous repair with interrupted 6-0 prolene sutures after debridement to native intima.
- Autogenous reconstruction with vein patch or vein graft.

Special considerations during vascular repair:

- Use of generous spatulations of anastomosis
- Fine vascular suture (polypropylene, 6-0 to 8-0)
- Placement of vein bypass grafts when necessary
- Interrupted sutures for vascular anastomosis are used when substantial remaining skeletal growth is anticipated
- Systemic heparinization is used for vascular repairs when not contraindicated by associated injuries
- Local infusion of papaverine is used effectively to alleviate vasospasm when this was found to contribute to ischemia
- Liberal use of fasciotomy.

**NERVE INJURY**

Acute traumatic damage to a peripheral nerve may occur as a result of traction, contusion, compression, or laceration. A nerve trunk can be stretched by as much as 15% of its length without injury. As the nerve is stretched beyond this limit, the axons (efferent) and dendrites (afferent), which have little tensile strength, fail before the surrounding connective tissues (epineurium and perineurium), which are stronger. Traction injuries may be associated with fractures, at the time of injury or during reduction or fixation; with dislocations and stretch injuries; and with gunshot wounds. Although spontaneous recovery is typical of most of these injuries, complete nerve loss can also occur.

Contusion injuries from a blunt blow to the nerve carry a similar prognosis to traction injuries, with spontaneous functional recovery being the normal
Soft Tissue Trauma

293

Recovery from compression injuries depends on how long the nerve has been compressed and the degree of compression.

A lacerated nerve has no chance of spontaneous recovery, and the discontinuity must be surgically repaired. Results of nerve repair in children are always better than those in adults. More distal injuries have a better prognosis for recovery than proximal ones, and a pure motor or sensory nerve has a better prognosis than a mixed nerve.

**Classification of Nerve Injuries**

In the Sunderland classification, the following terminology and definitions are used:18

1. **Neuropraxia**: A localized conduction block without axonal disruption. Tinel’s sign is present, and complete recovery should occur.
2. **Isolated axonotmesis**: The axon is disrupted, but the Schwann’s cell tubes are intact. Wallerian degeneration occurs distal to the site of injury. Recovery is usually complete if the lesion is not too proximal for successful reinnervation.
3. **Axonal injury with endoneurial scarring**: The nerve is in continuity, but there is enough disruption of the axons that incorrect reinnervation occurs. This leads to a partial recovery, but one that is better than with excision and end-to-end repair.
4. **Neuroma in continuity**: The nerve sheath is intact, but the axons have been disrupted, and there is scarring across the nerve. The treatment is excision and repair by end-to-end anastomosis or interposition nerve grafting.
5. **Neurotmesis**: The nerve is completely divided, and repair is required.
6. **Combination of the above injuries exist within a single nerve.**

**Tests of Peripheral Nerve Function**

These are outlined in Table 24.1. A combination of tests may be done to elicit the function.

**Nerve Repair**19-21

An acute primary repair may be undertaken if the wound is clean, the mechanism of injury is a sharp
laceration, the patient’s condition is stable, and the surgical team and its facilities are available. If this constellation of circumstances is not encountered, perform a delayed primary repair within 8-15 days. Early repair is preferable in a clean wound because extensive nerve retraction has not yet occurred and less mobilization is required.

Secondary repair (> 2 weeks after injury) is indicated in heavily contaminated wounds if soft-tissue coverage is poor and requires flaps, if the amount of nerve damage cannot be assessed early (e.g. in patients with gunshot sounds, head injuries), or if the diagnosis is initially missed. Some motor recovery may be expected after repairs as late as 1 year after injury; partial sensory recovery may result from repairs as late as 2 years after injury. Success diminishes with delay, however, because muscle atrophies and endoneurial tubules undergo fibrosis. The anatomic goal of neurorrhaphy is, simply, to exactly realign the axons so that regenerating axon sprouts will reconnect to their preinjury end points.

Figure 24.2 depicts the cross-sectional anatomy of a peripheral nerve.

Three surgical techniques of neurorrhaphy are in current use epineurial repair, fascicular repair, and group fascicular repair (Figs 24.3 to 24.4B).

Epineurial repair is the standard method of nerve repair carried out by placing several sutures peripherally in the epineurium after aligning the nerve ends according to fascicular pattern and epineurial landmarks (Fig. 24.3). This technique has the advantage of being less technically demanding, being less traumatic to the nerve ends, and placing less suture material in the repair site. Epineurial repair is indicated for small nerves, for nerves with only one or two fascicles, and for primary repair of a clean laceration in a larger nerve.

In fascicular (also called funicular) repair, individual fascicles are dissected free of enveloping epineurium and sutured fascicle to fascicle through the perineurium (Figs 24.4A and B). This repair is not widely used because of the increased amount of suture material required at the site of repair and the difficulty in confirming the actual alignment of each of the fascicles.
Group fascicular repair is similar in principle to fascicular repair except that recognizable groups of fascicles are joined instead of individual fascicles. The repair of more than five fascicles or groups is impractical, because it excessively injures the nerve end and leaves too much suture material within the wound. Group fascicular repair is the technique employed in nerve grafting. Group fascicular repairs work best when there has been a crushing component of the nerve injury or a delayed repair requiring the trimming of a portion of the nerve ends.

Nerve grafting: If segmental loss prohibits end-to-end repair without excessive tension, interfascicular nerve grafting is indicated. The sural nerve is typically used as the graft. The lateral antebrachial cutaneous nerve can also be used.

MUSCLE INJURY

A strain is an injury to the musculotendinous unit. Muscle injuries are classified as either (a) acute muscular strains and avulsions, (b) contusions, or (c) exercise-induced muscle injury or delayed-onset muscle soreness (DOMS).

Muscle injuries can be caused by strain or by a direct blow. Muscle strain may be generated by passive overstretching or by sudden voluntary eccentric or concentric concentration.

The severity of muscle strains is categorized similar to ligament injuries: first-degree (mild) strains are defined by minimal structural damage, minimal hemorrhage, and early resolution; a second-degree (moderate) strain is defined as a partial tear, most often at the myotendinous junction, accompanied by pain, significant hemorrhage, inflammatory pain, and functional loss; and third-degree (severe) strains are accompanied by obvious hemorrhage, swelling, and, often, complete and palpable muscle tissue disruption.

A muscle contusion results from an external force that is sufficient to cause muscle damage. Contusions may be graded in severity according to the restriction of motion (ROM) of the subtended joints. A mild contusion causes a loss of less than one-third of the normal ROM of the adjacent joint, whereas severe contusions limit motion to less than one-third of normal excursion. Contusions result in vascular disruption, producing two types of injury inter-

TENDON INJURY

Because of their prevalence in sports, injuries to tendons and tendon insertions have received considerable attention. Normal tendon has a tensile strength that measures 45-98 N per millimeter, but tendon begins to fail at 8-10% strain. Available evidence from surgical biopsy suggests that inflammation occurs after a tendon tear. Table 24.2 outlines the terminology used to describe tendon injury.

Management

The first principle is to diagnose the tendon injury by careful clinical examination. A second principle involves adequate exposure of the wound site. The third basic principle in the treatment of tendon injuries is to identify any associated injuries to the adjacent bones, nerves, or blood vessels. If possible, repair all the injured structures during the initial surgery. The sequence of repair is usually bone, ligament, tendon, nerve, and important blood vessels.
The basic objective of tendon surgery is to appose the lacerated tendon ends to allow the healing process to reestablish the continuity of the disrupted collagen bundles and the smooth gliding surface of the tendon. Restore the tubular form to the tendon, avoiding both gapping and bulging of tendon tissue at the repair site.

Numerous suture techniques have been described for tendon repair (Fig. 24.5). Most of them include a "core" suture, which passes through the endotendon substance of the tendon ends across the laceration site to provide strength and stability to the repair until healing takes place. Additionally, a peripheral suture is placed circumferentially around the laceration site.

**Ligament Injury**

A sprain is an injury to a ligament. Disruption of ligament is followed by hematoma and soft tissue inflammatory repair. Full recovery may take more than 1 year, and the ultimate tensile strength may be reduced by 30 - 50%. An increased amount of ligament scar helps to counteract mechanical weakness, but other biomechanical properties (e.g. bending stiffness) are not improved. Therefore, once a ligament is damaged, "normal" ligament tissue is not restored. Collagen fibers straighten completely at about 4% elongation.
Schemes for Assessing Ligament Injury
These have been described in Table 24.3.

SYNOVIAL INJURY
The synovial membrane is a thin layer of cells loosely classified as a specialized form of connective tissue. Synovitis is a frequently associated complaint of tendon and ligament sports-induced injury. Medications such as corticosteroid injections or NSAIDs reduce synovial inflammation through direct suppression of the arachnoid acid cascade.

REFERENCES
Vascular injuries in children are relatively uncommon. When they do occur they pose difficulties in recognition and the results could be catastrophic if appropriate measures are not instituted early.

Ligation of the major bleeding vessel was the only treatment available until early half of 20th century and the amputation rate in World War II was 49%. In the Korean War, reconstructive techniques were implemented and the amputation rate fell to 13.6%. With ever increasing civilian trauma, attention has been given to primary repair of nerves and skeletal fixation during the primary injury thus improving functional limb salvage. Presently trauma is the leading cause of pediatric mortality in USA. It is to be noted that gunshot injuries are one among the leading causes of such trauma.

The true incidence of vascular trauma in India is difficult to estimate. A study by Tandon JN et al from Agra suggests that falls and traffic accidents are the most common causes of childhood accidents and mortality due to trauma. This is consistent with the experience from Ohio. With the very high number of bicycle and motorcycle usage in India, the potential for handlebar injuries causing blunt arterial trauma should be borne in mind. Another major source of injuries could be child labor where sharp objects (e.g. in carpet weaving) or mechanical accidents lead to occupational trauma.

CHARACTERISTICS OF PEDIATRIC INJURIES

Prolonged arterial spasm is characteristic of vascular trauma in the pediatric age group. This is a common phenomenon and lasts at the most up to three hours. It should reverse after this time-period. Nevertheless, the commonness of this situation could induce a false sense of security in the attending physician and precious time may be lost before beneficial treatment could be instituted. Children cannot communicate subtle complaints of weakness and paresthesia. Absence of atherosclerotic process as seen in adult vascular system and rich collaterals mean that children could partially compensate for arterial occlusion. Hence, they could maintain a viable limb and could even have normal distal pulses in the presence of significant arterial injury. However, this collateral circulation may be inadequate for a normal growth and these children may develop claudication or limb length discrepancies later on in life if normal circulation is not restored. Ironically, formation of A-V fistulas could result in local hypertrophy of limb. These factors together mean that the attending physician should maintain ‘high level of suspicion’ to avoid long-term disabilities. In addition, the small caliber of the blood vessels pose challenges for surgical repair.

MECHANISMS OF TRAUMA (TABLE 25.1)

Vascular injuries can occur in two different settings in children. Under the age of 2 years, they are usually iatrogenic and occur in children who are ill owing to the coexisting conditions that necessitated the potentially harmful interventions [e.g. cardiac catheterization or arterial access] in the first place. Rarely vascular injuries could occur as a complication of major operative procedure.

Children who are more than 2 years of age are prone to different types of injuries since their increased
mobility is not accompanied by improved judgement. They could have multiple system injuries or coexisting musculoskeletal injuries. Children could be victims of direct abuse or could sustain violence being innocent bystanders.

**Blunt Injuries:** It could cause intimal disruption, dissection, contusion and thrombosis. Surrounding hematomas and tissue swelling can cause a tamponade effect on the vessel as well as impede formation of effective collaterals.

**Bony Fractures:** It could cause secondary damage to anatomically vulnerable vascular structures and nerves. This may be in the form of vascular traction, penetration by bony spikes or entrapment of vessel wall. The edema accompanying the injury could impede venous return in the closed muscle compartments of extremities. The vicious cycle progresses to impede arterial flow and leads to muscle ischemia, necrosis and fibrosis (Volkmann’s ischemic contracture).

**Penetrating Injuries:** Are commonly caused by glass, knives and other sharp objects. Vehicular accidents can create flying sharp objects which act as low velocity missiles causing vascular injury. Vessels could be completely transected causing hematoma which allows vascular contraction and temporary cessation of bleeding. If a tangential injury is sustained, such an outcome is precluded and incessant bleeding results. Associated venous injury facilitates formation of an arteriovenous fistula, which limits distal run-off leading to limb ischemia by causing an ‘arterial steal’ and could potentially result in high output cardiac failure. High-velocity missiles as in gunshot wounds cause temporary cavitation and arterial and venous thrombosis due to the absorption of kinetic energy. In shotgun injuries, pellets can enter vascular system and could embolise to extremities.

**ASSESSMENT**

The interests of child with injuries is best served by a team approach. Children with vascular trauma could have associated airway (e.g. penetrating neck injuries), breathing (e.g. hemothorax) or circulation problems which could be life-threatening and need prompt recognition and treatment. Fluid resuscitation takes precedence when the child is in shock. In cases where IVC injuries are considered possible, it is prudent to obtain vascular access through the upper limb veins and vice versa. Often associated injuries like skeletal fracture may distract the examiner’s attention and vascular injuries may not be recognized unless specifically looked for. Palpation of pulses and assessment of skin temperature could provide early clues. Lack of spontaneous movement of the limb and tenderness elicited during passive movement of major joints could provide corroborative evidence that a vascular injury exists. Physical examination is very sensitive especially when repeated and combined with noninvasive Doppler assessment.

**IMAGING MODALITIES**

**Doppler Studies**

Doppler signals can be used to examine clinically feeble pulses especially in an edematous extremity. Ankle-Brachial pressure Indices (ABI) can be determined by recording accurate blood pressures. A comparison of resting and post-exercise ABIs can give an idea of critical stenoses. A Duplex scan (ultrasound combined with Doppler) can be used to measure the diameters at critical sites such as vascular and graft anastomosis. Also they may be useful in identifying pseudoaneurysms. Color flow is an additional facility to measure turbulence of flow. Combined with clinical symptoms and examination these can potentially avoid the need for invasive arteriography in large number of clinical situations.
**Digital Subtraction Arteriography**

Critical details of vascular anatomy may be obscured in an angiogram by overlapping structures. Traditionally cut films were used to subtract the background images by a labor-intensive process of superimposing a plain mask film and contrast film and reimaging on a third film. With digital technology and computer enhancement this can be done instantaneously and most arteriograms are performed this way. Arterial injection of contrast means less contrast need to be used. This type of arteriogram still remains the gold standard.

In small children with a small blood volume, sufficient concentration could be achieved through intravenous route (IV-DSA) and this is particularly useful in evaluating long-term patency of vascular repair/graft. Still, a rapid bolus is required to achieve the concentration and hence a peripherally inserted longline to reach a large central vein or even right atrium is required. To avoid movement artefacts most children need sedation. Intravenous DSA can miss intimal disruptions < 1 mm. On the balance these difficulties are to be weighed against the possibility of avoiding second arterial injury due to an arterial access and significantly less radiation. Parker PM and associates employed IV-DSA to guide management of acute arterial injuries in 9 children. They avoided unnecessary exploration in 4 patients by excluding arterial injuries, identified 1 pseudoaneurysm for ligation and abandoned a planned skin flap since there was no blood supply to the flap. They contend that IV-DSA can be the definite diagnostic procedure in the acute phase.4

**IATROGENIC INJURIES**

**Umbilical Artery Catheters**

Umbilical artery catheters (UAC) are used in neonatal practice to give a convenient access to the arterial system for blood pressure monitoring and frequent blood gas sampling. They have revolutionized the care of extremely sick premature babies; yet, there is attendant morbidity and mortality attributable to them. The most common complications include thrombosis, infection, hemorrhage and hypertension.

Thrombosis is a result of endothelial damage produced by indwelling UAC catheters thus exposing the highly thrombogenic subintimal smooth muscle layer. Rajani et al studied the effect of low-dose heparin (1 mg/ml) in neonates with umbilical artery catheters. They established by a randomized controlled double-blind study that heparin infusion at this dose through UAC prolonged the duration of catheter patency and did not alter the partial thromboplastin time.4 Mokrohisky et al. demonstrated that low positioning of umbilical-artery catheters could increase the incidence of associated complications in newborn infants. They recommended thoracic positioning of catheter-tip.5 Previous studies have established that catheters with an end-hole are safer than catheters with side holes. There is evidence that heparin may be effective in doses as low as 0.25 U/ml as a continuous infusion. Boluses did not have the same effect. Heparin infusion did not alter the incidence of aortic thrombosis. Whereas it can be said that low-dose heparin infusion does not increase the incidence of intra-ventricular hemorrhage in general, whether the same is true in cases of extremely premature babies (< 31 weeks) who are at the highest risk to develop this complication is not known yet.6 With the implementation of these changes and the availability of small sized catheters, there is an apparent reduction in the morbidity associated with UAC in recent years and further progress needs to be made in the prevention of aortic thrombosis.

Small catheter related thrombi may respond to simple withdrawal of catheter. Minor ischemic complications including transient ischemia of limbs may resolve conservatively. Major aortic thrombosis could present in various ways – severe cardiac failure, hypertension especially in cases with aortorenal thrombosis, impaired renal function and bilateral lower limb ischemia.

Angiography still remains the gold standard for the diagnosis of aortic thrombosis. Non-invasive diagnostic modalities like ultrasound, color-flow doppler are obviously preferable and have been employed by some authors. Radionuclide studies [DTPA] may be useful. The reported incidence of thrombosis varies with the sensitivity of screening method used and may exist even in asymptomatic patients. For monitoring clot lysis and resolution ultrasound is the method of choice.

The treatment of established aortic thrombosis remains controversial. Krueger and colleagues (vide supra) advocated early and aggressive surgical
thrombectomy. On the contrary there are isolated reports of spontaneous clot resolution in cases with infrarenal aortic thrombosis treated only with supportive care.7

The results of thrombolytic therapy seem to be promising. Streptokinase, urokinase and recombinant tissue plasminogen activator (r-tPA) have all been used with apparent success. Thrombolytic agents act by directly or indirectly activating plasminogen and the resultant proteolytic factor ‘plasmin’ lyses fibrin. Plasminogen exists in plasma as a free form and in thrombus as a fibrin-specific form. Streptokinase (indirectly) and urokinase (directly) activate both the plasma and the tissue plasminogen. Hence, they produce a systemic ‘lytic’ state. This is particularly disadvantageous in premature neonates who are at increased risk hemorrhagic complications including intraventricular hemorrhage. Streptokinase is antigenic in nature and has a long half-life of 30-60 min and hence, is not currently recommended. As r-tPA is ‘fibrin-specific’ maximum activity is generated on the surface of the thrombus providing the least chance of provoking systemic bleeding. However, its superiority over urokinase for this purpose is not established by direct comparative trials in neonates.

In adults r-tPA is the most used thrombolytic agent. Watkins S et al have recently reported their experience in a neonate with bilateral lower limb ischemia caused by thrombotic occlusion as a result of twin-twin transfusion.8 This neonate had a severe left leg ischemia necessitating fasciotomy below the knee shortly after birth. Subsequently the baby developed bilateral lower limb ischemia with multiple emboli. At the dose of 50 mg/kg/hr, tPA was administered through an umbilical arterial catheter over 13 days. The entire right leg survived and the left foot survived with residual deformity (Figs 25.1A to C). Despite the prolonged duration of administration there was no bleeding complications and the cranial ultrasound remained normal.

Similar results are reported in a retrospective series Hartmann J et al who treated 14 neonates with catheter related thrombosis over six years. They recommend an initial bolus of tPA [0.7mg/kg over 30 min] followed by 0.2 mg/kg/hr as a continuous infusion with a low dose heparin prophylaxis of 2-6 IU/kg/hr.9 This protocol was derived from adults. There was no incidence of severe bleeding or intraventricular hemorrhage in their series. Dillon et al successfully employed even lower doses. They also suggested that fibrinogen level should be maintained greater than 100 mg/dl.10 Further multicentered trials are needed to establish a safe and effective protocol for thrombolysis in neonates.

Figs 25.1A to C: Serial angiography in a neonate with bilateral iliac occlusion performed before t-PA infusion. A, and at 3 days B, and 9 days C, after commencement of the infusion. Arrows point to the site of thrombosis. The occlusion can be seen to reverse effectively. Peripheral Vascular Access

Arterial lines are useful for access in sick neonates for continuous blood pressure monitoring, arteriography and cardiac catheterization. Radial, dorsalis pedis, posterior tibial, ulnar, axillary and femoral arteries have been utilized for this purpose.

Common complications associated with intra-arterial catheters include vasospasm, intimal disruptions and flap formation, thrombosis and intramural hematoma. Unless recognised early, limb salvage might be impossible when the complications involve major vessels of the limb. Prevention of injuries is the key. Radial artery is by far the safest. Nevertheless Allen’s test should be performed to ascertain satisfactory collateral circulation prior to selection. Percutaneous access, using the shortest length of catheter required, avoiding high pressure boluses, continuous heparin infusion, firm skin fixation and wrist immobilization – all help to minimize complication rates. In a multivariate analysis Franken et al established that catheter size is the principal factor in determining the incidence of vasospasm based on radiographic evidence. A large catheter to arterial size ratio should be avoided.11

Wardle SP and colleagues have used 65 femoral arterial and venous catheterization in 53 neonates with a median gestational age of 29 weeks after all the other vascular accesses were exhausted.12 Transient ischemic episodes occurred in 17%, catheter related sepsis occurred in 19% necessitating removal, but there were no major catheter related complications. This success is obviously due to thin walled pliable catheters of size 3F or 4F tapered over a guidewire inserted using a standard Seldinger’s technique by experienced personnel.12

Factors influencing occurrence of vascular injury during angiocardiography include multiple previous entries and multiple catheter exchanges. In addition to the above-mentioned measures – accessing left heart through patent foramen ovale whenever possible, shortening catheter indwelling time by rapid execution of procedure and removal as soon as possible – minimize injury. After removal of catheter, firm finger pressure should be applied cephalad to site of skin entry, where the entry into the artery itself is likely to be. Distal pulses and limb perfusion should be carefully monitored after the procedure. In the rare instances when pulse loss occurs, heparin infusion should be commenced.

There are other factors which can affect the potential for injury as well. Epithelial disruption of any kind, hematological abnormalities (hypercoagulability) and hypovolemia at the time of intervention can affect the microcirculation and thus predispose patients to injury. Sadly, when this happens ischemia could result in peripheral gangrene necessitating amputation. In the presence of dry gangrene adequate time should be allowed for collaterals to form and line of demarcation to evolve before deciding the level of amputation (Figs 25.2A and B). Early recognition, aggressive investigation and

Figs 25.2A and B: Peripheral gangrene in a preterm neonate as a result of indwelling arterial line positioned in dorsalis pedis artery. The line of demarcation was allowed to mature and three weeks later a mid-tarsal amputation was performed
prompt intervention are vital in preventing such a formidable outcome.

The choice of therapy in patients with viable limbs and demonstrable pulse deficits seems to be controversial. Since limb-length discrepancies could occur in this group of patients some authors advocate aggressive surgical approach with thrombectomy and/or microvascular reconstruction. The small caliber of the vessels poses distinct surgical difficulties and hence risk of restenosis is high. Moreover, many of these injuries occur in children who are extremely sick due to their primary medical condition. These factors have led others to recommend a conservative policy. A delayed repair could be performed if exercise intolerance or limb length discrepancies develop. A delayed repair has been shown to reverse the growth disparity if adequate time period exists before growth potential ceases. Hence, it is obvious that whichever choice is made prolonged follow-up is necessary with particular attention to history of exercise induced claudication and radiological assessment of limb length in doubtful cases.

TRAUMATIC INJURIES

Unlike iatrogenic injuries, trauma – blunt or penetrating – usually occurs in children over 2 years of age who are larger and are generally fit to undergo operative correction. The outcome is optimal if surgery is performed within 6 hours of injury. One cannot overemphasize the fact that a ‘high index of suspicion’ is essential especially in a country like India where delays to reach such a surgical facility might be considerable.

Peripheral arterial injuries are often due to blunt injuries accompanying skeletal fractures or penetrating injuries causing direct vascular damage. Pain, pallor, paresthesia, pulselessness, paralysis and poikilothermia (coolness) are indications that obvious arterial occlusion exist. Other ‘hard’ signs of arterial injury are active bleeding, expanding or pulsatile hematoma and bruit/thrill. Their presence indicates that direct exploration should be performed in theatre and that time-delays to perform angiograms are to be avoided. However, in cases of multiple penetrating injuries of the same extremity an angiogram to ascertain the level of injury may be justifiable.

The ‘soft’ signs of arterial injuries include history of bleeding, small non-expanding hematoma, unexplained hypotension, injury to anatomically related nerve (sensory/motor deficit), and proximity to a major vessel. In these occasions an angiogram should be considered. One shot angiogram performed by surgeons when single hand-held injection of contrast (10-35 ml of diatrizoate) into the arterial system is made in antegrade or retrograde fashion and this is manually timed to obtain a single plain film. This concept is now being used in the United States as Emergency Center angiogram in patients suspected to have peripheral injuries with soft signs. Alternatively color-doppler along with clinical examination is felt to be very sensitive in excluding vascular injuries. Angiogram performed in radiology suite remains the gold standard.

Penetrating Injuries

In patients with penetrating injury near a major vessel and in cases of gunshot injuries where distant injuries are possible, major vascular trauma should be considered. Bleeding should be temporarily controlled by direct pressure. Blind attempts to control bleeding using clamps and use of tourniquet could be harmful. In theatre, both proximal and distal control should be obtained at a distance from the actual site of injury if possible before hematoma is opened. Small vascular clamps should be used. The anatomy of injury should be defined. Lateral repair is possible in large arteries with tangential injuries. In complete transections contused ends should be resected. Fogarty catheter should be used to remove clots from proximal and distal ends. Spatulation of both ends has been shown to be the key to success. End to end anastomosis is achieved using interrupted 6.0 or 7.0 monofilament sutures placed as widely possible as is consistent with hemostasis. In contradistinction to the continuous suturing technique preferred in adults, interrupted suturing allows subsequent growth in children and minimizes the potential for stenosis. If tension-free anastomosis is not possible, reversed autogenous saphenous vein grafts are preferred. Brisk backbleeding indicates adequate collateral flow and generally predicts good outcome. Intraoperative doppler can assist in making a judgement about flow in distal vessels. Where uncertainty persists a completion angiogram may be useful in excluding the presence of distal emboli.
Major venous injuries should be preferably repaired before arterial reconstruction. Minor distal veins could be ligated safely. Fasciotomy should be performed if necessary. Nerve injuries could also be repaired during the same time. Routine antibiotic prophylaxis is not required though other factors like possible contamination and time since injury should be taken into consideration before making this decision. Suitable tetanus prophylaxis measures should be taken.

**Blunt Injuries**

Arterial injuries could accompany major blunt impact trauma and these patients could have multiple system injuries. Assessment of neurological deficit might be difficult. Arteriography should be performed when there is any suspicion.

Upto 3% of patients with long bone fractures or limb joint dislocations could sustain associated arterial injuries. Involvement of superficial femoral artery in fractures of distal femur, popliteal artery in dislocation of knee joint and brachial artery in supracondylar fracture of humerus are typical examples of such injuries. Associated disabling nerve injuries are common.

Priority should be given to early reduction and stabilization of the fracture. If there is severe ischemia or if the procedure will take more than 30 minutes a temporary vascular shunt should be considered to sustain distal blood flow during orthopedic manipulation. Post-reduction vascular assessment is to be performed using palpation of pulse, clinical assessment of perfusion and registration of Doppler signals. It is prudent to perform open explorations if this is not satisfactory. If arteriography is desired it is best performed on-table under same anesthesia.

**Compartment Syndrome**

Volkmann, in 1881, described paralytic contractures following periods of arterial insufficiency of even few hours. This is due ischemia of muscle causing edema and elevated pressures a closed limb compartment. When the compartmental pressure supercedes venous pressure, outflow gets cut off further aggravating edema and this causes further ischemia. Massive crush, bony fractures, bleeding, orthopedic manipulation, Bier’s block, associated venous injuries and infection can all aggravate the vicious cycle. If not promptly interrupted, this cycle leads to permanent contractures as a result of ischemic myonecrosis and the resultant fibrosis. Clinical features during the acute setting include edema, attitude of flexion, hard feeling and tenderness to touch and passive stretch. Monitoring can be done using a wick-catheter technique to assess compartmental pressures. Pressures > 30 mm Hg indicate fasciotomy. It is a safe policy to perform fasciotomy when in doubt. Fasciotomy should include the entire length of the compartment – in the forearm it should extend from the antecubital fossa to the carpal tunnel, in the leg four compartment decompression is effected through two incisions. Though some authors advocate fibulectomy as a method of decompression, this could lead to valgus deformity in children.

It is to be noted that most series on peripheral vascular injuries have a 3-5% incidence of amputation. In cases with massive crush injuries sometimes a primary amputation could be lifesaving. Some patients with combined musculoskeletal, vascular and neural injuries may be better served by amputation and early rehabilitation.

**TRUNCAL INJURIES**

**Cervicothoracic Injuries**

Although thoracic great vessel injuries are rare in children, they are attendant with high mortality rate. With a rapid acceleration-deceleration type injury aortic disruption occurs at the junction of fixed and mobile part. Thus, in both vertical and linear high speed impacts junction of aortic arch and descending aorta just distal to ligamentum arteriosum is the most vulnerable site. Patients with penetrating injury to ascending aorta rapidly die of tamponade and those with aortic arch injuries die of rapid exsanguination. When descending aortic injuries are contained by adventitia a pseudoanerysm results. These patients reach hospital safely but if not identified and treated have a 30% mortality rate. Some of the warning features would include dyspnea, back pain, diminished femoral pulses and upper limb hypertension. Even if they are asymptomatic, a widened mediastinum on chest X-ray should prompt arch aortography. Emergency thoracotomy and repair, possibly under bypass is required. For isolated injuries of descending aorta a ‘clamp-sew’ technique without
bypass might be justifiable but prolonged aortic clamping has inherent increased risk of cerebral hypertension, paraplegia due to spinal cord ischemia, distal thrombosis and renal failure. Dacron graft repair has been successfully employed for repair of aortic arch.

Penetrating neck injuries in children are rare. Consequently current practice is based largely on the experience gained in adults. Controversy exists in identifying the type of injuries which require mandatory exploration and those that need selective exploration based on clinical or radiological criteria. Neck is divided into three zones for this purpose. Zone I includes structures below the cricoid cartilage up to clavicle, Zone II comprises of structures between cricoid cartilage upward up to the angle of mandible and Zone III extends above angle of mandible up to the base of skull. Injuries to Zone I and Zone III are investigated using a combination of angiography, esophagogram, esophagoscopy and bronchoscopy. Traditionally violation of platysma was considered to be an indication for mandatory exploration for Zone II injuries.

With improvements in imaging technique obviously fewer patients will need mandatory exploration. Cox CS and colleagues employed a selective policy whereby hemodynamically unstable patients underwent emergency explorations and stable patients underwent abovementioned investigations and explored only if an obvious injury which needed operative correction. Asymptomatic patients were kept under observation only.17

**Abdominal Injuries**

Penetrating injuries, severe blunt injury or iatrogenic trauma (e.g. tumor resection or Veress needle for laparoscopy) could cause abdominal vascular injuries and they may be associated with visceral injuries. Emergency laparotomy for uncontrollable hemorrhage is the rule. In stable patients renal vascular injury should be excluded using contrast enhanced CT scan or a one shot IVP where facilities are limited. Aortic injuries could be treated with direct repair, vein graft or prosthetic graft. The **Infrarenal** IVC can be ligated. Successful ligation of even the **pararenal** IVC, performed as a life saving measure in seat-belt injury, has been reported.18 If needed, direct venous repair could be performed under finger pressure control. Retrohepatic IVC injuries are particularly difficult to manage. The suggested strategy is to pack, resuscitate and then to obtain intrapericardial and suprarenal caval controls. Pringle maneuver completes hepatic isolation to facilitate repair.14 Venovenous extra corporeal bypass (femoral - right atrial circuit) has been successfully employed as well in tackling these difficult injuries.

**RECENT ADVANCES**

**Microsurgical Techniques**

The usefulness of powerful operating microscopes with magnifications as much as X30 and X40, 9-0 to 11-0 monofilament sutures and team approach has helped the emergence of microsurgical techniques and almost all vascular grafts performed in adults can be now performed in children including neonates although this still borders on the experimental. It is to be noted the principles of vascular surgery remains the same but microsurgery helps to implement these principles accurately in the tiny blood vessels as small as 0.5 mm.19 In addition to saphenous veins, dorsal veins of the foot which possess thick muscularis have been employed by these authors. The types of vascular reconstructions described in the pediatric literature are summarised in Table 25.2.

Long-term follow-up of patients who had autogenous saphenous vein grafts by Cadneau JD and associates, has established that these grafts are effective and durable. They also found that limb–length discrepancy can be reversed and symptoms of claudication relieved using appropriate revascularization techniques.20 Aneurysmal and non-

aneurysmal dilatations, graft stenosis or complete occlusion are some of the complications they encountered.

**PREVENTION**

The incidence of iatrogenic injuries appears to be decreasing mainly owing to the preventive strategies. The traumatic vascular injuries are to be prevented by precautions against childhood injuries by making home and public places safe for the child. Steps should be intensified to curb child abuse. For the victim of trauma supportive care and rehabilitation should begin in the in-hospital phase and must be followed in the society with particular attention to educational needs.

**REFERENCES**

Burns are the most devastating type of trauma that the human beings suffer. The postburn scars leave behind indelible blemishes, and the victims may suffer till the end of their lives. In spite of the modern methods available in burn management and advancing knowledge of the basic pathophysiology of burn injuries, India cannot boast about diminishing mortality and morbidity in burns. The incidence of burn injuries is increasing and mortality is also high. Significant morbidity in terms of long-term sequelae such as functional, cosmetic, social and psychological impairment is also seen. Children are at high risk because of their natural curiosity, their mode of reaction, their impulsiveness and lack of experience in calculating the risk of the situation. Though most of our burns occur in the poorer socioeconomic strata of society, burns in children are also seen in the affluent sectors; careless attitude of the parents, negligence and lack of priorities contribute towards this scenario.

**Epidemiology**

Children unfortunately are the innocent victims of circumstances that result in major fire accidents. Superficial flame burns rate the highest amongst the etiological factors. Open fire cooking, children playing in the kitchen, where cooking is undertaken at the floor level, rodents toppling on open chimney lamps due to lack of electricity are common causes. Scalds due to hot liquids in the domestic setup ranks next in the etiology. More serious types of scalding occurs when older children (2-4 years) fall into hot water or hot milk kept on the floor for cooling under the fan. Neonates suffer burns due to hot water bottles, which are used as warmers.

Electrical burns are very common in the domestic setup, when children place their fingers into open plug sockets and suffer low voltage burns. Playing near dish antennae on top of multistoried buildings could result in serious high voltage electrical burns in the upper limbs. Contact with live wires is a common type of electrical burn when children play and try to retrieve kites. These could result in major burn injuries with entry and exit wounds.

Acid burns are not very common in children, but corrosive esophageal injury occurs due to accidental ingestion of acid which is kept in kitchen closets for cleaning purposes. Children sometimes are innocent victims of homicidal acid burns.

**Incidence**

The material included in this chapter relates to the analysis of pediatric burns (0-18 years) treated in a tertiary facility of Kilpauk Medical College Hospital during a period of twenty years and in a well equipped private trust children’s hospital. In this study we have analyzed a total 427 patients who were admitted to Kanchi Kamakoti Childs Trust Hospital, Chennai for over a period of nine years. The data (Chart I and II) clearly denotes the occurrence as per age, etiology, percentage of burns and mortality.

**Age and Sex**

Most of the children belonged to the group below 10 years. Male children predominated.

**Types of Burns**

Scalds due to hot liquids topped the list. Next common was flame burn. We did have acid burns and electrical burns. Other studies showed that compared with older
children, children younger than 4 years were significantly more likely to be admitted with scalds rather than flame burns, had smaller burn injuries, and were less likely to have an inhalation injury.¹

**TIME OF OCCURRENCE**

Children suffered burns more during daytime and there were more flame burns during the festival season (September to November).

**MORTALITY**

Children tolerated burn injury better than adults if the body surface area (BSA) involved was 10-30%. If the BSA involved was over 30% the mortality was higher. Neonates who suffered accidental burns due to use of hot water bottle as warmer, especially in the villages, usually succumbed to the injuries. In larger series, after adjusting for sex, burn size, inhalation injury, and type of burn (flame versus scald), the risk of mortality was substantially higher for children aged 0-1.9 years and for children aged 2.0-3.9 years as compared with children aged 4 years or older.¹

Mortality also depended upon the delay in resuscitation due to late presentation and due to the innumerable topical applications used on the burnt area at the time of sustaining the injury. The major cause of death in this study was *Pseudomonas septicemia*.

Retrospective and prospective trials have demonstrated that injury characteristics (lower age, larger burn size, presence of inhalation injury), resuscitation variables (delayed intravenous access, lower admission hematocrit, lower base deficit on admission, higher serum osmolarity at arrival to the hospital) and hospital course events (sepsis, inotropic support requirement, platelet count < 20,000, and ventilator dependency) significantly predict increased mortality.²

**PATHOPHYSIOLOGY OF BURNS**

Problems in the pediatric burns are mainly due to physiological immaturity; this is especially true in infants. The temperature regulating mechanism is labile as the ratio of surface area of the body to weight is more. Rapid shifts in the core temperature occur. Deep burns occur rather rapidly due to the thin skin of the infant that has scant dermal appendages, which are close to the surface, permitting the burn to penetrate into the depths easily. Children are also more susceptible to fluid overload and dehydration. Infants require higher energy and their peripheral circulation is labile. Their metabolic demands are also on the higher side. With all these special problems, the children with burns present a special management issue.

Burn injury is associated with anatomic, physiological, endocrinologic, and immunologic alterations. Cutaneous injury triggers a reaction at a local and systemic level through the release of multiple inflammatory mediators.³ When the injury is extensive, this becomes a systemic reaction and the cascade of cellular alterations can lead to generalized inflammation and multiple system organ dysfunction (Fig. 26.1). These problems need to be identified and treated properly to prevent or minimize the extent of the damage.⁴

Burn shock is consequent to the massive fluid shifts that occur soon after burn injury. Direct thermal injury results in changes in the microcirculation and capillary permeability increases. Multiple inflammatory mediators are also secreted which increase the vascular permeability throughout the capillary vascular bed all over the body. This results in the leak of intravascular fluid into the extravascular spaces resulting in burn edema, which is maximum at the end of 12 hours post burn in minor burns and lasts till 24 hours in major burns. Hypovolemia occurs due to the fluid shifts at the expense of circulating blood and plasma. This results in burn shock with reduced cardiac output, increased heart rate, oliguria, acidosis and air hunger. The inflammatory mediators that are responsible are bradykinin, histamine, prostaglandins, leukotrienes and hormones. Products of platelet degradation, and interleukins 1 and 6 also act as mediators of burn shock (Fig. 26.1).

In burnt patients the levels of sodium adenosine triphosphate are reduced in the tissues, which alters the cell transmembrane potential and the concentration of sodium increases in the extravascular compartment. This also contributes to burn edema.

Severe burns can thus cause increased vascular permeability and edema, altered hemodynamics, immunosuppression, hypermetabolism, decreased renal blood flow and increased gut mucosal permeability.
Pediatric Burns

309

CLASSIFICATION OF BURNS

Classification of burns can be done according to the agent inducing the injury and according to depth and extent of the total body surface area involved (TBSA).

Agents Causing Burn

- Thermal
  - Scald
  - Contact with hot objects
  - Flame
- Electrical
- Chemical
- Radiation.

Depth

A clear understanding of the depth and structure of the skin is needed to understand the grades of burn (Fig. 26.2).

First Degree Burn (Superficial) (Fig. 26.3)

Only the superficial epithelium is involved. There is always varying degree of erythema and regardless of the type of therapy used, this type of burn heals without scar formation. For about six to ten hours, burn is painful and then gradually it becomes less painful. Sunburns and flame burns are generally of this type.

Second Degree Burn (Partial Thickness) (Fig. 26.4)

Here the entire epidermis and a variable depth of dermis are involved. These are commonly seen due to splashes of hot liquids, flash burns, longer contact with flames and limited exposure to chemicals. Depending upon the extent of dermal involvement it is further divided into superficial and deep partial thickness burn.

The superficial type is painful and has blisters. Since sweat glands and hair follicles are spared the healing is satisfactory and scarring does not occur. These heal in 2-3 weeks time and are painful during healing phase due to regeneration of nerve fibers.

The deeper variety is not very painful and is generally without blisters, but since the reticular layer of the dermis is involved these usually do not heal spontaneously, and when it heals after several weeks, it does so with hypertrophic scarring. The appearance will be almost like third degree burn. A sterile ‘pin-prick test’ with a hypodermic needle can be very valuable in assessing the depth of the burn.

Third Degree Burn (Full Thickness) (Figs 26.5 and 26.6)

Here the entire thickness of the skin and adnexae are involved. The burn is not very painful and is parchment like in appearance. These do not heal spontaneously and have to be excised and grafted. When the third degree burn is extensive, it gives rise to a systemic response, which may result in shock. If it is allowed to heal by itself, it may result in crippling contractures. These are seen due to prolonged contact with any of the agents causing second-degree burns as seen above.

Fourth Degree Burn (Fig. 26.7)

Involvement of tissues and structures beneath the skin such as muscles and bones signifies a fourth degree burn. These are obviously insensate and a charred appearance is seen. Classically seen due to molten metal, high voltage electrical burns and prolonged contact with flames.
EXTENT OF BURN

TBSA burnt should be quantified early in assessment; it is the single most important factor for management and prognosis. There are various methods to calculate it:

1. Rule of nines: According to this algorithm—Head and neck comprise ~9% of BSA, front and back of trunk ~20% each, each arm ~9%, front and back of leg ~9% each and the remaining 1% is made up by the genitalia. This rule is quite reliable in patients who are >15 years old but is not suitable for use in children (Fig. 26.8).5
Fig. 26.6: Deep partial thickness burns of the thighs and gluteal region

</table>
According to palm hands: A rough estimate of the BSA burnt can be made by the number of palm hands of the patient required to cover the area. Palm surface area roughly equals 1% across all age groups.

Lund-Browder chart: Allows for precise calculation of the BSA burnt across all age groups (Table 26.1).

**BURN WOUND HEALING**

Skin is the largest organ in the body, with multi-structural and multi-functional components with regional variations. The ischemic, hypoxic and edematous burn wound takes a very slow course for healing compared to a traumatic wound. Unique characteristics of burn wound healing requires a thorough understanding of normal wound healing which is a very complex and dynamic process consisting of many co-ordinated cellular, biochemical molecular processes. The wound healing goes through phases of angiogenesis, granulation tissue formation, processes of matrix formation, remodeling and epithelialization to the formation of a scar.

**Epithelialization**

In a regular wound epithelialization begins within hours after injury. In superficial and superficial partial thickness burns epithelialization occurs spontaneously from the dermal remnants of hair follicle and sebaceous glands. In deep partial thickness burns the epidermal cells undergo phenotypic alteration at the margins of the normal skin and loose their adherence to one another and to the basement membrane, which allows for the lateral movement of epidermal cells. The migrating epidermal cells dissect the wound space separating the eschar from viable tissue guided by an array of integrins, which the migrating cells express on their cell membrane. One or two days after injury the epidermal cells at the wound margin begin to proliferate behind the actively migrating cells. The stimulus for proliferation and migration of epidermal cells is epidermal growth factor. If the area of the burn is large, re-epithelialization may not completely cover the raw wound and split skin grafting may be necessary to hasten the wound healing. In smaller burn areas, within ten to twelve days, epithelialization is complete and the burn wound gets closed.

**Immunological Response to Burn Injury**

Today it has been realized that in massively burnt patients (> 40% TBSA) chaotic cytokine array is responsible for higher mortality rate and not infection as was thought earlier. The appropriate term for the immunological failure that is seen is ‘Systemic Inflammatory Response’. As soon as burn injury occurs, macrophage margination and activation occurs. This results in the release of three cytokines IL1, IL6 and TNF-alpha. Macrophages also produce products of lipid peroxidation namely leukotrienes and prostaglandins. All these are very toxic to the patient and these produce T cell failure, inhibit lymphocytes, hemoglobin synthesis and also depress the granulocyte colony formation.

Skin is recognized as the largest immune organ and the effect of heat could well figure in the origin of the pathophysiology encountered. The area of skin burnt quantitatively is related to mortality and cellular functional failure. This immune failure could be the cause of death in children during the shock phase, rather than infection.

**EMERGENCY ROOM MANAGEMENT**

The initial management of the severely burned patient follows the guidelines established by the Advanced Life Support course of the American College of Surgeons according to which, like any other trauma, airway and breathing assume the highest priority.

**Airway and Breathing**

Airway management is the first and the foremost priority as there is high incidence (up to 30%) of associated inhalational injury in a severely burnt patient which can be immediately life threatening. Inhalational injury may be present with minimal cutaneous burns and may not be evident at presentation but can develop rapidly. Inhalational injury should be suspected if there is any history of exposure to smoke in a confined space, loss of consciousness, impaired mental status or disorientation and obtundation. Important clinical signs to be looked for are – any hoarseness of voice, stridor (impending airway obstruction), facial burns, singed nasal hair, wheezing and expectoration of black carbonaceous sputum. Affected patients should be...
given 100% oxygen by mask (to wash out carbon monoxide), oxygen saturation should be monitored and equipment kept ready for intubation. Ideally fiberoptic bronchoscopy should be done on any suspicion and signs such as airway edema, mucosal necrosis, hemorrhages, ulcers and pseudomembranous casts should be looked for. If any of these are present the patient should be intubated and respiratory care protocol established.8

The airway injury increases the surface area involved and triggers both local and systemic edema. The direct heat injury to the respiratory mucosa, together with chemical irritation, leads to sloughing of the mucosa and cast formation. The combination of this mechanical obstruction with atelectasis can lead to barotrauma and respiratory insufficiency. If the chest wall has been burned, full inspiratory effort may be restricted.3

The final point to be remembered is the fact that the burn patient could also be a victim of associated trauma, hence decreased levels of consciousness or oxygen desaturation should not be blamed only on burn shock or inhalation injury, but could be due to associated head injury.

**Circulation and Intravenous Access**

It is important to start two intravenous portals, one for infusing fluids and the other for giving drugs through the unburnt skin. Central line though ideal, may invite sepsis and could be disastrous and hence should be inserted only if required urgently. If the child has already gone into shock with falling blood pressure, then a central line must be started.

After appropriate initial stabilization, fluid resuscitation plays the most important role in patient care and survival. The abundance of formulae that have been derived to help the practitioner with management are a testament to this importance. Because of the large open areas of skin and leaky capillaries, the body requires enormous amounts of fluid to maintain adequate organ perfusion. Most practitioners use lactated Ringer’s solution for resuscitation. Colloids are usually reserved for the second 24 hours.3

A Foley’s catheter should be placed and urine output is used as the ultimate objective finding. In an adult, 0.5-1 mL per kilogram per hour of urine is a well-known marker for adequate end-organ perfusion.

In a child, the concentrating capacities of the kidney are less well developed, and 1-2 mL per kilogram per hour is recommended. Inhalation injury dramatically increases the fluid requirements.3

A nasogastric tube should be placed to drain the stomach. Stress ulcer prophylaxis with histamine-2 (H2) receptor blockers and/or antacids is to be started.

**Eliciting history for medicolegal purpose:** To ensure proper epidemiological documentation and also for medicolegal records, a detailed history should be elicited from the conscious patient and in the case of children from the parents. This would enable implementation of preventive program.

**Recording the weight of the patient:** Recording of the weight of the burnt child is important for calculating and administering fluids and drugs. Ideally weight is recorded as soon as possible at the emergency room.

**Investigations**

Consider complete blood count, type and cross-match, carboxyhemoglobin (whenever suspected and feasible), coagulation studies, chemistry panel, arterial blood gases, and chest radiograph (which may not show changes for the first 24-72 hours).

**Escharotomy and Fasciotomy**

Burn eschar may act an inelastic constricting tourniquet impairing circulation and even respiration. This is seen generally in extremity and chest burns though can occur in neck and abdominal wall burns also. This phenomenon is seen only with deep second and third degree burns only. The constricting effect may not be there initially and develop later on during resuscitation; 8-24 hours period is most critical period. A frequent assessment of the peripheral perfusion can help in early diagnosis. Parameters to be checked are capillary filling time, pulses and oxygen saturation. Doppler can aid the diagnosis in difficult cases. For prevention, extremities with deep burns should be kept elevated and splinted in a functional position. In suspected vascular insufficiency, escharotomy should be performed at the earliest as delay and the subsequent reperfusion injury may have lethal consequences. This procedure involves an incision through the burn eschar to relieve the constriction caused by it. This procedure can be done at the bedside
with an electrocautery with the patient under sedation, as the eschar is insensate. A rapid restoration of the circulation suggests a successful procedure; if the blood flow is still not restored then a consideration should be given to fasciotomy, i.e. incision of the deep fascia to alleviate the compartment syndrome.

**FLUID RESUSCITATION IN PEDIATRIC BURNS**

It is important to bear in mind that a burnt child continues to be a special challenge, since resuscitation therapy must be more precise than that for an adult with a similar burn. Important point to bear in mind is the fact that a burnt child requires intravenous resuscitation for a relatively smaller TBSA (10-20 %) unlike an adult. Primary goal of resuscitation is to support the child throughout the initial 24-48 hours period of hypovolemia that sets in due to extravascular fluid sequestration during postburn shock period.

A delay in fluid resuscitation not surprisingly is a major contributor to mortality in massive burns. Volume contraction due to fluid lost through the burn wound and into normal tissues as a result of increased systemic capillary permeability, when finally resuscitated, contribute to perfusion-reperfusion injury, thus activating neutrophils and releasing free radicals that could contribute to a systemic inflammatory response. The most significant contributor to mortality among the resuscitation measurements is not the amount of fluid given in the first 24 hours, but how soon after the injury fluid was started. The challenge that this represents to the burn community is to provide better communication to emergency care responders, emphasizing institution of resuscitation immediately during the treatment of the thermally injured.²

The pertinent questions are:
1. How much fluid should be infused?
2. What type of fluid should be infused?
3. Does the child belong to high-risk burns like inhalation burns, when they may require more fluids, for resuscitation?

**Calculation of the Requirements**

Cope and Moore in 1947 gave the first rational scheme of fluid resuscitation in burn patients. Though their formula is no longer in use all the modern formulas derive their basic scheme from their formula, i.e. requirements are calculated according to the extent of the burn and the weight of the patient, initially for the first 24 hours. Half of this amount is given in the initial 8 hours and the rest over next 16 hours. Though for adults Parkland’s formula is the one that is in most common use, the only formula for calculation in pediatric burn patients is the one devised by Shriners Burn Hospital.³ According to this formula:

For first 24 hours – Total fluid requirement is 5000 ml/m² TBSA burn + 2000 ml/m² as maintenance, 50% of this volume is given in initial 8 hours and the rest in ensuing 16 hours. Ringer’s lactate is the fluid used for resuscitation.

Thereafter – 3750 ml/m² + 1500 ml/m² is used for next 24 hours; a part of total of it may be made up by the enteral feeds. Urine output of > 1 ml/kg/hr and stable vitals signify an adequate replacement.

**Place of Colloid**

There is a controversy regarding the use of colloids in the initial resuscitation scheme. It is known that the plasma proteins are extremely important in the circulation since they generate the inward oncotic force that counteracts the outward capillary hydrostatic force. But protein solutions are not given in the initial 16 hours, as they also leak through the dilated capillaries, and are no more effective than more salt water. After 16 hours, if colloids are added to the crystalloid regimen, the reversal from shock is phenomenal. Either fresh frozen plasma 0.5 - 1 ml/kg TBSA or 5% albumin can be given. A reasonable indication of giving albumin early on, i.e. after 8 hours is serum albumin less than 2 g%.⁸

**Place of Whole Blood**

In extensive third degree electric burns or in third degree burn over 50% TBSA, actual entrapment of RBC and cell death results in severe hypoxia. This situation can be reversed by whole blood transfusion and preferably fresh blood improves the situation better. Fresh whole blood transfusion is usually given. This can be combined with crystalloids.

**Urine Output Monitoring**

Measured volume bags are preferably used. Child should void 1 ml/kg/hr of urine if resuscitation is adequate.
Diuretics are generally not indicated during acute resuscitation period. But in children sustaining high voltage electrical burns with myoglobinuria/hemoglobinuria, there is increased risk of renal tubular obstruction. Forced alkaline diuresis is indicated in such situations with urine output as high as 3-5 ml/kg/hr. To alkalize the urine, sodium bicarbonate is added, while an osmotic diuretic like mannitol achieves a high urine output.

**PROBLEMS IN RESUSCITATION**

It is important to identify acidosis. Electrolyte estimation must be done periodically and acidosis must be corrected without delay. There is a risk of hyponatremia and hyperkalemia early on.

Thermal injury results not only in massive fluid shifts that cause hypovolemia, but also in release of inflammatory mediators from burn wounds. These mediators deleteriously affect cardiovascular function and lead to burn shock. The end result of a complex chain of events is decreased intravascular volume, increased systemic vascular resistance, decreased cardiac output, end organ ischemic and metabolic acidosis. Without early and full resuscitation therapy these derangements progress to acute renal failure, cardiovascular collapse and death.

Resuscitation in itself is not without complications. Burn edema is worsened with resuscitation, particularly crystalloid solutions. The above given formulae are generalizations only; each child should get individualized treatment to avoid complications.

**INFECTION CONTROL**

Infection is the most common complication seen in the burn patients. Initially gram-positive organisms are the ones that cause sepsis but as early as 3 days post-burn gram-negative organisms start predominating. Systemic antibiotics are not recommended in burn patients for prevention of burn wound sepsis, as the burn tissue is a poorly perfused tissue. Also this practice leads to the emergence of resistant strains. They are certainly recommended in special circumstances such as:

- **Perioperatively**— Around the time of burn wound excision to limit the incidence of the bacteriemia. They should be guided by the quantitative burn wound cultures.
- **Autografting**— At the time of autografting to prevent local loss of the graft and also to prevent infection at the donor site. A first generation oral cephalosporin is good enough till the first dressing change if the cultures are not available.
- **Infection elsewhere**— In the presence of infection elsewhere such as pneumonitis, thrombophlebitis, urinary tract infection and sepsis, systemic antibiotics are obviously indicated.

Topical therapy is all that is required for most of the burn wounds. Appropriate topical therapy reduces microbial growth and chances of invasive sepsis. It should be soothing in nature, easy to apply and remove and should not have systemic toxicity. Such an ideal antimicrobial probably does not exist. The ones that are most commonly used are given in Table 26.2.9

**DRESSINGS**

Option of closed dressing and open dressing methods are available. In Open method, topical antimicrobials are applied and the wound is left open to warm dry air. Pseudomonas infections are rare but this method requires a strict environmental control and is painful. The fluid requirements also increase due to greater evaporative losses. This method is useful for facial and scalp burns. In closed dressings topical antimicrobial creams are applied and then covered with gauze dressings. This method is less painful though more labor intensive. Closed dressings are preferred for the extremities and over the back.

**SURGICAL MANAGEMENT OF THE BURN WOUND**

A proper assessment of the burn wound guides the choice of the surgical therapy.

**First Degree Burn**

As there is minimal loss of the barrier function of the skin, the infection and fluid loss are not common. Management aims at providing pain relief and optimal conditions for wound healing. Topical salves and oral analgesics are the only medications required.

**Superficial Second Degree Burn**

These require daily dressings with topical antimicrobials till spontaneous re-epithelialization
occurs in 10-21 days. Alternatively, temporary biological or synthetic dressings can be used.

**Deep Second Degree and Third Degree Burns**

Early burn wound excision has been shown to be beneficial in these types of burns.\textsuperscript{8,10} Advantages are

1. Decrease rates of infection as dead and devitalized tissue is removed.
2. Removal of source of inflammatory mediators.
3. Decreased scarring and more functional rehabilitation.
4. Decreased stay in hospital.
5. Early excision (< 48 hours) is associated with less blood loss.

Two types of burn wound excisions are described

1. **Tangential excision:** Implies sequential excision of burnt skin layers to reach the viable tissue layer. It is more time consuming and is associated with more blood loss and requires a certain experience.
2. **Fascial excision:** This involves removal of all tissue down to the level of deep fascia. This procedure is technically easier and is associated with comparatively less blood loss. As this procedure is cosmetically disfiguring it should be used in only compelling situations such as life-threatening burn wound sepsis.

Blood loss during the surgery can be controlled by use of tourniquets, elevating the limb and local application of thrombin solution or epinephrine soaked pads.

**Wound Coverage**

After burn wound excision, the tissue bed consists of dermis and the subcutaneous fat. It is necessary to cover this raw area to promote healing and to provide for better cosmetic and functional outcome.

1. **Autograft:** Ideal coverage is the patient’s own skin. It is generally possible to get enough split skin autograft in < 40% TBSA burns. Meshing allows more area to be covered and also allows for seepage of the exudates in the postoperative period. Maximum meshing allowed is 4:1. More meshing ultimately leads to more scarring; for this reason the grafts to be used on face and joints should preferably be not meshed.

2. **Autograft with allograft overlay:** If the autograft is inadequate a 4:1 or even 6:1 meshed autograft is used and over it 2:1 meshed allograft is placed. Allograft falls away as the autograft epithelializes

---

* All the agents have a place in comprehensive burn wound management fragment rotation of agents (weekly) decreases the side effects and resistance
underneath. In massively burnt patients, rejection is not a major issue as there is profound immunosuppression. It is mandatory to screen the donor for HIV, CMV, HBV and HCV before using these grafts.

3. *Allograft:* Allograft can be used for temporary coverage of the wound till the donor sites heal and further grafts can be taken from them. Such situations can arise in massively burnt patients (> 40% TBSA).

4. *Xenograft:* Porcine skin is readily available and it resembles human skin morphologically. It adheres well to the dermis and then is gradually degraded; the main drawback is its inability to prevent infection.

5. *Amniotic membrane:* Amniotic membrane can provide an excellent temporary biological coverage till more autograft is available (Figs 26.9 to 26.11). It is freely available, is non-antigenic and has some infection resisting properties. Cord blood sample should be tested for HIV, CMV, HBV and HCV prior to its use.

6. *Synthetic dressings:* Various biologically engineered membranes such as keratinocyte sheets, silicon mesh with porcine or human collagen and silicon mesh with fetal keratinocytes are available in the west but their cost and availability still precludes common clinical use.8

Reasons for the non take-up of grafts:
1. Fluid collections underneath the grafts—Meticulous hemostasis, meshing and good pressure dressings help prevent this complication.
2. Shearing stress on the grafted surfaces—It can be prevented by proper immobilization and splinting.

Fig. 26.9: Membrane applied over the areas after cleaning the wound

Fig. 26.10: Sixth day after membrane application
3. Infection—Good perioperative antibiotic cover based on cultures should be used.
4. Residual necrotic tissue in the bed—Adequate excision takes care of this aspect.
   Proper care of the donor sites to allow for reuse cannot be overemphasized, as every inch of the skin is precious. Donor area if not properly cared for behaves in the same way as a second degree burn.

HYPERMETABOLIC RESPONSE AND NUTRITION

Hypermetabolic Response

Burns > 40% TBSA cause a tremendous increase in the resting energy expenditure amounting to even 50-100%. The following factors contribute:
- Increased release of IL-1, IL-2, TNF-alpha, thromboxanes
- Increased release of stress hormones such as catecholamines, glucagon and cortisol.

All these promote systemic vasoconstriction and may lead to renal and mesenteric ischemia. This hypermetabolic response can be modified to improve the outcome:
1. Ambient temperature should be kept between 28-30 ºC.
2. Early enteral nutrition in the postburn period reduces the incidences of bacterial translocation and counters the catabolic state.
3. Beta-blockers can block the deleterious effects of catecholamines to decrease the heart rate and the cardiac output.
4. Growth hormone has also been shown to help in catch up growth by fostering a positive nitrogen balance. It also improves immunity and helps in faster healing at the donor sites.
5. Adequate pain relief also helps in decreasing the stress response. Specially during dressing changes intravenous pethidine can make dressing changes less distressful for these sick children.

Nutrition

Early establishment of enteral feeds as soon as the child is stabilized via a nasogastric tube decreases the metabolic rate, gastric atrophy, stress ulceration and bacterial translocation. Parenteral nutrition leads to more chances of systemic sepsis, thus enteral route with all its advantages is preferred. An adequate calorie intake provided as 40-70% carbohydrates, 10-20% fats and 20-40% protein should be the goal. Calorie requirement is calculated according to the Shriners Burn Institute formulas.
• Infant formula –1800 kcal/m² maintenance + 1000 kcal/m² area burnt
• For 1-11 years-1800 kcal/m² maintenance + 1300 kcal/m² area burnt
• > 12 years-1500 kcal/m² maintenance + 1500 kcal/m² area burnt

COMPLICATIONS AND REHABILITATION
Apart from the myriad acute metabolic and systemic complications the burn patient might experience, the following complications deserve a special mention.

1. **Burn wound sepsis:** Burn wound sepsis is indicated by change of the color to black or dark brown, hemorrhage of the fat underlying the eschar, progression of the partial thickness injury to full thickness, dirty foul smelling exudates, premature separation of eschar or appearance of eruptions. Treatment involves change of topical antibiotics, systemic antibiotics and excision of the burn wound.

2. **Pulmonary complications:** Inhalational injury as such and other conditions like profound immunosuppression, systemic sepsis and ventilation predispose the burnt patient to pneumonia. Management includes judicious use of antibiotics, aggressive physiotherapy and respiratory care.

3. **Gastrointestinal complications:** Hypokalemia in the acute phase, sepsis, hypovolemia all contribute towards ileus in the postburn period. Management includes nasogastric suction and correction of underlying etiology. Gastric ulceration and bleeding- Curling’s ulcers are also common due to impaired perfusion and the stress response. Antacids are no longer recommended for prevention as these increase gastric pH and colonization of the stomach. Sucralfate and early enteral feeds are the strategies that are most helpful.

4. **Orthopedic complications:** Osteomyelitis, non-healing fractures, ulcers and heterotrophic calcification are also common.

LONG-TERM COMPLICATIONS

**Hypertrophic scar:** It is the phase of redness and induration that is seen during the healing phase of deep second degree and third degree burns. Spontaneous resolution occurs in most of the cases. Pruritus associated with these scars can be managed by local application of emollients, 1% hydrocortisone ointment, local triamcinolone injection or systemic anti-histaminics. Pressure garments also help in fast resolution.

**Contractures:** Burns occurring at the flexor aspects of joints and if deep are especially prone to develop contractures during the healing phase. All scars and split skin grafts have a tendency to shrink, and this tendency is more with thin grafts. Contractures are best prevented by

- Use of thick grafts at the joints.
- Splinting the joints for three months in a functional position after grafting (while keeping in mind that prolonged splinting may cause periarticular fibrosis and joint capsule contractures).
- Pressure garments and silicone gel dressings provide a uniform pressure over the healing area and thus may help in prevention of contractures.

Established contractures require surgical management:

- Local re-arrangement of skin as single or multiple Z-plasties
- Free grafts— A thick free graft can be placed after the excision of the contractures is small. For a large contracture a relaxing incision is given at the site of maximum tension and a free graft is placed in the resulting defect
- Flaps— Full thickness flaps that can be pedicled or myocutaneous flaps can be utilized to release the contractures.
- Tissue expanders— It can be used to expand the nearby normal full thickness skin which can then be used as a rotational flap to release the contracture.

REHABILITATION
Burns produce a severe psychological set back in many individuals and especially in children. Their proper growth and development depends upon their psychological rehabilitation. Nurses and medical staff must be children friendly.

Social rehabilitation also has to be emphasized. They must be accepted by the society at large. Occupational therapy and rehabilitation form an integral part of burn therapy.

REFERENCES
Hemorrhage into the gastrointestinal tract due to abnormal communication of blood vessels with intra- or extra-hepatic biliary tract is called hemobilia. In some rare occasions, communication occurs between the branches of cystic artery and the lumen of gallbladder as in necrotising cholecystitis or trauma, leading to hemobilia.

‘Bilhemia’ is relatively a similar condition where low pressure venous communication leads to flow of bile into the venous circulation leading to a rapidly developing jaundice.

Bleeding into gastrointestinal tract secondary to an enterobiliary fistula is excluded from the definition of hemobilia by Sandblom. Since traumatic hemobilia is not a common entity in the pediatric population, it should be managed in a specialized institution. Traumatic hemobilia has been described following both blunt and penetrating liver trauma, though the incidence is low in children as compared to adults.

Surgical trauma is the commonest cause of hemobilia that includes therapeutic or diagnostic transparenchymal maneuvers (PTC, biopsy, etc.). Non-surgical trauma includes both blunt or penetrating liver injuries and the reported incidence of hemobilia is 1-1.5% of all hepatic traumas (Grade 2-Grade 5). Blunt trauma 1.8% and penetrating trauma accounts for 1%.

PATHOPHYSIOLOGY

Sandblom with his experimental model tried to explain the pathophysiology of post-traumatic hemobilia. 1

1. Intrahepatic biliary leak causes lysis of clot and erosion of damaged arterial wall.

2. Formation of hepatic artery pseudo-aneurysm that later ruptures into adjacent biliary radical leads to hemobilia.

Surgical closure of liver laceration at initial presentation following trauma may lead to creation of arteriobiliary fistula leading to hemobilia.

CLINICAL PRESENTATION

Traumatic hemobilia is an unusual complication following liver injury characterized by triad of gastrointestinal hemorrhage, biliary colic and jaundice. The biliary colic may present as pain in the right hypochondrium. The gastrointestinal hemorrhage may present as melena or hematemesis. One should always elicit an antecedent history of trauma.

Hemobilia usually manifests by 7-10 days following trauma but a review of literature records hemobilia from 1 day-3.5 years after injury caused by communications between intrahepatic blood vessels and the biliary tree. Thus, one should keep in mind that occasionally hemobilia may present even days or months after the injury.

The differential diagnosis includes other causes of enterorrhagia, obstructive jaundice and anemia specially in those cases who have delayed and atypical presentation with jaundice or progressive anemia with or without melena/hematemesis and have doubtful history of antecedent trauma to correlate. In the long-term, patients may present with complications like biliary tract stricture, calculi, sludge or cholangitis.

INVESTIGATIONS

The diagnosis may be suspected on clinical grounds and verified by a combination of various modalities.
Duodenoscopy, CT scan abdomen, USG with Doppler, hepatobiliary scintigraphy, ERCP, MRI and MR angiography and cavitogram have their own specific roles and are very useful for corroborative evidence, comprehensive evaluation and follow-up in the management of hemobilia.

A large number of modalities are required for quick diagnosis and localization of site of hemobilia. Thus, patients of traumatic hemobilia should be treated in a multidisciplinary tertiary care center.

Quick diagnosis is warranted for localization and control of bleed as mortality increases with the delay. Delay also leads to infective complication of intrahepatic bile leak that further aggravates the morbidity.

**Ultrasonography and Color Doppler**

Ultrasonography with color Doppler study detects any space occupying lesion in liver, aneurysm arising from hepatic arteries/branches, biliary clots and site of liver injury. But fails to visualise site of bleed.

**Upper GI Endoscopy**

With the advent of side viewing pediatric scopes, it is now possible to visualise active bleed from the papilla. It also rules out other causes of upper GI hemorrhage.

**Endoscopic Retrograde Cholangiopancreatography (ERCP)**

The role and value of endoscopic retrograde cholangiopancreatography (ERCP) in the pediatric age group is increasing though at a slow pace. Presence of hemobilia is an indication for ERCP. In select group of patients, it can delineate the rent in the biliary radical, posthemobilia clots in CBD and gallbladder and post-traumatic stricture in b bile duct. Endoscopic retrograde cholangiopancreatography (ERCP) revealed biliary leak in right duct in 14 (70%) and in left duct in six (30%) patients in a series. Endoscopic treatment with nasobiliary drainage without sphincterotomy has been reported as the optimal method of management of traumatic hepatobiliary injuries in hemodynamically stable patients from a series of 20 patients out of which 7 were children. Transient mild pancreatitis may occur as a complication of ERCP.

**Angiography**

Selective hepatic artery angiography is the investigation of choice, as it visualises the site of bleed and offers opportunity to embolise the bleeder and achieve early control of the bleed which otherwise can be life threatening many a times. An intrahepatic false aneurysm in a ten-year-old boy with post-traumatic hemobilia has been successfully embolized during diagnostic angiogram. Selective angiography during episode of active bleeding not only confirms the diagnosis but also localises the site of bleeding and helps controlling it by embolization.

**Radionuclide Scans**

HIDA scan may show visualization of biliary radicals without tracer pooling and non-excretion to gut due to rapid recycling through vascular communication. Blood pool scan helps in visualizing site of active bleed from GIT and liver, but is inferior to angiography in localisation.

Blood pool scintigraphy of the liver demonstrated accumulation in the central part of the right liver lobe in a 9-year-old girl with severe hemobilia developing one week following surgical evacuation of the subcapsular hematoma due to blunt abdominal trauma. The blood pool scan was also helpful in the post-treatment evaluation as it became normal after embolization of the right hepatic artery.

**MRI and MR Angiography**

MR angiography has been used to detect active bleeding from the parenchymal injury site and clots. Its useful in identifying the vascular lesions causing hemobilia. MRI angiography has been reported to reveal a ruptured pseudoaneurysm of the ramus dexter of the proper hepatic artery that was successfully treated with embolization.

**Contrast Enhanced CT Scan**

It is usually done for initial assessment of severity of visceral trauma (Fig. 27.1A). Spiral CT helps in delineating vascular and biliary anatomy, localization of site and any intrahepatic cavity formation.

**MANAGEMENT**

There is considerable controversy with regard to the management of traumatic hemobilia.
Non-surgical Treatment

Non-operative management has become the therapeutic method of choice in hemodynamically stable patients with liver trauma. There are a few reports of endoscopic management of traumatic hepatobiliary injuries. Successful non-operative management with repeated angiographic monitoring has been reported in cases in which the bleeding is not massive (< 50% blood volume replacement). However, a mortality of 60-70% has been reported with this approach in literature.

Angiographic Embolization

Angiographic embolization has been the preferred treatment in recent years. However, 20-30% of cases show recurrences (usually 2-3 weeks post-embolization) after an average of two to three attempts.

Arterial embolization is done after placing appropriate catheters as close as possible to the bleeding site (Fig. 27.1B). Embolizing materials used are gelfoam, polyvinyl alcohol particles or steel coils, alone or in combination. Postembolization angiography may be performed to confirm adequacy of embolization. Surgery may be indicated in cases of failed embolization. Angiographic embolization has been reported as an effective treatment with a low complication rate to stop liver hemorrhage. However, few notable complications have been reported like gallbladder infarction.

Surgical Management

Surgical options include hepatotomy with suture ligation of bleeder and repair of biliary rent if feasible, ligation of hepatic artery or its branch, segmentectomy and lobectomy.

Early intervention and direct suture ligation of bleeding vessels or procedures like lobectomy or segmentectomy have not been reported as encouraging in a immediate post-traumatic situation with high morbidity and recurrence. Ligation of common hepatic artery or one of its branches, although a simple procedure, also has a significant morbidity and recurrence rate. Ischemia and sepsis are main complications often requiring formal lobectomy.

Surgical management of traumatic hemobilia by direct ligation of the bleeding vessel has also been done successfully in children without postoperative problems. The authors have had to resort to surgical management in a 10-year-old patient with hemobilia with two failed attempts of angiographic embolization with gelfoam and coils and one attempt of percutaneous embolization of a pseudoaneuerysm under ultrasound guidance to control the bleed. Thus...
failure of embolization techniques with recurrence of massive gastrointestinal bleeding are an indication of early surgical intervention.

Hepatotomy may be done for exact visualization of the rent. Suture ligation of the bleeding vessel and repair of biliary rent may be done under vision. Closure of the hepatic cavity may be done with gelfoam.

FOLLOW-UP

A close follow-up of these children for recurrence or complications, should be kept in practice, so that any recurrence after 2-3 attempts of embolization treatment or development of septic/ischemic complication will be urgently dealt with surgical management. Because these patients carry a higher incidence of morbidity and mortality, further prolongation of conservative methods is not advisable.

Investigations like color doppler ultrasound and contrast-enhanced computed tomography may be done to assess the post-treatment status of the patient. Blood pool scintigraphy of the liver may also be helpful. Long-term observation of cases of traumatic hemobilia for development of post-hemobilia complications like cholelithiasis, stricture, sludge or stone in CBD is recommended.

SUMMARY

Traumatic hemobilia is an unusual but life threatening complication following liver trauma. Any patient with suspected diagnosis of traumatic hemobilia should be managed in a multidisciplinary institutionalized care where facilities of pediatric endoscopy angiography, embolization, hepatobiliary scan and none the less MRI and CT scan should be available. Initial stabilization with blood transfusions if required and angiographic embolization is the initial preferred treatment.

THORACIC SURGERY
"Biography is the only true history;" the history of gastroesophageal reflux borrows from the biographies of many remarkable names, including Bettes, Nissen, Billard, Chevalier Jackson, Allison and Barrett- more of whom later.

In this chapter, the current thinking on gastroesophageal reflux (GER) will be explored, but first it is necessary to describe the condition, to relate its definition to the important parameters, and outline those facets which are particularly significant to patients in the pediatric age-group.

**DEFINITION**

GER may be a physiological phenomenon, but in clinical practice may well prove to be pathological, (esophagitis, peptic esophagitis, or the more severe erosive esophagitis). From a pediatric point of view, its importance is related to its frequency, and potential for creating serious problems. It is generally agreed that there is a sphincteric mechanism at the lower end of the esophagus. Although its exact nature is unclear, its main function is to prevent gastric contents from passing proximally into the esophagus. Recent studies have shown that the proximal passage of gastric contents is not always pathological but, under certain circumstances, may result in morbidity, even mortality, more often than not resulting from pathological changes in the esophagus itself.

But in addition, there may be an anatomical component, as well as physiological and pathological components (potential or otherwise), and it is therefore relevant to consider problems at the gastroesophageal junction in terms of:

1. The physiological problem (GER) which is a direct result of sphincteric incompetence.
2. The anatomical problem, whereby a hiatus hernia is present and the gastroesophageal junction (GEJ) is situated at a level higher than normal.
3. The pathological problem, esophagitis, which is secondary to GER, and this may be erosive or non-erosive, and recent evidence has shown to include both acid and alkaline components.

This concept of division of the problems at the GEJ into these three components is particularly valuable in discussions with the parents of infants with GER, and in all teaching programs.

**RELEVANT ANATOMY AND PHYSIOLOGY**

It is impossible to understand the mechanisms responsible for gastroesophageal reflux without a knowledge of the relevant anatomy, and this must, whenever possible, be correlated with information on both normal and abnormal physiology.

There are three anatomical components: The esophagus, which acts as the pump; the lower esophageal sphincter, which is effectively the valve: and below this, the stomach, which is the reservoir. The esophagus has an intra-thoracic component and a short, but extremely important, intra-abdominal component. The lower end of the esophagus, where it passes through the hiatus in the diaphragm, is somewhat dilated, and this is referred to as the phrenic ampulla. The very important lower esophageal sphincter is comprised of elements from the muscular mantle of the tubular esophagus, with contributions from the inner layer of the esophagus and the external layer, the latter diverging in a fan-shape leading...
distally to the high-pressure zone. In addition, there is the gastric sling, which is part of the muscle of the greater curvature of the stomach, helping to build the angle of His (Fig. 28.1).

Boix-Ochoa points out that the high-pressure zone in the lower esophagus is only 0.8 cm at 27 weeks' gestation, but reaches a length of 1.0 cm at term. He stresses the "trinity" of factors responsible for the anti-reflux mechanism (Fig. 28.2).
1. The length of the intra-abdominal esophagus; (Fig. 28.3)
2. The gastroesophageal angle;
3. The crural fibers of the diaphragm and their pinch-cock action.

As a consequence of these factors, the inspiratory decrease in intra-thoracic pressure and the increase in intra-abdominal pressure are counter-acted.

But there is a fourth factor: The phrenoesophageal membrane, which is not a ligament but a fibroelastic membrane which holds the fundus and lower esophagus in place.

All these factors should be - and usually are - taken into account when surgical measures are adapted to re-establish gastroesophageal competence and combat GER.⁴

Whenever, possible, anatomical factors must be correlated with physiological factors, and here the functional capability of an intact LES is vital (Fig. 28.4). A deficient LES does not allow development of the normal physiological mechanisms designed to prevent GER.

---

**Fig. 28.1:** The phrenoesophageal ligament anchors the distal esophagus to the crural diaphragm, therefore contraction of the crural diaphragm (respiration) exerts with the sling fibers of the right crus a pinch-cock-like action on the LES producing a mucosal flap valve preventing the GER

**Fig. 28.2:** The antireflux barrier is the interaction of different factors. This anatomic and physiologic interplay constitutes the antireflux mechanisms

**Fig. 28.3:** The cornerstone of the GER mechanisms is the lower esophageal sphincter with its intra-abdominal segment, the quality of this segment is balanced with a longer intrathoracic segment to compensate in the some way for its apparent weakness

**Fig. 28.4:** High pressure zone: When the LES barrier is challenged by an increase of intragastric pressure it responds by active contraction exceeding the increase, which shows we are before a dynamic response which increases the tone of the area (HPZ) independently from any other factors
Boix-Ochoa carried out extensive studies on premature babies (4028 cases in all) and found that they have low LES pressure - a fact which correlates well with clinical experience.

Of further anatomical significance is the demonstrable asymmetry of the muscular thickness of the GEJ, and the finding that, with an increase in the thickness of the inner circular muscle, this is continuous with the gastric component — thus constituting the gastric SLING and CLASP fibers.

In an important contribution, Mittal draws attention to the dual mechanism, comprising the intrinsic smooth muscle of the esophagus and the extrinsic skeletal muscle of the diaphragmatic hiatus. The crural diaphragm is usually 2 cm in length and it follows that part of the LES is intra-abdominal.

An important and normal physiological phenomenon is transient relaxation of the LES (TLESR) which both causes, and fails to prevent, GER. It is interesting, also, that evidence shows the crural diaphragm contracting earlier than the rest of the diaphragm - an important factor in preventing GER (Fig. 28.5).

It is generally recognized that the disturbed anatomical situation when a hiatal hernia is present is associated with hiatal incompetence. From a pathological point of view, one end result of GER is esophagitis, which may be non-erosive or erosive - and referred to as gastroesophageal reflux disease (GERD).

The innervation of the LES must also be taken into account. There are two opposing neuronal systems:
1. Cholinergic; and
2. Non-adrenergic, non-cholinergic; and each may have either stimulating or inhibitory effects. More recently, emphasis has been placed on the role of nitric oxide (NO) and its inhibitory effect on LES relaxation, and on the CAJAL interstitial cells. VIP and CGRA, may also play a role.

The literature on the subject of gastroesophageal reflux is now voluminous, and it is only possible to refer to segments of the literature; but nevertheless, the following should be seen in context of the details outlined in the Chapter, in an attempt to correlate the symptomatology and the influence of treatment, which would otherwise be quite incomplete.

1. There are age-related factors, as exemplified by Orenstein’s question: “Do infants respond differently to esophageal distention?” An answer is that the baby’s prosperity to regurgitate will probably disappear with age.
2. Esophageal clearance (Caste”) with esophageal peristalsis, and its assessment by radiology and manometry, correlated with the role of saliva, which also plays a role.
3. Esophageal “acidification” and the evidence that the LES pressure falls with this acidification, which no doubt helps establish a vicious circle (Blackshaw).
4. TLESRs, and its impact on “physiological” and “pathological” reflux.
5. The "physiology" of belching.
6. Others have commented on the absence of age and gender effects.

Boix-Ochoa summarized the situation, implicating TLESRs, the speed of esophageal clearance and mucosal resistance, and the fact that GER results in chronic esophagitis, aspiration pneumonia, stricture, and at times, the mucosal changes identified as Barrett’s esophagus. Thus he demonstrated the clinical correlation, as well as the vicious circle aspect (Figs 28.6 and 28.7).

GERD is now recognized as a chronic condition with associated symptoms, such as heartburn; but endoscopy is only positive in 50% of such cases. Males are affected more than females, but not in the younger age-groups in whom regurgitation is a very common event. Associated features may include weight-deficit, apnea, pneumonia irritability and hematemesis. In
many people there is an essential need for investigation, particularly with pH-metry, barium studies, endoscopy and biopsy. Reflux can be recognized as regurgitant or non-regurgitant, and it is necessary to distinguish reflux from vomiting from other causes and from rumination. The latter is possibly associated with psychosocial factors. GER may lead to GERD which clearly is definitely multifactorial and significant parameters which can be recognized, include age, sex, body-mass index, presence of a hiatus hernia and the number of reflux episodes.

Scintigraphy may be valuable, in particular for demonstrating pulmonary aspiration and decreased esophageal clearance.

Gastric emptying studies are valuable in children, and there is evidence that fundoplication may result in worsening of symptoms if foregut dysmotility is present (Fig. 28.8).

A miscellany of chemical and hormonal factors is involved in these circumstances, including nitric oxide (NO), substance P, carbon monoxide (CO), heme oxygenase, prostaglandins and possibly of more clinical significance—erythromycin.

Other factors include: Calcium channel blockage; the possible role of proton pump inhibitors (PPI) in facilitating the healing of esophagitis the manometric definition of LES -and techniques currently in use, especially the Dent’s sleeve technique and more recently. The role of endoscopic measurement of the LES; LES manometry, facilitates recognition of anamorphic localization, exact pressure and length and helping in clinical decisions on the roles of medical and/or surgical treatment. Electromyography of the esophagus, which is less of a clinical tool than one for research. There has also been a recent increase in interest in duodenogastroesophageal reflux and the effect of mucus secreted by the esophagus. Recognising GER and atypical symptoms, including respiratory symptoms such as asthma, laryngitis, apnea, malaise and sudden death is also important.

Manometry if available, is of considerable value, including ambulatory manometry. The pepsin factor has also gained importance. Pepsinogen gives rise to pepsin, which in turn acts on protein, breaking it down into peptides, and these are potentially injurious to mucosa. Cholinergic stimulation may be drug-related.
with the drugs including Bethanechol, Metaclopramide, Cisapride and Erythromycin. However, recent evidence suggests Cisapride may have potentially dangerous side effects.

**HIATUS HERNIA**

Recognition of a hiatus hernia is essential, as it results in a reservoir of acid in the supra-diaphragmatic pouch, and also interferes with esophageal clearance and causes a defect in the LES, combined with attenuation of the phreno-esophageal membrane. In the past, the presence of a hiatus hernia was automatically associated with reflux and was an indication for surgery. By definition, hiatus hernia is present when the EGJ and a portion of the stomach are situated above the esophageal hiatus. Today, however, it is appreciated that the situation is more complex, with factors including an inadequate anti-reflux barrier, volume factor and mucosal resistance; esophageal reflux disease (GERD) being associated with a hiatus hernia.

Radiological evaluation is technique-related. This may show an esophageal mucosal ring which can simulate a stricture or incidental changes associated with esophagitis, including erosion and ulceration. pH-monitoring has, of course, become the gold standard. An early contribution was made by Spencer in 1969, and another some years later by Johnson and de Meester, who stated that 24-hr pH-metry, was necessary to evaluate the total percent of reflux time.

Gastric motility and gastric distension are important factors, but opinions differ regarding the role of fatty foods. Gastric stasis and gastric dysrhythmia are also important, and in this context, it must be stressed that gastric stasis is only one factor. Antroduodenal motility studies as performed by Lorenzo in patients in the pediatric age-group were correlated with the existence of GERD and LES relaxation. Duodenogastroesophageal reflux involves acid, pepsin and bile salts, but it is important to recognize that GERD is only at one end of a spectrum of motility disorders. Perhaps it is relevant to note the role of NO on pyloric tone and gastric emptying.

Finally, the importance of the LES as a protective barrier cannot be over-estimated. Minimal physiological reflux is permitted, but the role of gastric emptying must always be recognized. If GERD exists with a competent LES, medical treatment is indicated. But if manometry shows a low LES, there is definitely a role for surgery, and the presence or absence of esophagitis, stricture or a Barrett’s esophagus, particularly if these persist, leads one toward surgery. Some observers feel that surgical results should be evaluated by manometry, and others have stressed the value of ongoing endoscopic evaluation.

**PATHOLOGY AND PATHOGENESIS**

The significant pathology in patients with gastroesophageal reflux (GER), regardless of age, is esophagitis, part of the GERD complex. This is sometimes referred to as peptic esophagitis, and sometimes squamous esophagitis, the latter term having the advantage of distinguishing the condition from Barrett’s esophagus. The process is inflammatory, and affects the squamous lining of the esophagus.

There are several ways to grade the severity of the esophagitis.

The classification introduced by Skinner is particularly useful, having the additional advantage of correlating the changes with the endoscopic findings. Four grades were recognized and described:

**Grade 1:** Distal esophageal mucosal edema. The may obscure the squamo-columnar epithelial junction.

**Grade 2:** Mucosal erythema with superficial ulceration, typically linear and vertical and with an overlying fibrinous membrane exudate that is easily wiped away, leaving a bleeding surface. This is not “scope trauma”.

**Grade 3:** Mucosal erythema with superficial ulceration and associated mucosal fibrosis — A so-called dilatable “early” stricture.

**Grade 4:** Extensive ulceration with fibrous luminal stenosis. This may indicate irreversible pan-mural fibrosis.

The original classification system proposed by Savary and Miller recognized the following four grades:

**Grade 1:** Single or isolated erosive lesions, oval or linear, but affecting only one longitudinal fold.

**Grade 2:** Multiple erosive lesions, non-circumferential, affecting more than one longitudinal fold, with or without confluence.
Grade 3: Circumferential erosive lesions.

Grade 4: Complications: Columnar epithelium, ulcer, stricture and/or short esophagus—alone or associated with Grades 1-3. Later, some observers have separated Grade 4 into 4a and 4b, depending on the presence or absence of acute erosive and/or ulcerative changes.

It is essential that the surgeon understand the grading system, regardless of whether he is the endoscopist assessing the findings, because therapeutic decisions will be influenced by the severity of the esophagitis. Detailed comments on the various grading systems have been made by, among others, Armstrong, Tyagat and Lundel and Boyce.

It is not sufficient, however, to consider only the macroscopic appearances of esophagitis; it is also important to be familiar with the historical changes which are identifiable. These include lengthening of the papillae so that they occupy more than 2/3 of the thickness of the mucosa. There is also hyperplasia of the basal zone, which may occupy more than 50% of the total thickness of the mucosa. The nuclei of the basal cells are enlarged, and hyperchromatic, but unlike the nuclei of dysplastic cells, they are relatively uniform in size and shape.

Perhaps of greater significance is the finding of intra-epithelial eosinophils, or intra-epithelial neutrophils. This finding is stated to be diagnostic of esophagitis. By contrast, intra-epithelial lymphocytes have little clinical importance because they can be found normally in the esophagus.

This then is the primary pathology, but the pathological process can only be considered alongside the pathogenesis and although peptic esophagitis is essentially the result of refluxate containing acid, the alkaline component of the refluxate may also be significant. Experimental and clinical observations in recent years have drawn attention to duodenogastric-esophageal reflux.

The discussion of pathology also necessitates consideration of what may be referred to as secondary pathological processes, including the development of columnar-lined lower esophagus (Barrett’s esophagus).

When GER is associated with aspiration into the respiratory tract, it is inevitable that there will be pathological conditions such as bronchitis and aspiration pneumonia—although these are not the only respiratory manifestations seen in GERD.

THE CLINICAL PICTURE

The symptomatology of gastroesophageal reflux has been described in a wide variety of published articles, and in pediatric surgery and gastroenterology textbooks. Reference to these provide adequate details regarding the clinical details (Fig. 28.7).

It is important, however, to recognize that there are three groups of those patients who present in the pediatric age-group.

GROUP 1

Those with Digestive Symptoms

This is the predominant group in infants and children, and the predominant symptom is vomiting. It is pointed out by Jolley (1998), based on his investigations into the findings with prolonged esophageal pH recording, there are three patient types of GERD, which he refers to as Types 1, 2 and 3. These reflux pattern types correlate with the clinical radiographic and manometric findings, and the prognosis. Thus, in the majority of infants, the symptoms will resolve but this does not necessarily mean that the reflux has ceased and these infants should certainly be kept under observation.

This approach must be born in mind, although it is now well-known, and as Herbst and Meyers 28 stressed, 1981 it is essential to be familiar with the natural history. The evidence has indicated that, in the majority, the symptoms are present by the age of two months, and that 60% have a benign course and are free of symptoms by the age of 18 months.

Some authors have pointed out that about 30% have some persistent symptoms - at least to the age of four - and 5% develop strictures.

This then is the natural history of non-bilious emesis. Appropriate clinical and radiological investigation will enable this group of infants to be distinguished from those with an alternative diagnosis, e.g. pyloric stenosis, urinary-tract infection, etc. however, most babies who "split up" will improve, usually at about the age of 8-9 months, and no doubt that is related to the assumption of a more upright position throughout the day. It follows that the majority who fall into this group will improve, regardless of therapy, and clearly decision-making is largely based on the clinical history and the age of the patient. Although in most instances, vomiting is now
Gastroesophageal Reflux in Children

associated with failure to thrive, at times it may be forceful and voluminous and vomiting of this nature may not necessarily dispute the possibility that the basic problem is reflux. The age of this group of patients makes it difficult to assess such symptoms as pain and heartburn, which are so common in adults, but it is believed that restlessness and irritability may be an indication that the reflux (GER) is associated with esophagitis (GERD). The pediatric surgeon must be familiar with the natural history of vomiting in infancy due to reflux, and recognize the fact that he may well see a specific group of patients whose symptoms have not resolved, as would be expected in the majority of infant refluxers.

GROUP 2
Those who Fail to Thrive
Babies who have GER may fail to thrive, even presenting with acute dehydration with electrolyte imbalance. As expected, there will be a correlation between failure to thrive and the degree of vomiting, but it is definitely less than 100%. When electrolyte imbalance is present, which is certainly unusually, there may be difficulties in differentiating GER from pyloric stenosis.

GROUP 3
Respiratory Symptoms
In recent years, it has become clear that various respiratory symptoms may occur as a consequence of GER, including episodes of apnea, choking, respiratory arrest and apparent life-threatening events. Other respiratory features include recurrent aspiration pneumonia, recurrent wheezing, chronic cough, stridor and chronic lung disease. Patients presenting with any of these symptoms may need to be investigated to determine whether GER is present.

Numerous articles have appeared on this subject, and many authorities have stressed the fact that the causal relationship is not always clear: Reflux may lead to respiratory-tract involvement; or respiratory disease may result in reflux; or their relationship may be coincidental. It is in this group of patients that a complete investigatory profile is required and two investigations which are most likely to be of value here are 24-hour pH metry and scintography. Herbst (1981) summarized the situation as follows: "Once the reflux material gets to the level of the pharynx it may be aspirated and cause pulmonary problems. This is a major problem in children; pulmonary symptoms were present in 47% of patients in our center who had surgical repair. These pulmonary problems may mimic those of recurrent obstructive bronchitis or recurrent aspiration pneumonia. In older patients and adults, usually the lower lobe is involved. Because infants spend a large portion of their time recumbent, there is a predilection for the upper lobes, especially the right. Choking and apnoea may be a major problem, especially in the first year of life. Usually it occurs during or just after feeding and may be associated with bronchospasm".

GROUP 4
Other Associated Conditions and Syndromes
It is particularly important to recognize the Sandifer syndrome, in which there is intermittent head- cocking. Although the mechanism is not clear, clinical evidence indicates that the symptoms are quite definitely related to GER.

Down’s syndrome is also associated with GER, as are other neurological abnormalities. Later in the chapter, reference is made to GER in association with various neurological abnormalities and following repair of esophageal atresia.

INVESTIGATIONS
At the outset, it is important to stress that investigations may have clinical implications or may represent the fruits of a wide variety of research activities. Many of these later may eventually become standard clinical investigations, but at present must be considered experimental, e.g. the measurement and assessment of significance of bile salts and bile acids in the refluxate.

To the clinician involved in the care of patients with gastroesophageal reflux, in children and adults, a wide variety of investigative modalities is now available, respiratory one of the most exciting developments in the whole area of GER. At the same time, the pediatric surgeon must recognize that in the vast majority of cases, as outlined in the section of symptoms, investigation will not be required. Even if investigation is considered necessary, it may well be possible to limit
Pediatric Surgery—Diagnosis and Management

it to a radiographic study, provided this study is carried out by an experienced radiologist and, if possible, the clinician in charge of the patient is present when the study is performed. The presence of clinician has advantages for both radiologist and surgeon.

The two broad objectives of investigation are:
1. To confirm or deny the presence of GER—recognizing of course that some tests are not 100% sensitive. However, the "gold standard" in this group is recognized to be 24-hr pH-monitoring.
2. To provide information regarding the severity of GER and whether this has proceeded to GERD. The classic and most useful investigation in this group is again 24 hr pH monitoring, but this will frequently need to be supplemented by endoscopy and biopsy.

With these facts firmly in mind, the surgeon of today will know that the following investigations are possible, although not all may be available in this institution.

Radiography

This will certainly not be necessary in all cases. In most infants with non-bilious vomiting. It is usually possible to make a confident diagnosis of GER, along with the prediction of a good prognosis with resolution of symptoms. A barium swallow and limited barium meal is designed to diagnose GER and provide information regarding esophageal function, the presence of absence of an anatomical abnormality (hiatal hernia) and the presence of a stricture in the esophagus. It is best to remember that the narrowing diagnosed as a stricture may be the result of spasm or edema, and is not necessarily an indication of esophageal fibrosis. If a hiatal hernia is present, due notice must be taken of its size, but also it is important to distinguish this from the normal dilatation of the lower end of the esophagus, which is referred to as a phrenic ampulla.

pH Monitoring

This has evolved and been modified since the original description by Tuttle, but in this context attention should also be drawn to the Bernstein test, which was designed to distinguish pain the chest due to reflux from the other causes of chest pain. Today, however, the gold standard investigation is 24 hr pH monitoring, which may be combined with manometric findings.

The contribution of Skinner remains relevant today, although it dates back to 1970. He reviewed the role of esophageal function tests, specifically directing our attention to four tests: manometry, acid perfusion, pH-reflux and acid-clearing. He also related findings to pre- and postoperative studies, specifically with reference to a wide variety of operations including the Belsey Mark IV, the Nissen fundoplication, the Hill operation, the Collis procedure (with or without vagotomy) and the original Allision repair, to name but a few.

Euler and Ament recommended the Tuttle test be include in the diagnostic evaluation of pediatric patients presenting with GER. But this was twenty years ago, and today it is essential not only to be selective in deciding whether pH metry should be performed, and to recognize that more modern tests have replaced the technique described by Tuttle. Euler and Ament have pointed out that the esophageal intraluminal pH test has proved safe, simple and sensitive, indicating as it does hydrogen ion reflux from the stomach to the esophagus across the LES anti-reflux barrier.

For pediatric patients, Johnson and Jolley made a valuable contribution. Their scoring system for 24 hr pH-monitoring is an adaptation of the adult system published by Johnson and De Meester. The test should be performed by a pediatric gastroenterologist with appropriate laboratory facilities and analysis of the pH recording shows:
- frequency of reflux
- the longest single reflux episode,
- the percentage of time the pH was less than 4.
- The state of wakefulness of the patient

These observers describe three patterns of reflux, and indicate that their findings suggest that those with Types 1 and 3 were less likely to resolve with time. Type 2 was more likely to undergo spontaneous resolution.

Esophageal Manometry

While views differ, there is no doubt that this modality, if available, can provide useful information. The most useful study surrounding pH metry, manometry enables recognition of the site of the LES, permitting accurate placement enabling pH measurements at various levels in the esophagus above the LES.
Manometry also provides information regarding the tonus in the LES, and interestingly enough, this is not always low in patient with GER. Other information can be obtained regarding esophageal clearance and peristaltic waves (primary, secondary or tertiary). As with 24 hr pH monitoring, the information must be correlated with the clinical picture and the results of other studies, to facilitate decision-making regarding treatment and to monitor the individual patient's progress. It must however, be stressed that sophisticated manometry studies should only be performed in selected cases, and by a pediatrician experienced in the technique.30

Scintigraphy

Radionucleide studies have a definite role to play, but should only be used in selected cases. Orenstein pointed out in 1993 that scintigraphy "can detect neutral postprandial reflux, identify aspiration, quantify gastric emptying and may avoid esophageal intubation". Her view was that simultaneous pH probe and scintigraphy being most sensitive in the early postprandial state, whereas the pH probe is most sensitive in the fasting state. As early as 1981, Herbst and Meyers suggested that possibly the gastric scintiscan has a number of theoretical advantages; in particular, the radiation dose is less than that for a single chest film. Fonkalsrud et al were strong advocates for pyloroplasty when significant delayed gastric emptying has been documented, and their method was to use radioisotope techniques with the inclusion of technetium-99m sulphur colloid with the normal diet and to quantify the magnitude of gastric retention at various time intervals. To summarize, scintigraphy has a role, particularly in those patients where delayed gastric emptying or pulmonary aspiration is suspected. But as many authorities have pointed out (including Spitz and co-workers) it is only a modality which should be invoked for selected cases.

One of the most important contributions in the detection of reflux-associated with pulmonary aspiration was by Arasu and co-workers. who found that a gastroesophageal scintiscan was positive only in 17/30 patients with GE reflux. They concluded that the GE scintiscan was complementary to barium studies but that neither scintigraphy nor radiography approached the accuracy of more sophisticated tests.

Endoscopy and Biopsy

It is very tempting, but unnecessary, to perform esophagoscopy and biopsy in many patients with GER, but again, selection is required. Unnecessary endoscopy can only lead to increasing parental anxiety, which in turn, may be reflected in the behavior of the infant. However, although there may be radiographic evidence of esophagitis certainty of this diagnosis demands endoscopy and biopsy, and the findings have been summarized in this chapter under the heading, Pathology. En passant, the value of endoscopy in assessing the nature of esophageal narrowing is undoubted, as is its ability to facilitate dilatation of the stricture if one is present. This of course may be complementary to various operative procedures and if esophagoscopy permits appropriate dilatation. the more invasive method of gastrotomy and retrograde passage of Hegar’s dilators is not required. However, these are relatively minor points and the most important aspect of endoscopy is to enable recognition of two complications of GER: (1) esophagitis; (2) presence of columnar lined esophagus, the so called Barrett epithelium.

Endoscopy should be performed by an experienced endoscopist, and the surgeon will need to decide whether he will do it himself, or rely on an appropriate colleague. But it is essential the surgeon should at least be present at the time of the examination.

Much has been written about the technique and role of esophageal biopsy and the need to document the sites from which the biopsy specimens are taken, and the involvement of an experienced pediatric pathologist is of course essential. The endoscopist must be familiar with appropriate techniques involving rigid or flexible endoscopes, and decisions will need to be made regarding the repeating of endoscopy and ongoing surveillance.

A recent contribution by Auters mentions the use of a proton pump inhibitor in patients with Barrett’s esophagus, pointing out that even with considerable improvement of the endoscopic lesions, the esophagus is still exposed to the irritating action of the refluxate. There are many other contributions discussing the findings, prognosis etc, and correlating these with the findings on endoscopy and the equally important findings on biopsy.31-33

Thus, the various investigatory modalities available are now well documented, and although the pediatric
surgeon should be familiar with them all, he needs also to be selective. For the most part, investigation is more important in the adult population. Fortunately, should operative treatment be required for GER, the results tend to be more satisfactory in the pediatric age-group. But nevertheless, should symptoms persist postoperatively, such patients should be re-investigated. And as with preoperative investigation, selection of the appropriate modality is all important.

**DIAGNOSIS**

Consideration of the symptoms, on the one hand, and the results of investigation on the other, enable the diagnosis of GER to be made with a high degree of certainty. Abnormal physical signs may not exist, but note should be taken of the child’s habitus and pulmonary findings. Despite knowledge of the natural history of GER, diagnostic delay is by no means unusual, particularly in those children whose GER leads to failure to thrive, or in the group with respiratory problems. In these two groups in particular, various differential diagnoses must be considered, always bearing in mind that GER frequently co-exists with other conditions. This is particularly true when GER is associated with co-morbidity, as in children with neurological impairment or following esophageal atresia repair (Figs 28.9 and 28.10).

The following diagnoses can be recognised, but there may be overlap from one group to another.

1. **The spitters**: These represent the majority of babies and infants with GER and have been well described by Jolley. A clinical diagnosis can usually be made, but under special circumstances, including parental anxiety, limited investigation may be required—rarely more than a radiographic study. Provided adequate explanation is combined with appropriate communication, there is no reason why this need add to parental anxiety.

2. Where clinical suspicion is high, but the diagnosis may be in doubt. In this group, further investigation is required and this may take the form of 24 hr pH metry or esophagoscopy and biopsy or both.

3. Additional symptoms are present, e.g. irritability and “heart burn” (which is difficult to evaluate in children), and thorough investigation is essential, the nature of which will depend on modalities available. Manometry may be helpful; gastric scintigraphy has a definite role in the final analysis, the pathway to follow is ideally the same as for the second group.

4. Clinical suspicion is aroused and investigation reveals an esophageal stricture. Endoscopic examination will usually determine the severity and response to dilatation.

5. When Barrett's esophagus is present, the symptoms are those of GER and/or an associated stricture.

6. Respiratory symptoms dominate the clinical picture—either the GER produces these symptoms, particularly with asthmatic children or following repair of esophageal atresia, which should lead to appropriate investigation.

7. A miscellaneous group, including the Sandifer syndrome, and in the neurologically impaired child.

In summary, therefore, diagnosis of GER should not be difficult, (Fig. 28.11) but difficulties arise, particularly when the symptomatology is atypical.

**Prognostic Factors in GER**

- Efficacy of antireflux mechanisms
- Volume of gastric fluid
- Potency of refluxed material
- Efficacy of oesophageal clearance
- Tissue resistance of the oesophageal mucosa

---

**Fig. 28.9**: Prognostic factors in GER

**Fig. 28.10**: Surgical decision after GER persistence post-medical therapy. To take the surgical decision we have to evaluate several factors by means of more sophisticated diagnostic procedures.
Particular note should be taken of respiratory features because life-threatening episodes may be associated with aspiration into the respiratory tract. To date there is no definite link with sudden infant death syndrome (SIDS) and Campbell (personal communication) has not found evidence of esophagitis in the postmortem examination of babies who have died as a result of SIDS.

**TREATMENT**

The spectrum of treatment of GER is extremely wide. At one end of the scale, little or no treatment is necessary beyond reassurance of the parents. At the other end however, complex surgical procedures may be required. However, it is too simplistic and unhelpful to divide the therapeutic regimes into two groups—nonoperative and operative. Rather, various treatment groups should be considered, commencing with the infant with an excellent prognosis—which is the large percentage of cases—and concluding with the group requiring complex surgery, e.g. those requiring esophageal resection and replacement, including some patients who have been demonstrated to have a columnar-lined esophagus (Barrett’s esophagus) unquestionably more prevalent in adult practice.

**Therapeutic Group 1**

These latter are this is the group referred to by Jolley as "spitters". Characteristically, the vomiting is frequent but not forceful and the babies continue to thrive. The majority will, in the course of time cease to vomit. This spontaneous improvement is largely related to the beneficial effect of the upright posture, which is a normal development over time. In this group, the appropriate treatment is reassurance for the parents. The problem is essentially a social one: the staining of clothes and furniture, malodor, etc. The parents must be given a complete explanation of their child’s problem, because for them there is a real problem.

While most babies in this group are unlikely to be referred to a surgeon, some are, and the surgeon must therefore be familiar with the natural history of reflux in the infant, and the various therapeutic techniques available, including the adoption of the upright posture, possibly more frequent, smaller feedings and thickening of these feedings. A dogmatic approach to these non-operative treatments is to be avoided, but, as many experienced pediatricians have put it, "it's worth a try".

Various agents, including corn flour and rice, have been used to thicken feeds, with Karicare being the product most recently used at the Royal Children’s Hospital. Pharmacological therapy is rarely required. Although if the vomiting is particularly troublesome, a short course of a prokinetic agent may be indicated. But as stated by Orenstein, pharmacological measures must include drugs which are either prokinetic, e.g. Bethanechol, Metoclopramide or cisipride, or acid-suppressing, viz. hydrogen ion blockers or proton pump inhibitors. In 1992 Reynolds and Putnam provided excellent information regarding prokinetic agents. It needs to be stressed that the vomiting is self-limiting in this group; that the cornerstone of treatment is reassurance and that investigation is either not required at all or limited to a barium meal. Posture is important, but should not include the prone position, as this has been linked to sudden infant death syndrome (SIDS).33

**Therapeutic Group 2**

This is in extension of the first group and differs in the intensity of the vomiting and/or associated symptoms. These babies with GER are irritable, fail to thrive and cause great concern to their parents. Under these circumstances, the presence of GERD (particularly esophagitis) must either be confirmed or excluded. Investigations need to be individualized, the spectrum of severity of symptoms necessitating careful assessment while keeping parental anxiety to a
minimum. However, the presence of additional symptoms, i.e. those more serious than the "spitting" type, should lead the clinician in charge to consider investigations over and above the simple radiographic study. The two possible investigations are: (1) 24-hr pH metry; (2) esophagoscopy and biopsy. Wisdom will dictate the management of the individual baby and often a trial of simple measures should precede the more invasive requirements associated with investigation. Many of the babies in this group can be expected to improve spontaneously; but the surgeon must be aware that such symptomatic improvement does not necessarily indicate cessation of reflux, and ongoing clinical surveillance is essential.34-38

**Therapeutic Group 3**

There is a fine line between this and the first two groups, the only thing separating them being the finding on radiology of a hiatus hernia. The identification of such a hernia has to be related to the symptomatology and requires an experienced pediatric radiologist. In simple terms, the measures adopted for the first two groups are indicated for this group too, plus the need to consider operative repair of the hernia if -and the important word is if -the hernia is large. Thus, note must be taken of its size. The need for individualization of treatment is paramount, and the surgical repair to be performed will vary according to the experience and attitude of the surgeon.

Details regarding appropriate surgical measures will be considered later.39

**Therapeutic Group 4**

It is tempting to list several clinical features which necessitate an antireflux operation be performed, but again the old adage applies: "Neither never nor always are absolute". Nevertheless there are several situations, other than a large hiatus hernia, which usually demand surgical intervention.40

1. Failure of a medical regime with persistence of esophagitis.
2. The presence of esophageal stricture.
4. Respiratory diseases proven to be secondary to GER, including
   - Episodes of apnea, choking, respiratory arrest and apparent life-threatening events;
   - Recurrent aspiration pneumonia
   - Recurrent wheezing
   - Chronic cough
   - Stridor
   - Chronic lung disease.

   It is impossible to be dogmatic regarding some patients who should be considered for surgical repair, but all parameters-particularly clinical and investigatory-will need to be evaluated. An occasional indication is hematemesis, but only if it is severe and/or there is ongoing esophagitis.

**Therapeutic Group 5**

This is an extension of Group 4, and includes surgery in special situations where resolution is unlikely to occur, e.g.

- Following repair of esophageal atresia
- In some neurologically impaired children
- In children with Sandifer's syndrome
- Ongoing failure to thrive secondary to GER.

It is important to recognize these various therapeutic groups but such recognition must be correlated with the total clinical picture and social situation of the patient. Reference to the literature emphasizes that there is still and probably always will be some controversy about the indications for, and efficacy of, the various surgical therapeutic regimes available. All options must be considered and related to the findings and the known natural history of GER.

Ten years ago, Boyle pointed out that there had been an evolution in the investigation of refractory respiratory symptoms and the role of "protective" surgery in children with severe neurological impairment or physical handicaps, who require placement of a feeding gastrostomy to provide essential nutrition.

The precise indications vary from center to center.41-43 Schwagten, in reviewing the experience at the Royal Children's Hospital, Melbourne, found definite trends in the use of fundoplication in children with gastroesophageal reflux. He pointed out that fundoplication was performed there with increased frequency from 1978-1985, and that the years 1984-86 reflected a "catch-up" period with indications for its use extended to patients with severe neurological impairment who had long-standing, uncontrolled reflux. He also looked at fundoplication with gastrostomy, stating that, "whereas in the early 1980's
it was standard practice in many institutions to perform a fundoplication with any gastrostomy, current reviews of this practice have reported a high rate of delayed gastric emptying, especially in neurologically impaired patients, with subsequent recurrence of GER and high rates of complications. This has led to increased caution in recommending fundoplication without definite proof of GER in patients requiring gastrostomy."

Schwagten follows with an excellent summary of the dumping syndrome: Pallor, sweating, retching, diarrhea and refusal of feeds which occurs when an abnormally rapid gastric emptying time precipitates initial hyperglycemia and subsequent hypoglycemia. He concludes, management of complicated GER "fundoplication is an accepted part of the Although the overall results of surgery are good with the majority of patients achieving symptom resolution, a significant number have ongoing problems. Our study has limitations and the biases of any descriptive retrospective view, but despite these weaknesses, information is available regarding the main complications."

Indications for fundoplication broadened its use in those with severe neurological impairment and uncontrolled reflux, and changes occurred in the management of patients in the neonatal period. Complications included unwrapping with recurrence of reflux hiatal hernia, adhesive small bowel obstruction, dumping syndrome, post-operative persistence of esophageal stricture, excessively tight wrap, and poor esophageal clearance (mostly in esophageal atresia patients).

This study identified the patients most likely to develop complications. It concluded that the results could assist in the preoperative assessment of the likely benefits of fundoplication in children who often have other complex problems. Stricture was considered the most important indication for fundoplication surgery; all other indications were regarded as relative.

**OPERATIVE TECHNIQUES**

**Nissen Fundoplication**

Pride of place is given to the Nissen-Rosetti procedure, in which a 360° wrap stomach around the intra-abdominal esophagus is constructed. There have been many reports of the results following the procedure. Not all have been favorable, but the experience at the Royal Children’s Hospital, Melbourne has shown that good to excellent results can be anticipated. No doubt, there is a difference in the results to be expected between children and adults, and this becomes clearer when reports from authorities such as Hill and Nyhus are studied. Clearly, the difference between the beneficial effects of the Nissen procedure relate to the underlying pathology in the two groups, as beautifully pointed out by Boix-Ochoa.

An advocate of the procedure in the pediatric patient is Randolph, who wrote as follows: "The operative technique for Nissen fundoplication has been well described. However, certain features are necessary for success in the infant. The abdominal route is quite simple in infants, and is now our favored approach. The left lobe of the liver is detached from the diaphragm and easily folded to the right of the esophagus. It is useful to pass a mercury sound through the esophagus into the stomach; depending on the age and size of the child, sounds ranging from number 24 to number 30 are used (this is not the routine procedure at the Royal Children’s Hospital, Melbourne, where surgeons rely on the passage of a large nasogastric tube).

The phrenicoesophageal ligament is divided completely to reveal the crura and the vagus nerves. The latter are carefully spared and the crura are sutured behind the esophagus, utilizing general bites in the muscle. Non-absorbable sutures are used for this. Several of the short gastric arteries are divided to free the fundus (not all pediatric surgeons believe this is necessary).

Care is taken not to damage the spleen; a window along the lesser curvature is prepared which will permit the fundic wrap to be brought around the cardia without injury to the vagi or the left gastric artery I although at times the left gastric artery may need to be sacrificed. With the fundic wrap in place, sutures are passed through the lateral portion of the fundus, the anterior esophageal wall and the medially placed fundus, using three or four sutures of non-absorbable material. If an adequate amount of fundus is brought around, later dissolution of the repair will be avoided. It is important that the sutures should grasp a significant amount of gastric muscle and be secured without creating tension. The fundus is then sutured to the diaphragm to fix the repair and with
the earlier dissection, there is an adequate length of intra-abdominal esophagus provided. Individualization will be necessary regarding the decision whether to perform a gastrostomy. However, it can serve as a convenient vent if gastric decompression is needed in the early postoperative period and is left in place for approximately three months.

Randolph’s description highlights the important technical features of the procedure which satisfy the important requirements to provide a functional antireflux barrier. In other descriptions, relatively minor variations are mentioned, including the Toupet procedure in which the wrap is less complete (270° instead of 360°). This procedure was introduced largely to avoid some of the complications of the Nissen fundoplication, particularly gas bloat, dysphagia and dumping syndrome. Fortunately, however, these are relatively rare, and we have been encouraged to continue performing the Nissen fundoplication, even in patients with esophageal motility disturbance, e.g. esophageal atresia or when GER is a complication following cardiomyotomy for achalasia.

**THAL Fundoplication**

This procedure has proved to be very satisfactory in Ashcraft’s hands, and the following is his contribution to this alternative option, including some general observations, as well as a description of his surgical technique. With the heading, **THAL Fundoplication**: technique, results, complications and re-operation, Ashcraft has written as follows:

The THAL fundoplication is one of the partial wrap options for the surgical treatment of gastroesophageal reflux (GER). It is created by applying the free wall of the gastric fundus to the anterior aspect of the intra-abdominal esophagus, and is also known as the Dor-Nissen procedure. The Boix-Ochoa procedure is quite similar. The same physiological result may be anticipated using the posterior partial wrap fundoplication (Toupet). Proponents of the partial wraps believe that a successful wrap cures the problem of GER, while leaving the patient with ability to vomit and to burp if the need arises. Obviously, in the pediatric patient, the need for one or both of these very physiological functions is more common than in the adult patient population. There are some pediatric patients, particularly those with significant neurological impairment, who are perhaps better served by a complete wrap (Nissen), because there is little hope of any conscious control of the GE junction. Almost always the Nissen will be accompanied by a STAMM or other form of gastrostomy used for feeding and/or gastric decompression.

“Our experience with the THAL fundoplication has been entirely with open procedures. Because of several features of the operative procedure which we feel are very important, there has been little disturbance of gastrointestinal function, and therefore only a very short hospital stay has been necessary. On an average, my personal experience with over one thousand THAL fundoplication results in the patient not requiring postoperative nasogastric drainage, oral liquids being started within 12 hours of operation, and the patient discharged from hospital within 48 hours. Laparoscopic fundoplication has most commonly been done during the Nissen procedure, because it is far easier to perform than the That or the Toupet. There are several endoscopic surgeons in the United States who have accumulated significant endoscopic experience with the THAL, but whose time to feeding and discharge to feeding is not significantly shorter than ours. The benefit therefore is probably related to the issue of one scar versus several smaller ones. There is no question that the endoscopic procedure requires increased costs of equipment and supplies.

The diagnosis is established most frequently by extended pH-monitoring. We require a barium study in all patients prior to operation to exclude the possibility of achalasia.

**Surgical technique:** The patient is anesthetised expeditiously and without distending the stomach or the gut. A nasogastric tube of appropriate size is passed by the anesthetist for purposes of intraoperative gastric decompression and to aid in the identification of the gastroesophageal junction. The tube also provides some rigidity for the esophagus during the creation of the fundoplication steps are then carried out: The following steps are then carried out:

1. An upper abdominal transverse incision is made from the left costal margin at the nipple line to the opposite costal margin, dividing both recti. The abdomen is entered cephalad of the transverse colon and the small intestine is protected from handling by the mesocolon. Sufficient relaxation is required to prevent the patient from “bucking” and eviscerating himself.
2. The anterior free wall of the stomach is grasped with a gauze pad and retracted downward. The left lobe of the liver is also grasped and dissected free from the underside of the left diaphragm. It is folded downward and retracted to the right by the second assistant.

3. Incision of the peritoneum at the hiatus is done in a transverse direction and a blunt dissector used to spread areolar tissue on either side of the easily-seen and palpated esophagus. A dissector is passed behind the esophagus from the right to the left, grasping a dacron tape that will be used for traction purposes posterior (right end) vagus nerve has not been included within the tape, the tape is replaced.

4. The G-E junction is adjusted downward while the hiatus is pushed on either side of the esophagus in a cephalad direction. The hiatus is not intentionally enlarged, but the lower 2-4 cm of esophagus is thus mobilised.

5. The distal esophagus is retracted to the patient’s left by the first assistant, exposing both limbs of the crura behind. They are approximated using a figure-of-eight suture of permanent material. It is important to leave a space behind the esophagus so that the hiatus is not narrowed excessively. It is very important not to tie this hiatus-closing suture too tightly, or the muscle will necrose and the hiatus will be larger than it was originally. The suture, having been tied with its needle intact, is now placed and used to anchor the posterior wall of the esophagus to the hiatus, which helps hold the distal esophagus within the abdominal cavity.

   The retractor is removed from behind the esophagus and the dacron tape ends are separated. A permanent suture, e.g. 2/0 or 3/0 Gortex is placed and tied at the G-E junction on the left. A fundoplication is created using a continuous suture going up the left side the esophagus suturing stomach to esophagus. The suture line crosses over the front of the esophagus to reach the right side where it is turned downward to the right G-E junction. Thus an inverted "U" is created, holding the anterior free wall of the stomach to the anterior free wall of the intra-abdominal esophagus. It is not necessary to divide any of the short gastric vessels to perform this fundoplication. Its length is assessed by palpating the nasogastric tube through the layers of stomach plied to the esophagus.

Nasogastric tube is removed, the liver replaced in its bed and the wound closed. Boix Ochoa attaches the gastric fundus to the underside of the left hemidiaphragm to exaggerate the angle of His prior to replacing the liver and closure. But we have not found this procedure to be necessary.

**Special Situations**

When faced with a request for a feeding gastrostomy in a neurologically impaired patient, we nearly always perform a concomitant fundoplication. This is done because most patients when fed by gastrostomy will begin to reflux, even without evidence of GER before. Performing a fundoplication in the presence of an established gastrostomy increases the likelihood of a wound infection and dehiscence. In approximately 50% of patients having repair of esophageal atresia malformations, reflux is a significant problem. In most of these patients, a fundoplication is necessary. It is very important that the fundoplication not obstruct the passage of food or drink, because the motility of the distal esophagus is abnormal in these patients. “We think, therefore, that the partial-wrap fundoplication is certainly the best for these patients.”

There can be little doubt that the THAL fundoplication, as practiced by Ashcraft and his colleagues, provides excellent results in infants and children. The surgeon planning to use this procedure would be well advised to pay a visit to Ashcraft and study his technique.

**Boix-Ochoa Procedure**

Boix-Ochoa (1988) wrote as follows: "All pediatric patients should be treated conservatively before an operation is attempted." Although as a generalization this is true, there are definite exceptions to this rule, as outlined above. Boix-Ochoa goes on to state, "the percentage of patients treated medically or surgically changes enormously from one publication to another, confusing more than a few. The author thinks that this depends on whether the patient has been seen by the surgeon at the onset of symptoms, or whether he had been referred by a pediatrician after therapy has been tried. It is necessary to bear in mind a series of fundamental facts that are derived from the knowledge of the significant physiology. These facts being: 3,4,8,27"
1. Reflux does not necessarily mean sphincter incompetence, and incompetence does not necessarily mean sphincter pathology.
2. During the first stages of life, GER can be considered as physiological, or the result of a delay in the maturation of the anti-reflux mechanism.
3. A healthy closing mechanism may become incompetent due to displacement or by being overcome by a pathological opening pressure.
4. By reducing esophagitis, the vicious circle can be broken, enabling the possibility of the LES to evolve to maturity.
5. Definite differences exist between children and adults: In the latter, the LES has been subject to years of chronic illness, and it is often impossible to retrieve the situation.
6. Conservative treatment will tend to lessen opening pressures and attacks on the esophageal mucosa, while surgical treatment will only potentiate closing mechanisms.

**Operative Treatment**

In older children, patients with hiatus hernia, infants with life-threatening apneic spells, severe esophagitis with stenosis, chronic bronchopneumopathy and social problems, are indications for the only appropriate option, which is surgical treatment. Boix Ochoa, like many others, has pointed out that the surgeon has at his disposal a great variety of surgical techniques that offer good results with low mortality and few complications. He also pointed out that, in the beginning, surgical techniques failed because the aim of the early pioneers was only to correct an anatomical abnormality, and thus the operations introduced by Allison (1951) and others fell into disfavor. More recently, interventions have focused on repairing the mechanisms which control reflux and assure a competent LES. Techniques should aim at increasing the high pressure zone, as well as the length of the intra-abdominal esophagus (Fig. 28.12).

With this as a background, and in keeping with the investigatory modalities to be considered, Boix Ochoa describes a technique which aims at restoring and reinforcing the anatomical relationships (Boix Ochoa, 1983). He describes the following steps:

1. Restoration of the length of the intra-abdominal esophagus.

**Fig. 28.12:** The Boix-Ochoa technique does not increase the pressure in the LES but enhance and enlarge the area of which the closing pressures act. This technique only restores the normal physiology by increasing the pressure area with the lengthening of the intra-abdominal esophagus and the restoring and sharpening of the His angle.

2. Tightening the hiatus and anchoring the esophagus to it.
3. Restoring the angle of HIS by suture from the fundus at the level of the first short gastric-splenic vessels to the rim of the right hiatus, and with the reinforcing suture between the fundus and the esophageal wall. Three in a triangle suspending sutures from the fundus to the diaphragm unfolding the fundus like an umbrella.

**Fig. 28.13:** Boix-Ochoa technique for GER in children. The length of intra-abdominal esophagus in restored and anchored to the crura. The crura is tightened. The angle of His restored by a suture taken from the fundus (after sectioning 2-3 short gastric-splenic vessels) to the rim of the right hiatus, and with the reinforcing suture between the fundus and the esophageal wall. Three in a triangle suspending sutures from the fundus to the diaphragm unfolding the fundus like an umbrella.

4. The final step is opening up or unfolding the fundus, much as we would open up an umbrella.
We do this with suspending stitches between the fundus and the diaphragm, and occasionally combine this with an anterior gastropexy which facilitates healing free of tension. Boix-Ochoa has achieved excellent results with a follow-up of up to 16 years, convincing him that the physiological approach is sound (Figs 28.14 to 28.16A and B).4,51

**Laparoscopic Techniques**

Although the majority of antireflux operations are still performed as “open” procedures, an increasing number are now performed utilizing laparoscopic techniques. Thus at the RCH Melbourne, laparoscopy has become the favored method for some surgeons and the same applies to Beasley in Christchurch, New Zealand. However, it is to be stressed that a laparoscopic anti-reflux operation is not to be performed as an occasional procedure. There are an increasing number of reports in the current literature referring both to the value of laparoscopic anti-reflux surgery, particularly the Nissen procedure, and to its complications, reports which include the following.52-55

More recently the medical literature pointed out that a significant increase in the number of children with neurological disability has resulted from more aggressive treatment of prematurity and other childhood diseases. These children often have poor oral feeding with gastroesophageal reflux due to abnormal body habitus, supine positioning, spasticity and increased intra-abdominal pressure. Malnutrition, dehydration, aspiration pneumonia and poor control

---

**Fig. 28.14:** In 3006 cases (1975-2002) we needed only in 230 (7.65%) to take a surgical decision. Our material has a very low percentage (5-6%) of neurological impaired children.

| Results in 215 Patients: Follow-up from 6 months to 20 years a |
|---|---|---|
| Results | Patients | Percent |
| Initial good results | 190 | 88.4 |
| Failed surgical procedure | 3 | 1.4 |
| Symptoms persistence + abnormal pH monitoring | 10 | 4.65 |
| Roentgenographic recurrence (symptom-free) | 12 | 5.6 |

**Fig. 28.15:** Results in 215 patient with Boix-Ochoa technique

**Fig. 28.16A and B:** Preoperative and postoperative roentgenograms of GER treated with the Boix-Ochoa technique. A sufficient intra-abdominal segment and angle of His are present, and an unfolded fundus ensures the normal barrier and physiology.
Pediatric Surgery—Diagnosis and Management

of seizure disorders result from inability to swallow and retain both food and medications. Thompson continues as follows: "The success of surgical therapy for reflux has made the Nissen. That, and Boix-Ochoa, fundoplications the most commonly performed major abdominal operations at many centers in the United States. The recognition that gastroesophageal reflux contributes to the severity of reactive airway disease in many pediatric patients has led to increased utilization of fundoplication in these patients as well. Although fundoplication has been proved effective in preventing reflux and helping with the management of these conditions complications of the standard open Nissen technique have been significant, and have limited its use. An approach that limits perioperative morbidity and reduces the incidence of obstruction is therefore a particularly attractive surgical option. In 1992, several pediatric surgeons began to evaluate laparoscopic Nissen fundoplication as a means to perform the most effective antireflux operation with a more acceptable complication rate."

Lobe described the steps in laparoscopic fundoplication as follows:

- Position of patient—bougie in esophagus;
- Place camera operating and retraction ports;
- Dissect right diaphragmatic crus;
- Encircle esophagus and free fundus short gastric vessels;
- Close hiatus;
- Create and secure wrap.
- Gastrostomy, if required.

It is clear, therefore, that laparoscopic techniques are here to stay, and at the best, the pediatric surgeon will embrace the technique, and at least, will be familiar with recent reports and options available.

Other Surgical Procedures

These can be grouped as follows:
1. Variations of fundoplication
2. Alternative operative procedures
3. Procedures which have a limited but definite place
   - often depending on personal views.

   With regard to the first group, various variations of the Nissen fundoplication have been mentioned. One other is the so-called floppy Nissen fundoplication, which has emphasized the need to avoid a too tight wrap with its potential complications. Donohue and co-workers have discussed the need for a floppy Nissen fundoplication but experienced pediatric surgeons will become familiar with the desirable length of the wrap and the degree of tightness.

   The second group comprises alternative anti-reflux operations, some of which are now practiced widely and others, which are of little more than historical significance. The former group includes the Belsey Mark IV operation and the Hill operation: with few exceptions, the latter group includes the Boerema gastropexy.

   The third group refers to procedures, such as pyloroplasty, which are favored by some authorities but which largely depend on the results of investigations, particularly the gastric scintiscan.

   There is in addition a fourth group, the surgical management of an established peptic stricture which may be, depending on its severity, associated with shortening of the esophagus. Much has been written regarding this problem, although today there is emphasis on dilatation of the stricture combined with an anti-reflux procedure. Dilatation is preferably achieved in an antegrade fashion, but at times retrograde dilatation may be required via a gastrostomy. Should this approach be deemed impossible or prove to be unsatisfactory, then an alternative procedure could be the Collis gastroplasty (cut or uncut). But in the most severe cases, there is an occasional need for esophagectomy and replacement using jejunum, colon, and stomach. One procedure which is now of little more than historical interest is esophagogastrostomy, although some good results were obtained from this in the early days by Howard et al.

Gastroesophageal Reflux in Association with Specialized Conditions

In 1981, Wesley et al pointed out that II over the past ten years, gastroesophageal reflux in the pediatric age-group has been identified as an associated complicating factor in a number of conditions in which it was previously unrecognized or was thought to be rare. They referring to the following:

1. Following repair of esophageal atresia and tracheo-esophageal fistula;
2. After repair of gastroschisis and omphalocele;
3. As a cause of Sudden Infant Death Syndrome (SIDS);
4. As an imitator of neurological and psychiatric syndromes;
5. In conjunction with congenital or acquired brain damage.

This list is probably far from complete; for example, reflux has been identified in a number of patients with achalasia following a Heller procedure, so much so that some advocates of the Heller procedure believe it should be combined with an anti-reflux operation, rather than awaiting the later complication.

There are many examples of the truly causal relationship, among the most important being (1) GER in the neurologically impaired (NI) child; and (2) GER following repair of esophageal atresia. The problems and data surrounding these two groups will be addressed, but the clinician faced with suggestive symptoms in a patient with any condition must be aware of the potential relationship with GER.

**GER in the Neurologically Impaired Child**

This association is now well documented. An excellent example of its recognition was provided by Sondheimer and Morris who pointed out that "recurrent vomiting is a common and serious important problem in severely retarded children, the organic cause of which can be demonstrated by the application of appropriate investigative techniques". Varying views have been expressed as to whether an anti-reflux procedure should always be performed in brain-damaged children requiring a feeding gastrostomy. Wesley and co-authors concluded that a protective anti-reflux operation at the time of gastrostomy placement is not indicated, pointing out that the data suggests that 86% of children with a negative pre-operative evaluation for GER may undergo the operation unnecessarily. However, there are many authorities who believe that if a feeding gastrostomy is required for brain-damaged children, an anti-reflux procedure accompany it. Reference should be made to contributions from Jolley et al, Mollit et al, and Langer et al. In recent contributions, Ramachandran, Ashcraft et al have, stated that there are many who believe that an anti-reflux procedure should be performed routinely with a gastrostomy. In addition, various authorities have addressed the question as to whether the routine addition of a pyloroplasty is indicated. Many prefer the Thai fundoplication, with a later pyloroplasty, if necessary, and reserve the Nissen operation for more intractable disease and distressing vomiting.

Various authors have contributed significantly to the data surrounding the problems seen in neurologically impaired children, e.g. seizures, scoliosis and muscle imbalance. It has also been reported there may be abnormal esophageal peristalsis and a low basal lower esophageal sphincter pressure in the mentally-retarded child, situations which are known to contribute to GER and its complications. Because of the many other factors involved, medical therapy is less likely to succeed in this group of patients. Inevitably, a trial of medical therapy, important though it may be, may result in diagnostic delay and the development of complications. Various authors have stressed the relative frequency of NI children referred for opinion on the role of anti-reflux surgery in their management, e.g. Veit et al, highlighting the broadening of the use of anti-reflux surgery in recent years to include the NI group. As well, Spitz et al reported that 41 of 106 children undergoing anti-reflux surgery were severely mentally retarded. Other series present data on a variable number of NI children, but it is probable that this reflects patterns of referral rather than the true incidence of the problem.

It is clear that reference to the literature provides a great deal of information regarding the NI group, but at times this information reflects a degree of bias. For example, in 1999, Danielson et al pointed out that following "routine" anti-reflux surgery in this group, there is a high recurrence rate (up to 25%), which led them to suggest esophagogastric disconnection. Unfortunately, this and other radical procedures do have a role in the surgical management of some NI children. Hopefully, the need for such procedures will lessen in time, with earlier diagnosis leading to patients presenting with GERD, but without serious complications. In similar vein, De Cou et al commenced their contribution by stating, "feeding problems are legion in severely impaired children. Many patients do well with a gastrostomy, with or without fundoplication. Unfortunately, fundoplication is not without complications, emphasizing the need for other options in the management of these difficult patients." They suggest a feeding Roux-en-Y jejunostomy as part of the management of severely
neurologically impaired children, and justify this approach by pointing out that a small group of "classic" (needle catheter) jejunostomies reported frequent problems with leakage and prolapse. Contributors to the subsequent discussion included Jolley and Fonkalsrud, the latter questioning the advisability of placing highly concentrating feedings into the jejunum, which he described as a form of planned dumping.

Wilkinson, Dudgeon and Sondheimer compared the medical and surgical treatment of gastroesophageal reflux in severely retarded children. Having analyzed data regarding 31 severely mentally and physically handicapped children with GER who had been treated with a standard medical regime, they found that only eight (26%) had complete or partial therapeutic response, and came to the inevitable conclusion that continued medical therapy after initial failure to control symptoms is associated with significant morbidity and mortality. But they did suggest that children with abnormalities of deglutition may not be good candidates for surgery. All of their patients had a gastrostomy placed at the time of fundoplication, with the expectation that it would be temporary; but the gastrostomy was not removed in four patients—one who had persistent gas-bloat and three who were unable to take adequate feedings orally. Their final conclusion, that surgical treatment is associated with a high operative risk but has an ultimately acceptable outcome, was interesting.

In a contribution from Sondheimer and Morris addressing the problem of GER in severely retarded children, it was stressed that recurrent vomiting occurs with increased frequency amongst institutionalized, retarded children, resulting in significant morbidity from malnutrition, anemia and aspiration pneumonia. He pointed out that "often considered a symptom of psychogenic origin, it is treated by a variety of methods, ranging from behavioral to surgical. Such treatment methods. usually instituted without the benefit of thorough investigation into the possible organic causes of recurrent vomiting, are often ineffective in preventing the symptom and its sequelae."

The organic cause of recurrent vomiting in severely retarded children demands the application of appropriate investigative techniques.

A somewhat contrary view to the prevailing one is to be found in the contribution from Smith et al (1992). They concluded that, although the major goals of anti-reflux procedure are clearly achieved in many severely impaired children with GER, the claim that the Nissen fundoplication resolved the complications of swallowing disorders, and improved outcome, with an acceptably low risk in this complex group of patients, does not appear to have been established. They quote the fact that neurologically impaired children underwent reoperation four times as frequently and had over four times the combined failure rate of neurologically normal children, concluding that their experience confirmed the experience of others who report increased risk of death, recurrence of symptoms, para-esophageal hernia and small bowel obstruction, as compared with neurologically normal patients. Thus, their view is that further refinements in diagnostic and treatment strategies are needed to improve patient selection and reduce risks in this markedly impaired group of children.

Evidence that the debate remains unresolved is also provided by Tuggle et al. In discussing the efficacy of Thal fundoplication in the treatment of gastroesophageal reflux and the influence of central nervous impairment, they found that there was a marked difference in the success rate according to the presence or absence of such impairment. They concluded from their data that the modified that fundoplication is very effective in correcting GER in neurologically normal children, but is less effective in children with CNS impairment.

There are many more contributions to the literature on GER in neurologically impaired children—the symptomatology and the therapeutic implications.

**Gastroesophageal Reflux Following Repair of Esophageal Atresia**

As with the neurologically impaired group of children, there is now an extensive literature on the subject of gastroesophageal reflux following repair of esophageal atresia, and it has become evident that this is a very important subject. One major difference between this group and the neurologically impaired patients with GER is that the explanation of the etiology of the GER in the post-esophageal atresia repair group is more clear-cut than in the patients with NI. Most of the contributions to GER in the NI patients provide data without explanation as to causation; one
exception to this is to be found in the writings of Orenstein: "Neurologic disease is associated with a high prevalence of GERD which often persists beyond infancy. As many as 15% of institutionalized, severely retarded children have recurrent vomiting, mostly attributed to reflux. An unknown further proportion may have non-regurgitative reflux, responsible for esophagitis or respiratory symptoms. Neurological disease associated with hypertonia and spasticity may provoke reflux episodes by increasing abdominal pressure. Since children with spasticity have a high incidence of hiatal hernia, this rise in abdominal pressure often occurs without a protective increase in crural support of the LES. One study suggests that extensor spasm, air-swallowing and kyphoscoliosis play roles in the development of hiatal hernias found in these children."

Hypotonia may be present in other children with severe neurological disease. Hypotonia leads to supine or stumped postures which are also provocative for reflux episodes. Although Down’s syndrome occurs in 1: 660 newborns, 2-10% of infants undergoing fundoplication in various series have had this diagnosis. These children may be somewhat hypotonic, but esophageal manometry also showed a high frequency of simultaneous esophageal contractions in five children studied in detail.

The contrasting normalcy of the LES pressure suggests the possibility that the motility changes may have been primary rather than secondary to esophagitis.

Experience at the Royal Children’s Hospital, Melbourne, is in keeping with experience in most other centers. Since 1972, when the first fundoplication was performed there, there have been an increasing number of such anti-reflux procedures being performed, following repair of esophageal atresia, as indicated by Veit et al in discussing trends in recent years. Of particular significance has been the recognition that many anastomotic strictures appear to be reflux-induced and an appropriate anti-reflux operation avoids the necessity for repeated dilatations. To estimate the incidence of reflux in the older patients whose esophageal atresia has been repaired in infancy, a special follow-up clinic as been designed and it is anticipated that study of adult patients in this clinic will facilitate information on postrepair reflux. At the same time, evidence will be accumulated on the incidence of Barrett’s esophagus in this group.

In the "early" days, of operations for EA, postoperative emphasis was largely on survival. In recent years, survival has been the norm rather than the exception, in keeping with Meyers, a quarter of a century ago, describing EA as the epitome of modern surgery. With modern advances in anesthesia, antimicrobial therapy and neonatal intensive care, problems other than survival per se have occupied the attention of pediatric surgeons caring for babies born with EA and/or TEF. Thus it has become clear that a most important determinant of survival and subsequent progress has been the progress or otherwise of additional life-threatening anomalies. But another factor assuming increasing importance has been GER. This is so particularly, but not exclusively, in the long-gap group, and it is of particular significance in this group managed by esophagostomy rather than replacement.

A balanced view is provided by Johnson and Beasley in Chapter 23 of the monograph, esophageal Atresia. They highlighted the possible factors contributing to poor esophageal motility and reflux following esophageal atresia repair (1) inherent esophageal dysmotility; (2) injury to branches of the vagus nerve during surgical procedures; (3) upward displacement with tension of lower esophageal segment with reduction of the length of the intra-abdominal esophagus and alteration of the angle of His for the use of gastrostomy. They addressed the problems of symptoms and complications, highlighting the following: vomiting, respiratory symptoms and peptic esophagitis. They outlined measures to be adopted in management, both non-surgical and surgical, and provided information regarding the indications for operation. In discussing the appropriate surgical objective, they pointed out that this was control of reflux without causing dysphagia, and discussed the role of the various operative procedures available. They concluded that the Nissen fundoplication is probably the most widely used and tested anti-reflux procedure. Because esophageal atresia patients often have esophageal shortening and some will require concomitant gastrostomy to facilitate feeds because gross retardation is present, this combination is not ideally suited to the partial wrap, and the complete wrap of the Nissen fundoplication would seem preferable.
Thus, neurologically impaired children and those who have survived repair of esophageal atresia are the two most important groups of patients where GER complicates a specialized condition, but there are many other anecdotal reports of the association. It is inevitable that the future will bring increasing numbers of contributions relating to GER in both groups, and the well-being of both will be facilitated by further surgical research and closely monitored follow-up studies. Esophageal atresia remains the epitome of modern surgery, but survival is no longer the only determinant. With increasing emphasis on finding the appropriate care for the neurologically impaired child, studies will determine the improved outcome when appropriate investigation and/or medical and surgical treatment is applied to this group.

BARRETT’S ESOPHAGUS (BE)

Although BE is seen predominantly in adult patients with GER, in recent years there have been several reports of its occurrence in children. For this reason alone, the pediatric surgeon must be familiar with the condition, but of even greater importance is the now proven association of BE with adenocarcinoma of the esophagus. The consequent need for the diagnosis to be made and appropriate therapy instituted. Therapy includes the need for continued surveillance should BE persist despite anti-reflux surgery, which is the mainstay of treatment. The early history of BE is highlighted by reference to the contributions of Barrett and Allison, since when there has been an increasing number of reports, particularly detailing aspects of the histopathology. More recently, these reports have highlighted the association with adenocarcinoma of the esophagus. The role of endoscopy and biopsy cannot be overstressed, and the need for cooperation between surgeon, endoscopist and pathologist is paramount.

An excellent summary of BE was given by Cameron and Lomboy (1992), who wrote as follows: “In Barrett’s esophagus, the normal squamous lining of the esophagus is replaced by columnar epithelium. Barrett’s esophagus is associated gastroesophageal reflux, esophagitis and an increased risk of adenocarcinoma of the esophagus. It is thought to be an acquired condition in which acid resistant columnar epithelium replaced squamous epithelium damaged by acid peptic reflux. The diagnosis of Barrett’s esophagus is usually made by endoscopy and biopsy. Little information is available concerning the development and natural history of Barrett’s esophagus; however, more information has become available since 1992. Patients with this condition have been followed up to determine their subsequent course and the risk of developing carcinomas. However, when a patient is found to have a Barrett’s esophagus, the length of time the disorder has been present is usually unknown. Evaluation of the course of this disorder is difficult because of the large number of undiagnosed cases symptoms are not investigated. Many patients do not have reflux symptoms, or their. We recently estimated that for every known patient with Barrett’s esophagus there may be 24 unrecognized cases in the general population.

The diagnosis of Barrett’s esophagus has implications for long-term surveillance, and often for longevity, life-insurance and medical insurance. Accurate diagnosis is therefore important, and “the late presentation of a Barrett’s esophagus is a problem for all ages, perhaps because Barrett’s epithelium exhibits decreased esophageal patient sensitivity”. It is evident that Barrett’s esophagus is a much less prevalent condition in children than in adults, and the co-morbidities are virtually all conditions that are congenital or genetic, or arise from perinatal asphyxia. Their association with Barrett’s esophagus is explained by their predilection to cause severe chronic GE reflux. One implication of the shortened lifespan is that a regular endoscopic surveillance program for established Barrett’s esophagus might not be indicated since the underlying disease is a much more likely cause of mortality than adenocarcinoma arising in Barrett’s mucosa. However, of note, is the fact that children with esophageal atresia probably have a normal life expectancy, and ongoing surveillance of these children is now recognized to be all-important.

In summary, recognizing that certain children at high risk with severe reflux may be relatively silent, the clinician should have a high index of suspicion that reflux esophagitis or Barrett’s esophagus may be present, and not be hesitant to perform endoscopy with biopsy. Prompt, appropriate treatment of reflux esophagitis or other complications of GE reflux, can significantly improve the quality of life for affected children and their care-givers.
The cornerstone of treatment is undoubtedly anti-reflux surgery, followed by ongoing surveillance. Should BE persist, local therapeutic options include photodynamic therapy, mucosectomy, laser therapy, Argon plasma coagulation, or bipolar electrocoagulation. It is clear that not only will each patient need to be individualized, but the form of therapy advised will be determined by the availability of the various modalities.

Thus, Barrett's esophagus remains an uncommon entity in children. But as time passes, more and more patients with this complication of GER will be recognized and the results of treatment by a wide variety of modalities will be assessed. The final story is yet to be told but until then, all children diagnosed as having BE should be the subject of appropriate reports in the literature.

BIOGRAPHY IS THE ONLY TRUE HISTORY

A myriad of names appear in this chapter and yet they only represent a small number of those who have contributed to our knowledge of the different aspects of GER. A segment of this chapter on GER is designed to pay tribute to the vast number of clinicians, pathologists, radiologists, researchers and others, who have extended our knowledge of this subject. It is inevitable that, although the list is long, it is still incomplete, but nevertheless, it will enable the practicing pediatric surgeon to recognize leaders in the field and be stimulated to further his own knowledge. The importance of history cannot be over-estimated. The list is presented in date order, and when contributions involve multiple-authors, the first author is named and additional details appear in the Bibliography

- 18th Century: Term introduced by John Peter Frank
- 1805: Schmidt—describes ectopic gastric mucosa in the esophagus
- 1807: Bozzini—publishers TER Lichtleitner enabled to inspect upper end of esophagus.
- 1828: Billard—reported esophagitis in children
- 1836: Bright—"account of an remarkable misplacement of the stomach"
- 1853: Bowditch—a treatise on diaphragmatic hernia including some details regarding earlier literature on hiatal hernia.
- 1865: Desormeaux—endoscope to examine the esophagus. Visualized structures.
- 1865: Cruise—suggests esophagoscopy.
- 1867: Voltolini—esophageal spectum with a laryngeal mirror.
- 1868: Kussmaul performs the first esophagoscopy "worthy of the name".
- 1879: Öuncke—penetrating ulcers of the esophagus.
- 1880: Morell Mackenzie—constructs esophagoscope.
- 1881: von Mikulicz—credited with having devised the technique of esophagoscopy,
  Treatise on esophagoscopy and gastroscopy using platinum wire lamp, water-cooled, as light source.
- 1883: Kronecker—observations on manometer.
- 1884: Morell Mackenzie—defines esophagitis.
- 1891: Gottstein suggests the use of cocaine for esophagoscopy.
- 1896: Roentgen—the important discovery of X-ray, the significance of which cannot be overestimated.
- 1899: Mayo states "Ewald thought that peptic ulceration caused many of the strictures of the esophagus".
- 1906: Tileston defined 12 types of esophageal ulceration.
- 1922: Chevalier Jackson—"the diaphragmatic pinchcock".
- 1929: Jackson writes on peptic ulcer of the esophagus.
- 1942: Negus—described the act of swallowing.
- 1947: Neuhauser and benenberg—cardioesophageal relaxation as a cause of vomiting in infants.
- 1948: Benedict and Sweet—benign stricture of the esophagus with special reference to esophagitis and hiatus hernia.
- 1948: Allison—peptic ulcer of the esophagus. - described reflux esophagitis
- 1950: Barrett—"esophagitis is a blunderbuss term"
- 1950: Barrett—chronic peptic ulcer of the esophagus and esophagitis.
- 1951: Allison—reflux esophagitis, sliding hiatal hernia and the anatomy of repair.
- 1952: Sweet—esophageal hiatus hernia of the diaphragm.
— the anatomical characteristics and technique of repair and results of treatment in 111 consecutive cases.

• 1952: Barrett—chronic peptic ulcer of the esophagus in esophagitis.
• 1955: Harrington—operative repair of hiatus hernia.
• 1956: Nissen—Ein einfache operation zur Beeinflussung der reflux oesophagitus.
• 1956: Fike—the gastroesophageal sphincter in healthy human beings.
• 1957: Barrett—the lower esophagus
• 1958: Bernstein—a clinical test of esophagitis.
• 1958: Botha—mucosal folds of the cardia as a component of the gastroesophageal closing mechanism
• 1958: Tuttle—detection of gastroesophageal reflux by simultaneous measurement of intravenous pressures and pH.
• 1958: Ingelfinger—esophageal motility.
• 1958: Botha.
• 1959: Carre—the natural history of the partial thoracic stomach (hiatus hernia) in children.
• 1959: Nissen and Rosetti—Die behandlung dar Hiatus Hernien und reflux oesophagitis mit gastropexie und fundoplication.
• 1961: Hayward the lower end of the esopahgus.
• 1961: Nissen—gastropexy and fundoplication in surgical treatment of a hiatus hernia.
• 1964: Kinsbourne—hiatus hernia with contortions of the neck.
• 1974: Johnson and de Meister—24-hour pH-monitoring of the distal esophagus : a quantitative measure of gastroesophageal reflux.
• 1976: Boix-Ochoa—malnutrition of the lower esopahgus.
• 1976: Dent—a new technique for continuous pressure measurement.
• 1977: Rosetti—fundoplication for the treatment of gastroesophageal reflux and hiatus hernia.
• 1977: Bray—childhood gastroesophageal reflux, neurologic and psychiatric syndromes mimicked.
• 1978: Pellegrini—gastroesophageal reflux.
• 1978: Leibermann—Meffert - muscular equivalent of the lower esophageal sphincter.
• 1979: Sondheimer—gastroesophageal reflux among severely retarded children.
• 1984: Jamieson—what is a Nissen fundoplication?
• 1984: Ashcraft—the Thal fundoplication for gastroesophageal reflux.
• 1985: Hassall—Barrett's esophagus in childhood.
• 1986: Boix-Ochoa—a physiological approach to the management of gastroesophageal reflux.
• 1987: Barrett's esophagus in children a histologic and histochemical study in 11 cases.
• 1987: Romeo—disorder of the esophageal motor activity in atresia of the esophagus.
• 1991: Jolley—the risk of sudden infant death from gastroesophageal reflux.
• 1993: Lobe—laparoscopic Nissen fundoplication in childhood.
• 1996: Spechier and Goyal—the columnar - lined esophagus, intestinal metaplasia and Norman Barrett.
• 1998: Watson—the changing face of hiatus hernia and gastroesophageal reflux.

SUMMARY

As philosophised by Steve Jones, "So great is today's knowledge there is no one who has sufficient command of the field to debate it". Jones was referring to the study of evolution, with particular reference to Darwin’s magnum opus, 'The Origin of Species'. However, the philosophy is also applicable to GER, and although there are many clinicians, researchers, and others who are indisputably experts, their contributions are frequently limited to areas which
have interested them most - areas in which their expertise has enabled them to be productive and to provide valuable information for the many who are confronted with day-to-day problems in the field of GER.

This chapter attempts to summaries many of the important aspects of GER, commencing with basic information surrounding its anatomy, physiology and pathology. Without knowledge of these areas, it is impossible for the clinician – be he gastroenterologist, pediatrician or pediatric surgeon – to provide optimal care for his patient. It is just a short step from the basic areas to investigation, diagnosis and treatment. But it soon becomes apparent that different views are expressed reflecting the different eras and authorities, based on research and/or clinical experience. The segment devoted to Barrett’s esophagus (BE) in children demonstrates the need to be familiar with this entity, and this segment is followed by a summary of historical events under the heading, "Biography is the only true History" (from Emerson and Carlisle). The importance of a knowledge of the history cannot be over-estimated, and will help the pediatric surgeon in decision-making and communication skills.

It is clear from the many contributions, as well as clinical experience, that GER is somewhat different in infants and children from adult GER. While this is true, it is essential that each case be individualized, and investigated and treated on its merits. Over-investigations is to be avoided; by the same token, under-investigation may have serious consequences for the patient. Although the basic principles of treatment are the same, regardless of age, there are significant differences. For example, spontaneous improvement is the norm in infants, and frequently the only therapeutic requirement is reassurance for the parents. Carre’s findings emphasized this fact.

The principles of non-operative or medical therapy are similar, regardless of patient age. But fortunately, in the pediatric age-group, should operation be required, this will usually be a relatively simple procedure, the more complicated operations are usually reserved for complicated GERD in adults. In all age-groups, however, the advent of laparoscopic surgery has changed the pattern of management, and recently the situation was summarized by Walson et al, when they wrote: "Laparoscopy for anti-reflux surgery was first reported in 1991. The development phase allowed instrumentation and techniques to be refined, operating times to be shortened and learning curve problems to be recognized and overcome; laparoscopic surgery for reflux has since becomes commonplace. The published results of laparoscopic antireflux surgery, irrespective of the type of fundoplication, confirm the efficiency of the laparoscopic approach. Furthermore, in comparison with an open approach, laparoscopy controls reflux symptoms well and medium-term outcomes have not been compromised. The length of hospital stay has been shortened to two or three days, and these outcomes have also been confirmed in randomised trials of open versus laparoscopic Nissen fundoplication."

Earlier in their contribution, it is relevant to note that they wrote as follows. "it is paradoxical that recently the number of operations for gastroesophageal reflux and hiatus hernia has increased dramatically, even though extremely effective medication for these conditions is now available in many, if not all, western countries. The traditional indications for antireflux surgery still exist, but they have been impacted upon by cultural factors, cost and associated serious disease."

In conclusion, the pediatric surgeon is required to be selective in his decision to advise operation, and to recognize that the spectrum of GER is such that operation is only indicated in a relatively small percentage of cases.

Two other contributions are relevant to the overall summary, and with this conclusions which can be drawn.

Firstly, that of Carre from Belfast, who summarized the situation as follows: "Of recent years, many investigations in addition to conventional radiology have been devised and used increasingly to study gastroesophageal function and reflux in infants. Esophageal manometry, acid reflux tests, 24 hr intraluminal esophageal pH probe monitoring and gastroesophageal scintigraphy. These studies have confirmed that reflux is an exceedingly common event in early infancy. This is not unexpected, since the intra-abdominal section of esophagus is often virtually non-existent at this age, and consequently the important mechanical anti-reflux effect of having the terminal esophagus exposed to intra-abdominal pressure, is lost." Carre also reflected on the relative importance
of a partial thoracic stomach in children with reflux, concluding: "the all important recognition of a partial thoracic stomach in infants with reflux will therefore depend not only on an awareness by clinicians and radiologists of its clinical importance, but on the availability of a radiologist with experience of this problem." No doubt the significant word here is "experience", an aspect which is relevant to all facets of the problem of GER.

The other contribution is from Orenstein: 31,33 "Gastroesophageal reflux disease (GERD) is one of the most common motility disorders. Indeed, it is one of the most common pediatric disorders of any sort. During the last few decades, a great deal of progress has been made in understanding its pathophysiology and in defining optimal evaluation and treatment. This progress, however, has also illuminated the complexity of the disease, as well as the limitations of current therapy." The philosophy behind this statement, made in 1994, is still relevant and later in the contribution, the following appeared: "Several issues are indispensable to an understanding of gastroesophageal reflux. Reflux, regurgitation and vomiting are ambiguous terms and are sometimes misused. Another issue that confuses our understanding of reflux is that reflux is a normals and those with severe and obvious GERD."

Orenstein has contributed significantly to the literature on GER and in addition to her own contributions extending over two decades, she has provided an extensive set of references, a study of which facilities our present knowledge of GER. With the passage of time, the many practical and theoretical aspects of the problem have been clarified.

REFERENCES

RATIONALE

The normal or physiologic function of the lower esophageal sphincter (LES) is to allow the unrestricted passage of food or drink from the esophagus into the stomach. In addition, the normal LES relaxes to allow eructation of swallowed air or to allow vomiting when appropriate. Gastroesophageal reflux (GER) may be defined simply as the inappropriate return of gastric content into the esophagus. GER is an exceedingly common condition both in adults and children (Fig. 29.1). It is primarily an anatomical disorder that becomes much more difficult to manage as the complications of inflammation and scarring progress. Because the pressure gradient between the mediastinum and abdominal cavities is increased by both the patient’s weight and activity. The obesity and other activities that result in the increase in the intra-abdominal pressure, will aggravate GER and reduce the chances of successful treatment.

Once hardly considered to be a disease or disorder affecting pediatric patients, GER is now one of the major causes of morbidity in children not due to infections.1 It has been recognised as a factor in malnutrition, respiratory disorders, otitis and all the manifestations of esophageal mucosal erosion or esophagitis. It may be one of the major causes of “colic” in babies. Both medical and surgical therapy for GER is directed toward symptomatic relief.

The medical therapy for GER is directed toward reducing the production of gastric acid so that continued GER does not result in acid esophagitis or it is directed toward drugs whose function is to enhance prograde emptying of the stomach, reducing the chances for GER to occur. The medications for both of these attacks upon the problem are expensive or carry some significant risks of side effects that have caused some of them to be withdrawn from the market. Arguably the risks of permanent serious side effects may be small but the fact that the medications must be continued ad infinitum is of concern. Because medical therapy for GER provides relief of symptoms only when it is taken, it must be projected over a lifetime. Unrecognised or improperly treated GER may result in esophageal stricture or even sudden death due to laryngospasm. The non-operative treatment of GER may carry a much higher risk than does operative treatment. Many parents are unwilling to accept the risk of medical therapy so surgical treatment of GER...
in children has become one of the most commonly performed procedures in pediatric surgery at the time of this writing.

The author feels that a surgical procedure should produce a result that mimics the natural anatomy and function as nearly as possible. In very few areas does the surgeon have a choice of such different procedures as in the surgical treatment of GER. The natural function of the lower esophageal sphincter (LES) is to allow the unobstructed passage of food and drink from the esophagus while also allowing eructation or vomiting of food that is intolerable to the individual. The fact that everybody has some postprandial LES relaxation has been taken into account in the most definitive of tests for GER—the extended esophageal pH monitoring. The episodes of reflux that occur within two hours of ingestion of food are not counted in the scoring of reflux episodes or severity. Given that some reflux is not only normal but also necessary and given that the partial wrap surgical procedures for GER allow "normalcy," may be that the popularity of a fundoplication procedure that does not establish a physiologic state is based upon something other than reason. It is suspected that many of the proponents of the complete wrap simply learned that one procedure and have not considered changing. Many pediatric surgeons can't make the Thal partial-wrap "work" or that the failure rate is excessive. This may be based upon the misconception that any demonstrable reflux by a contrast study in the postoperative Thal patient is interpreted as a sign of failure. This finding would certainly be indicative of failure in the postoperative Nissen fundoplication. Contrast radiographic studies either for preoperative evaluation and diagnosis or for postoperative follow-up are acute studies that generally take place within the postprandial period discounted by the extended pH study. Although contrast radiographs absolutely should precede any operative approach to correction of GER, they are more useful to determine the angle of His and the ability or inability of the gastroesophageal junction to open or relax than they are for diagnosis of GER. The observation of an obtuse angle of His is the best diagnostic sign of GER on a contrast study.

The best test of success for any fundoplication procedure is the assessment of symptomatic relief. If the patient no longer has the GER symptoms he/she had preoperatively, no longer requires medication to counteract acid and does not have obstruction to the passage of food or to eructation and vomiting, the procedure may be termed successful.

There has been a recent swing toward minimally invasive surgery performed using multiple incisions, long (and often low-quality instruments) while observing the whole process on a video monitor. Although shortened hospital stay and more rapid return to work have been argumented for the economic feasibility of such techniques, the intraoperative time and costs have often more than wasted the economies gained. Minimally invasive surgery is a relative term.

The author's approach to the Thal fundoplication is a minimally invasive approach that carries with it the distinct advantages of a close personal relationship with the tissues to be rearranged. Using a transverse, upper abdominal incision, only the viscera above the transverse colon are exposed or handled. No incidental procedures such as appendectomy or umbilical herniorrhaphy are added. The rectus muscles are cut rather than stretched as in the usual midline approach and postoperative pain is much reduced as a result. Intestinal motility is not interrupted and the patient does not require nasogastric drainage. The patient may almost always be discharged within 48 hours. Anesthesia time is kept to a minimum. Even "talking" a very junior resident through a Thal procedure results in operative times of less than 40 minutes. Knots are tied the way God intended them to be tied-by hand. Continuous suture techniques distribute tension better than do multiple interrupted sutures. The one disadvantage is that of adhesions between stomach and liver are more intense than with endoscopic techniques.

The Thal fundoplication is created by applying the free wall of the gastric fundus to the anterior aspect of the intra-abdominal esophagus and is also known as the Dor-Nissen procedure or the Boix-Ochoa procedure. Boix-Ochoa in addition produces an umbrella like effect by attaching the fundus of the stomach at three places with the under surface of the diaphragm. The same physiological result as anterior wrapping theoretically may be anticipated using the posterior partial wrap fundoplication (Toupet) but much more dissection is required (Figs 29.2A to D). Additionally, over-distension of the stomach following the Toupet procedure may angulate the intra-
abdominal esophagus to the point of obstruction. Proponents of the partial wrap believe that a successful wrap cures the problem of GER and yet leaves the patient with the ability to vomit and to burp if the need arises. Obviously, in the pediatric patient the need for one or both of these very physiologic functions is more common than in the adult patient population. There are some pediatric patients, particularly those who have severe neurological impairment, who are perhaps better served by a complete wrap (Nissen) because there is little hope of any conscious control of the GE junction or of significant oral intake (Fig. 29.1). Very commonly in these patients any fundoplication is accompanied by a Stamm or some other form of gastrostomy used for feeding and/or gastric decompression.

The author’s experience has been entirely with the open procedures in over 1,000 cases with Thal fundoplications. The nasogastric drainage has not been used. The oral liquids are started within 12 hours of operation and the patient is discharged within 48 hours in the vast majority of cases. There are several endoscopic surgeons in the United States that have accumulated significant endoscopic experience with the Thal fundoplication but whose time to feeding and discharge is not significantly shorter than this. The benefit, therefore, is probably related to the issue of one transverse abdominal scar versus several smaller ones. The endoscopic procedure certainly required expertise, increased costs of equipment and the supplies. Also, being the recent development, long-term results with endoscopic procedure are still not known.

All patients required a barium study prior to operation to exclude the possibility of achalasia. About 1% of all the 2000 GER patients in the author’s experience had concomitant achalasia and required a distal esophageal myotomy in conjunction with the Thal fundoplication.

**SURGICAL TECHNIQUE (FIGS 29.3A TO D)**

The patient is best anesthetized expeditiously and without distending the stomach or the gut with nitrous oxide. A nasogastric tube of appropriate size is passed by the anesthesiologist for purposes of intraoperative gastric decompression and to aid in the tactile identification of the gastroesophageal junction. The tube also provides some rigidity for the esophagus during the creation of the fundoplication preventing distortion of the gastroesophageal junction during the suturing process.

- An upper abdominal transverse incision is made from the left costal margin at the nipple line to the opposite costal margin, dividing both left and right rectus muscles. The abdomen is entered cephalad of the transverse colon and the small intestine is protected from exposure by the mesocolon. Sufficient relaxation is required to prevent the patient from "bucking" and eviscerating himself.
- The anterior free wall of the stomach is grasped with a gauze pad and retracted downward. The left lobe of the liver is also grasped and dissected free from the underside of the left hemidiaphragm. The liver is folded downward and retracted to the right by the second assistant.
- Incision of the peritoneum at the hiatus is done in a transverse direction and a blunt dissector used to spread the areolar tissue on either side of the easily seen and palpated esophagus. The dissector is passed behind the esophagus from the right to the left, grasping and pulling through a Dacron tape that will be used for traction purposes. Using this tape retractor, the esophagus is lifted and the posterior (right) branch of the vagus nerve

---

Figs 29.2A to D: Diagrammatic depiction as seen from cranial view of A. Thal fundoplication (270 degree anterior wrap), B. Dor (180 degree anterior wrap), C. Toupet (180 degree posterior wrap) fundoplication and D. Nissen fundoplication with a complete (360°) posterior wrap.
identified. If the posterior vagus nerve has not been included within the tape, the tape is repositioned.

- Using the tape the GE junction is retracted downward while the hiatus on either side of the esophagus is pushed in a cephalad direction (Fig. 29.4). The hiatus is not intentionally enlarged during the mobilization of the lower 2-4 cm of esophagus.

- Using an "S" or small Richardson retractor, the distal esophagus is retracted to the patient’s left by the first assistant, exposing both limbs of the crura behind. The crura are approximated using a figure of eight suture of the nonabsorbable material. It is important to leave a space behind the esophagus so that the hiatus is not narrowed excessively. It is very important not to tie this hiatus closing suture too tightly or muscle necrosis will result in a larger hiatus than was originally present. The hiatus suture is tied with its needle still attached so that it may now be used to anchor the posterior wall of the esophagus to the hiatus. This additional posterior fixation of the distal esophagus within the abdominal cavity adds to the effectiveness of the procedure.

- The retractor is removed from behind the esophagus and the Dacron tape ends are separated. A permanent suture (preferably a 2-0 or 3-0 size) is placed and tied at the GE junction on the left. The fundoplication is created using a continuous suture technique going up the left side of the esophagus, suturing stomach to esophagus. As the suture line crosses over the front of the esophagus to reach the right side the suture line, incorporates the stomach, esophagus and the hiatus. As the right side of the esophagus is reached, the suture line is turned caudally to reach the lesser curvature gastroesophageal junction where it is tied. Thus an inverted “U” suture line is created holding the anterior free wall of the stomach to the anterior free wall of the intra-abdominal esophagus. When complete, the esophagus has been sutured to the anterior half of the esophageal hiatus by the fundoplication suture and to the repaired hiatus posteriory by the hiatus suture. It is not necessary to divide any of the short gastric vessels to perform this fundoplication.

- The length of the fundoplication is assessed by palpating the nasogastric tube through the layers of stomach applied to the esophagus. The Nasogastric tube is removed, the liver replaced in its bed and the wound closed. Boix-Ochoa attaches the His prior to replacing the liver and closure, a part of the procedure that has not been found necessary. Also, gastrostomy is not performed in routine except for the patient who needs to be fed...
by gastrostomy postoperatively. Many younger patients who have a complete-wrap fundoplication require a gastrostomy to prevent gastric bloating, a sometimes serious result of this type of GER procedure.

POSTOPERATIVE CARE

The patient is offered clear liquids six to eight hours after leaving the recovery room and is offered a diet for age the following morning. Once the patient is taking sufficient fluid he is discharged, sometimes as early as 24 hours postoperative. Virtually all patients who are not complicated by other disorders are out of the hospital within 48 hours.

RESULTS

As a group, of the 2078 Thal Fundoplications performed in 1915 patients (1974 and 1999), 78% were neurologically intact and 60% were under one year of age at the time of the initial procedure. Only 4% of these had esophageal atresia and 1% had achalasia.3

- Approximately 90% of patients are able to burp and vomit within two weeks following the procedure
- Those patients with severe esophagitis are more likely to suffer transient distal esophageal edema and obstruction requiring a liquid diet for more than a few days
- Only three patients have required reinsertion of the nasogastric tube for the gas-bloat complication that resolved within 24 hours
- There have been two deaths that occurred early in our experience as a result of the surgical procedure both due to unrecognised small bowel obstruction in severely impaired children
- Seventy five patients required a repeat fundoplication because of recurrent hiatus hernia with herniation of an intact wrap or disruption of the wrap. Three of these patients required a third fundoplication
- One patient had four Thal fundoplications in an attempt to reduce the multiple complications of a failed esophageal atresia repair.

FOLLOW-UP

Initially a repeat barium study used to be performed after four months of surgery to demonstrate that the wrap was intact (Fig. 29.5). Now the barium is done if the patients develop some symptoms.

REOPERATION FOR RECURRENT GER

Recurrence of GER has been due almost equally to disruption of the fundoplication suture line and to recurrence of the hiatus hernia.4,5 The first 400 patients did not have a mandatory hiatus closure which was called the "limiting stitch" and which is now placed in all patients. The recurrence rate was 7% in those initial 400 patients. Of late, the recurrence rate is 2-3%, mostly because of fundoplication disruption. For some inexplicable reason, it was often found the PTFE suture had been broken and the stomach was found separated from the distal esophagus. No patient was found to have developed adhesions between the stomach and the esophagus sufficient to prevent recurrent GER in face of a suture failure.

Reoperation is often complicated by extensive adhesions between the stomach and the underside of the liver. It is imperative to dissect all the adhesions both for visibility and for the necessary mobility to redo the fundoplication. All steps of the original procedure must be followed if one is to anticipate success. Clearly a thoracic approach for repeat fundoplication would not be feasible because of the gastrohepatic adhesions. Only in cases of extreme neurological dysfunction, Thal procedure may be converted to a Nissen.

SPECIAL SITUATIONS

When faced with the request for a feeding gastrostomy in a neurologically impaired patient, a concomitant...
Pediatric Surgery—Diagnosis and Management

Fundoplication should be performed.\(^5,7\) This is done because most patients when fed by gastrostomy will begin to reflux even without evidence of GER before. To perform a fundoplication in the presence of an established gastrostomy increases the likelihood of a wound infection and dehiscence. In approximately 50% of patients having repair of esophageal atresia malformations, reflux is a significant problem.\(^8\) In most of these patients a fundoplication is necessary. It is very important that the fundoplication should not obstruct the passage of food or drink because the motility of the distal esophagus is abnormal in these patients (Fig. 29.6). It is felt that the partial wrap fundoplication is certainly best for these patients.

**LONG-TERM RESULTS**

In the author’s series, 23 patients were studied who were more than 10 years post-Thal fundoplication. Many of these patients were originally operated upon as babies and had grown into their teens. The patients were selected on the basis of availability and willingness to undergo both a contrast radiographic study and a 24-hour pH study. The selection resulted in data that were not generally reliable for the entire population but approximately one-third of these had a small, presumably “traction” diverticulum at the level of the esophageal hiatus but all had normal pH studies. All were asymptomatic.

**SUMMARY**

The Thal fundoplication and its related partial-wrap fundoplications have resulted in short and long-term results equal to or better than the published results of the complete wrap. The complications relating to gastric over distension are not seen with the partial wrap procedures and patient/parent satisfaction is quite high.

**REFERENCES**

**Fig. 29.6:** Barium study outlining the filling defect following a food bolus obstruction. The patient had stricture of the lower esophagus and Thal fundoplication had been performed.
Achalasia comes from a Greek word that means "failure to relax". Cardiospasm is a synonym used to describe the same condition. Achalasia is a primary functional esophageal motility disorder characterized by failure of a hypertensive lower esophageal sphincter (LES) to relax and the absence of esophageal peristalsis.

Achalasia cardia is mainly a disease of young adults with less than 5% cases occurring in children. Achalasia cardia is thus a relatively rare problem in children, however, when present it can result in severe disabling symptoms like severe lung disease and growth retardation often requiring surgical intervention. It may occasionally be a cause of mortality due to respiratory complications.

**HISTORICAL BACKGROUND**

Sir Thomas Willis, in 1672, first described achalasia and treated the problem with a dilation using a whale sponge attached to a whale bone. In 1881, Von Mikulicz described the disease as cardiospasm, felt it was a functional problem not a mechanical one. In 1913, Ernest Heller, first successfully performed a esophagomyotomy. In 1929. Hurt and Rake realized that the disease was caused by a failure of the lower esophageal sphincter (LES) to relax. They coined the term achalasia, meaning failure to relax. The first anterior partial fundoplication was reported by Dor in 1962. Toupet reported the first posterior partial fundoplication in 1963.

**ETIOPATHOPHYSIOLOGY**

The cause of achalasia is unknown. Theories on causation invoke infection, heredity or an abnormality of the immune system that causes the body itself to damage the esophagus (autoimmune disease). The occurrence of achalasia in the first six months of life, the existence of a familial factor, the prevalent possible association with genetic diseases (familial dysautonomia, glucocorticoid insufficiency, Rozycki syndrome) suggest that achalasia in childhood may in certain cases represent a congenital problem, somewhat different from the adult form, which is considered to be an acquired disease.

However, the two main theories that have been developed to explain the onset of this disease are:

1. A primary neurogenic abnormality with a failure of the inhibitory nerves and progressive degeneration of ganglion cells.
2. An acquired deficiency of the myenteric plexus ganglion cells, secondary to GERD, Chagas disease, or viral process.

LES pressure and relaxation are regulated by excitatory (e.g. acetylcholine, substance P) and inhibitory (e.g. nitric oxide, vasoactive intestinal peptide) neurotransmitters. Children with achalasia lack nonadrenergic, noncholinergic, inhibitory ganglion cells, causing an imbalance in excitatory and inhibitory neurotransmission. The result is a hypertensive nonrelaxed esophageal sphincter. Microscopically, there is degeneration of ganglion cells in Auerbach's myenteric plexus. This condition is in some ways analogous to megacolon. Normally, there is a lower esophageal high-pressure zone, or lower esophageal sphincter. In achalasia the lower esophageal sphincter is hypertonic, producing resting pressures above normal and relaxing incompletely after swallowing. This produces a functional obstruction, resulting in dilation and elongation of the
body of the esophagus with rapid narrowing at the cardia. In vigorous achalasia, simultaneous nonpropagated high-amplitude pressure waves occur throughout the esophageal body.

The irritation caused by the presence of stagnant food in the esophagus may lead to esophagitis and ulcerations. Early in achalasia, inflammation can be seen under the microscope in the muscle of the lower esophagus, especially around the nerves. As the disease progresses, the nerves begin to degenerate and ultimately disappear, particularly the nerves that cause the lower esophageal sphincter to relax. Still later in the progression of the disease, muscle cells begin to degenerate, possibly because of the damage to the nerves. The result of these changes is a lower sphincter that cannot relax and muscle in the lower esophageal body that cannot support peristaltic waves. With time, the body of the esophagus stretches and becomes dilated. Microscopic examination may also show acanthosis.

**CLINICAL PRESENTATION**

Achalasia is characterized by dysphagia (most common), regurgitation of feeds, chest pain, heartburn and weight loss. There is usually a progressive dysphagia for solid and liquid food. The children learn to compensate for their dysphagia by taking smaller bites, chewing well, and eating slowly. This causes a delay in diagnosis and marked dilation of the esophagus. The dysphagia in achalasia also is different from the dysphagia of esophageal stricture or stenosis. In achalasia, dysphagia occurs with both solid and liquid food, whereas in esophageal stricture or stenosis, the dysphagia typically occurs only with solid food.

Rarely, children may also present with cough and aspiration pneumonitis, as they may be unable to explain the symptoms.

There is no contributory finding in the physical examination. There is no sex predilection, though some have reported a higher incidence in males. A high index of suspicion is required to ask for the contributory investigations.

**INVESTIGATIONS**

Characteristic chest X-ray findings in achalasia are a widened mediastinum, an air fluid level in the esophagus, an absent gastric air bubble, and aspiration pneumonia.

**Barium Swallow**

The esophagus appears dilated, and contrast material passes slowly into the stomach as the LES opens intermittently. The distal end of esophagus is usually narrowed and this is known as the bird’s beak sign (Fig. 30.1). Cine esophagogram demonstrates aperistalsis in the dilated section and tertiary contractions of the esophageal body may be observed with an air-fluid level. Elongation and dilation of the esophagus produce tortuosity, leading to a sigmoid esophagus in extreme cases.

**Stages of achalasia:** Achalasia in adults has been categorized by the diameter and length of the esophagus. An esophagus with a diameter of 2-3 cm is normal, grade 1 is < 4 cm, grade 2 is 4-6 cm and bird beak looking, grade 3 is > 6 cm, and grade 4 is a sigmoid esophagus.

**Esophageal Manometry**

This helps to confirm the findings picked up on a barium swallow and is currently the examination of choice to confirm achalasia. There is incomplete relaxation of the LES in response to swallowing, with a high resting LES pressure and incomplete or absent

---

**Fig. 30.1:** Barium swallow showing the dilated esophagus with narrowed distal end of esophagus known as the Birds beak sign
LES relaxation after deglutition, associated with a lack of peristaltic coordination of the esophageal body during deglutition.\textsuperscript{16,17}  

24-hour esophageal pH monitoring and scintigraphic studies  

This may help to rule out gastroesophageal reflux.

**CT Scan Chest**  

If the above findings are not contributory or contradictory to each other, a CT scan chest may be done to rule out a bronchocartilaginous ring at the lower end. However, even a CT scan chest may not pick up the cartilaginous remnant unless planned in smaller sections. The authors have found a bronchocartilaginous ring at the lower end only as a peroperative finding in 3 cases. Thus a high index of suspicion is essential.

**MANAGEMENT**  

The aim of treatment is to relieve symptoms by eliminating the outflow resistance caused by the hypertensive and non-relaxing LES. After the obstruction is relieved, food can pass through the aperistaltic body of the esophagus by gravity. Calcium channel blockers and nitrates have been used in the elderly to decrease the LES pressure, but they have no role in children.

**Dilatation**  

Dilatation with bougies and pneumatic dilatation may provide temporary relief of the symptoms. Pneumatic dilatation consists of placing a balloon in the lower esophageal sphincter and inflating it to disrupt the lower circular muscle fibers. There is a definite risk of esophageal perforation bleeding, and gastro-esophageal reflux with pneumatic dilatation, and it should be avoided.\textsuperscript{18} Gentle dilatation with bougies may be helpful in cachexic patients to build up the nutritional status to make them fit for surgical intervention. The response to dilatation is only 20%. Also, if redilatation is needed within 3 weeks, then it should be considered as a failure of the dilatation program and surgical treatment should be considered.

Nasogastric feeding may be given to build up the nutrition of these children. If the nasogastric tube is not negotiable, a gastrostomy may be considered in severely malnourished children.

Esophagoscopy is important to confirm the presence of retained food in a dilated esophagus, esophagitis and esophageal stenosis. During endoscopic examination, resistance may be encountered to the progress of the endoscope.\textsuperscript{24,14} The lower esophageal sphincter is tight, but the esophagoscope passes with gentle pressure.\textsuperscript{19}

The injection of clostridium botulinum toxin into the lower esophageal sphincter is a relatively new procedure.\textsuperscript{20,21} It has a high failure rate, offers only a temporary benefit, requires repeated injections, and may produce scarring that can make subsequent surgery more difficult and hazardous.\textsuperscript{12,22} This treatment should only be reserved for cases in which there is no possibility of a surgical treatment, and is not recommended in children.

**Heller’s Cardiomyotomy with Anti-reflux Procedure**  

Heller cardiomyotomy has been the treatment modality of choice. The classical surgical approach consists of performing myotomy of the esophagus and cardia (Figs 30.2A and B). Some authors have suggested a variation of the technique, removing a strip of muscle tissue (myomectomy). The myotomy/myectomy extends from the LES to 2 or 3 cm above the cardia, is generally associated with anti-reflux procedures, and is done with a view to the fact that

**Fig. 30.2A:** An operative photograph showing the lower esophageal junction, after mobilization of the peritoneum at the cardioesophageal junction.
Pediatric Surgery—Diagnosis and Management

cardiomyomectomy alone favors gastroesophageal reflux. A long myotomy ensures division of all the lower esophageal high-pressure zone circular muscle fibers and may prevent chest pain from nonpropagated simultaneous contractions or diffuse esophageal spasm. An inadequate myotomy fails to relieve the dysphagia, and one that is too long causes gastroesophageal reflux. An adequate myotomy produces gastroesophageal reflux, so most authors nowadays add a partial fundoplication. Both the Toupet and Dor procedures have their advocates. Most series however have preferred a Dor fundoplication after the myotomy.

Since the Dor partial fundoplication is an anterior wrap and covers a portion of the exposed mucosa, it helps protect against leakage from an unrecognized perforation or devascularization of the mucosa. However, it may carry a higher incidence of dysphagia and gastroesophageal reflux than the Toupet. Following myotomy, some authors have used esophagoscopy to confirm adequacy of the myotomy and air insufflation with the esophagus submerged in saline to ensure that there is no unrecognized perforation. If a perforation does occur, suturing can close it safely. A loose partial fundoplication is desirable as the aperistaltic esophagus has negligible propulsive activity. Dissection of the muscular layer for half of the circumference and suturing the cut edges of the myotomy to the fundoplication has been reported to produce traction that keeps the edges apart, lessening the likelihood that the edges will heal together and cause a fibrous stricture producing a recurrence of the high-pressure lower esophageal sphincter.

Laparoscopic/Thoracoscopic Repair

There is an ongoing debate about which approach is better for cardiomyotomy and anti-reflux procedure—open or Laparoscopy. A laparoscopic Heller myotomy is considered by many to be the appropriate primary treatment of patients with a confirmed diagnosis of Achalasia. Laparoscopic Heller myotomy has been reported to have excellent results, a short hospital stay, and a fast recovery time. There is excellent exposure of the gastroesophageal junction and the lower two thirds of the thoracic esophagus. The magnification of the operative field allows good visualization of the circular muscle fibers with less disruption and more accuracy. However, expertise is required for a successful outcome. There is definite risk of perforation during the initial learning curve, and one should not hesitate to switch to the open procedure in cases of doubt.

Another ongoing debate is the route for the procedure—thoracoscopically or laparoscopically. A thoracoscopic Heller myotomy and a partial fundoplication has been reported to have a high incidence of gastroesophageal reflux. The fundoplication is better done from the abdominal route.

Some authors have performed a transthoracic limited esophagomyotomy, extending no more than 1 cm onto the stomach, avoiding dissection of the hiatus and preserving the oblique sling muscles of the proximal stomach that form the "collar of Helvitus" without an antireflux procedure. They have reported that their incidence of postoperative dysphagia and gastroesophageal reflux is acceptable. Others have opined that it may be difficult to carry the myotomy far enough onto the stomach without going too far.
Laparoscopic approach is technically easier than thoracoscopy, as the instruments are in line with the long axis of the esophagus instead of being perpendicular to it. Laparoscopy provides easier access to the distal esophagus and proximal stomach, the most difficult and important part of the procedure. Transhiatal laparoscopy provides excellent access.

Rarely, older patients presenting in adulthood with a severely decompensated sigmoid esophagus may require esophagectomy, to prevent severe and frequent chest infections.

However, if the diagnosis is not confirmed and in children less than 5 years, the chances of finding a congenital lesion like bronchocartilaginous ring at the lower end of the esophagus are high and an open laparotomy is advisable. The cartilaginous ring/segment may be palpable during operation. In such cases, the authors have removed the anterior half of the ring, done a myotomy above the stenosed area and covered with a Thal fundoplication. The cartilage has to be removed very carefully with sharp dissection, taking care not to injure the underlying adherent esophageal mucosa. An inadvertent perforation should be checked with saline or air pushed through a nasoesophageal tube. In case there is a perforation, after closure of the perforation, the procedure should be completed in the same manner with the fundoplication patch so that the wall of the stomach forms a wall of the esophagus. However, the postoperative feeding may be delayed in such cases till a contrast study is done to confirm the sealing of the perforation.

RESULTS

The results are usually good, with relief in symptoms as soon as the patient is able to accept feeds after surgery. A contrast study may be done after 10 days to assess the results. Dilatation may be required in some cases. The most common causes of a poor result following esophagomyotomy are incorrect diagnosis, inadequate myotomy, fibrosis and narrowing of the myotomy and gastroesophageal reflux. In very few cases done in adolescence or adulthood, in those with prior myotomy or those who have developed a gastroesophageal reflux disease stricture, the giant megaesophagus may continue to empty poorly after myotomy and may require esophagectomy.

REFERENCES

Esophageal stricture can be defined as a narrowing of the esophagus, which requires treatment. Esophageal strictures in children are not an uncommon problem but may be difficult to manage. Strictures of the esophagus in pediatric age group are secondary to benign pathology. The common causes of strictures in childhood are: gastroesophageal reflux (GER), corrosive injury and postoperative-secondary to anastomotic scarring (Table 31.1). GER aggravates the strictures that are not primarily due to it. Hence treatment of GER is very important while managing the strictures of esophagus, irrespective of etiology. Anastomotic strictures are localized to the area of operative anastomosis and are amenable to dilatation in majority of circumstances, failure of which leads to limited resection and reconstruction. Corrosive strictures are long and irregular, difficult to manage with dilatation, have a risk of malignancy in the long-run and usually require esophageal substitution. The stricture secondary to GER are localized to lower-third of the esophagus, are short but difficult to treat. Early recognition and prompt appropriate treatment is the second best to prevention.

**DEFINITION**

There is no universally agreed definition of stricture; many definitions have been used by different authors. Coran in 1989 defined a stricture following esophageal atresia surgery as a narrowing which requires more than 2 dilatations.1 American Academy of Pediatrics in a survey conducted by it, defined stricture as a narrowing, which requires more than 4 dilatations.2 In our opinion, a stricture is defined as any compromise to the lumen of the esophagus, which requires dilatation.

**INCIDENCE**

It is very difficult to give the incidence of stricture in general as different authors have used different criteria and definition for strictures and have applied them to different subgroups of patients. The incidence of anastomotic stricture following the repair of esophageal atresia varies between 8 - 49%, depending upon the criteria for the definition of stricture formation.3-5 In the experience of Coran, it is present in 19% of the patients following repair of esophageal atresia with or without esophageal fistula.1 This comes from a series of 224 patients published in 1989 whereas Spitz, from London, in 1987 reported the incidence to be 18% in a series of 145 children. The figures from Melbourne in Australia, quote the incidence to be 30%.6 In our experience of over 120 cases the stricture rate is approximately 8% and half of these have required

6. Esophageal strictures from foreign body impaction
7. Degenerative disorders
8. Achalasia
more than 4 dilatations and one child required resection and reanastomosis.

**Esophageal Anastomotic Strictures Following OA Repair with or without TEF**

The commonest reason for esophageal anastomosis in pediatric surgery is for esophageal atresia with or without tracheo-esophageal fistula. Anastomotic stricture is the most common reason for further surgery to the esophagus after repair of esophageal atresia (Fig. 31.1).

Various factors implicated in esophageal anastomotic stricture following primary repair of esophageal atresia are: use of silk sutures, two layer anastomoses, end to side anastomosis, anastomotic tension gastroesophageal reflux (Table 31.2).2,7-12 Ischemia and anastomotic leak leading to localized inflammation and infection are also responsible for the stricture.2,7,13 An esophageal stricture can also occur coincidently in association with recurrent fistula, although there is no hard evidence of increased incidences of stricture when a recurrent fistula develops.

The type of esophageal anastomosis has also been thought to be a factor contributing to esophageal stricture. A survey conducted by the American Academy of Pediatrics looked into the incidence of esophageal strictures following double-layered vested anastomosis, the two layered end-to-end anastomosis and single layer end-to-end anastomosis.2 The stricture was defined as an anastomosis requiring four or more dilatations. The incidence of stricture with his definition was 25 % with Haight anastomosis, 14 percent with two-layered end-to-end anastomosis and 18 percent with single layered end-to-end anastomosis. Interestingly the incidence of anastomotic leak was inversely related to the incidence of stricture following these three types of anastomosis. Coran in 1989, also found a greatly increased incidence of stricture with a 2-layer anastomosis compared with 1 layer anastomosis.1

In experience of others also the anastomotic technique has a role to play in the prevention of stricture.8,11,13 We advocate an end-to-end anastomosis (single layer, interrupted sutures) with careful inversion of mucosa using vicryl sutures. There is minimal forceps handling of the esophageal ends especially the lower pouch. In our opinion extensive mobilization of the lower esophagus is unnecessary and undesirable. This not only disrupts the segmental blood supply to it but also damages the vagal branches, which supply this segment of the esophagus.14 The upper esophageal pouch has a longitudinal blood supply and hence can be safely mobilized up to the neck without any risk of vascular compromise. It can have a circular myotomy as well.15,16

It is very important to avoid, unnecessary dissection at the site of the fistula, and excessive mobilization of the lower esophagus (Table 31.3). The anastomotic tension should be kept to a minimum. Good blood supply to both the esophageal ends and complete mucosal apposition with inverting sutures (as loose, as few and as far as possible) are the key

---

**Table 31.2: Factors responsible for anastomotic strictures following repair of esophageal atresia with or without tracheoesophageal fistula (OA ± TOF)**

1. Tension on the suture line
2. Tenous blood supply
3. Type of anastomosis
4. Anastomotic leakage leading to localized inflammation and infection
5. Gastroesophageal reflux
6. Type of suture material
factors to minimize the chances of esophageal strictures.

Children was gastroesophageal reflux certainly have higher incidence of stricture formation. In our experience the neonates, who have anastomosis, performed under tension, leading to iatrogenic hiatus hernia, have higher incidence of stricture. The hiatus hernia leads to GER. In general and especially in these cases we strongly recommend picking up the GER on the first contrast study and institute full medical management (Table 31.4). We do an active follow up on the neonates with GER following OA with or without TEF, all of which are treated with standard medical management of GER: nursing in a special chair with 45° head end up, feed thickeners and H2 blockers (Ranitidine) or proton pump inhibitors (Omeprazole).

At the first clinical suspicion of development of a stricture we undertake esophagoscopy and institute early dilatation. At this procedure the lumen of the esophagus is assessed and depending upon the size, tightness and clinical response to the dilatation the further management is individualized for each patient.

ESOPHAGEAL ANASTOMOTIC STRICTURES FOLLOWING OTHER ESOPHAGEAL ANASTOMOSIS

The other reasons for esophageal anastomosis in pediatric age group are while dealing with a localized stenotic injury to the esophagus secondary to ingestion of corrosive, esophageal replacement procedures (anastomosis of the interposed colon, stomach, gastric tube or jejunum is carried out). In older children with caustic injury inadequate removal of the esophageal cicatrix is an important factor in the development of esophageal stricture following surgery for corrosive strictures. Gastroesophageal reflux is a contributing factor in these cases. It is very important to prevent a stricture when an elective procedure, requiring an esophageal anastomosis, is undertaken by adhering to the basics principles previously mentioned.

CLINICAL PRESENTATIONS OF ESOPHAGEAL STRICTURES

Diagnosis of an esophageal stricture is suspected from a careful history. Feeding difficulties, dysphagia and vomiting are the major symptoms in children with esophageal strictures. In neonatal period or early infancy they manifests as slow feeding and excessive regurgitation with or without cyanotic episodes. Older children often present with foreign body impaction of food in the esophagus. Some older children complain of dysphagia with solids foods, and require the help of oral drinks to push forward the food bolus. Anemia can be the presenting feature in peptic strictures.

DIAGNOSIS

Diagnosis of stricture is confirmed either by endoscopy or contrast swallow. In cases presenting with dysphagia or feeding difficulties a contrast swallow should be done before any endoscopic assessment or intervention. Constant narrowing on swallow is diagnostic of stricture. It also helps in demonstrating the length and severity of stricture. It is a must to look actively for gastroesophageal reflux when the stricture is not too tight and allows the contrast to reach stomach. Once the stricture is demonstrated on contrast swallow, an endoscopy is performed to complete its assessment. At the esophagoscopy a biopsy should be obtained when reflux is suspected. The stricture is dilated. When a child presents with a history of foreign body impaction a plain X-ray of the neck and chest is undertaken followed by endoscopy and removal of foreign body (if possible). A dilatation of the stricture is undertaken if the lumen of the esophagus is visible. In the presence of excessive edema it is preferable to delay the delay the dilatation.
TREATMENT

In patients with mild narrowing of the esophagus and an early diagnosis of the stricture a single or a few dilatations may be all that is required. In patients with associated gastro-esophageal reflux, it is necessary to treat the reflux. Gastroesophageal reflux is documented in about 40% of the patients after repair of esophageal atresia and about half of these develop significant anastomotic stricture. Although in the past such strictures were managed by dilation alone, there is now widespread acceptance that the reflux should be treated surgically. After a successful anti-reflux operation the stricture will usually improve over several weeks but may require one or two further dilatation. In the unlikely event that the stricture fails to resolve or respond easily to dilatation after an anti-reflux operation, the stricture should be resected. In our experience an early diagnosis and aggressive medical management of GER can decrease the incidence for the surgical treatment for the reflux.

METHOD OF DILATATION

Many methods of dilatation have been used over the years (Figs 31.2 to 31.5). They include prograde dilation or retrograde dilation, radial dilation or axial dilatation (Table 31.5). The safest methods of dilatation are: (1) prograde over a guide wire, which is inserted under a direct vision (2) If this fails then a gastrostomy is performed and guide wire is passed under X-ray control (prograde or retrograde). A string is then railroaded via the gastrostomy, across the stricture and brought out through the mouth for retrograde dilatation. After the dilatation the string is brought out transnasally and left in situ till the next dilatation, when it is retrieved orally for further dilatations (Fig. 31.6). This method can be used repeatedly. In the premature child when a stricture develops following the repair of OA, the authors have used syntel biliary and cholangiographic catheter, which is passed via a rigid esophagoscope. The balloon is placed under direct vision across the stricture, the latter is gently dilated with inflation of the balloon.

Prograde dilatation is done with Hurst mercury filled bougie or with more rigid gum elastic bougie. They do not require the presence of a string across the stricture. Retrograde dilatation is achieved using Tucker bougies railroaded through the stricture on a string through a gastrostomy. The method of dilatation

---
Esophageal Strictures

involving bougies is called axial dilatation. Ball et al described balloon dilatation under radiological control. The dilatation performed by balloon fall under the category of radial dilatation. The method of balloon dilatation (radial dilatation) has certain characteristic advantages over the bougie dilatation (axial dilatation). In the method of bougienage (retrograde or prograde) an advancing tapered dilator generates axial force, whereas balloon catheter generates radial dilating force. In a series of equivalent esophageal segments made by suture plication of esophageal segments in swine, McLean and LeVeen measured shear force and radial force generated by dilation with a Maloney’s bougie, a Savary-Gilliard bougie, and an esophageal balloon (Figs 31.3 and 31.4). The mean radial forces generated were similar in all the three techniques. However, the mean shear force with the balloon dilator was significantly lower than that with either bougie. In theory, the reduced shear force associated with balloon dilation might reduce the risk of esophageal perforation. The uses of steroids injected into the strictures have been advocated but is unproven for resistant stricture. It may have a place as a final try before proceeding to resection. A small number of strictures resistant to all forms of dilatation will certainly need resection. In an experience presented from Australia, in the early part of the series involving esophageal atresia with or without tracheoesophageal fistula, stricture resection was relatively common. Introduction of the Nissen fundoplication decreased the rate of resection of strictures. It was also noticed in the same series that resection of an anastomotic stricture was required most commonly with stage repairs and least commonly with primary one layer, end-to-end anastomosis.

Any method of dilatation carries a risk of septicemia including the formation of brain abscesses. In one series, 4 out of 9 patients had Staphylococcus aureus in postoperative blood cultures. These investigators recommend that appropriate antibiotic cover should be provided for patients undergoing esophageal dilatation.

The risk of perforation exists regardless of the method of dilatation and hence the need of postoperative vigilance and observation. In the presence of perforation the early symptoms are restlessness and pain. The pulse rate and the respiratory rate should be monitored regularly. A chest X-ray should be done as and when necessary. The feeds should not be started immediately and the first feed should preferably be a clear fluid in the form of diarolyte.

PREVENTION

Strictures following esophageal atresia with or without tracheoesophageal fistula can be prevented. A single layered end-to-end anastomosis using absorbable sutures, such as polyglycolic acid, gives a low incidence of stricture. The anastomosis should be constructed accurately with good mucosal apposition (with mucosal inversion) with the least possible tension between the ends. Interference of the blood supply of the esophagus (lower pouch) should be kept to the minimum. If these guidelines are followed the incidence of stricture will be reduced considerably. In neonates where anastomosis is under tension a postoperative elective ventilation with paralysis is instituted.

VASCULAR RINGS

The vascular malformations that involve the aortic arch and its major branches are known as vascular rings. They are of two main types: Complete rings and incomplete rings. The complete ring is made of double aortic arch. The incomplete ring is most commonly made of: Right sided aortic arch and the pulmonary artery to the right and anterior side, aberrant subclavian vessels crossing behind the esophagus, and

![Fig. 31.6: A child with esophageal stricture - dilatation over a string. The string runs across the stricture, comes out transnasaly at one end and via gastrostomy at the other end](mebooksfree.com)
ligamentum arteriosum or ductus arteriosus completing the ring on the left side (Figs 31.7 and 31.8). Compression of the trachea and esophagus by a vascular ring mechanism can occur because of the limited space available for the trachea and esophagus. The incomplete rings are common on oesophagograms but are an unusual cause of dysphagia. These anomalies occur in less than 1% of the population. The most common associated defects are congenital heart disease.

Patients with restrictive vascular rings can present with progressive respiratory symptoms or dysphagia—the latter being the commonest. The dysphagia associated with aberrant subclavian artery had been named Dysphagia Lusoria. Stridor or wheezing can be absent in the infant, but these symptoms develop over time because normal growth of the aorta results in symptomatic tracheal compression. The obstruction of the esophagus is incomplete and hence the symptoms of dysphagia are not apparent till the child is eating normal food. Thus children with vascular ring anomalies generally present with the first years of life, but not in the neonatal period. A plain chest radiography can identify a right-sided aortic arch. A contrast esophagogram done while evaluating dysphagia establishes the diagnosis. Thereafter magnetic resonance imaging, echocardiography or digital subtraction angiography further elucidate the anatomy (Figs 31.9 and 31.10).

Patients with symptoms require surgical division of this vascular ring. The approach is through a left posterior lateral thoracotomy. In complete ring (double aortic arch) the left arch is divided at its narrowest point which is either posterior to the origin of the left subclavian artery or between the ascending aorta and the origin of the left common carotid artery. In incomplete vascular ring it is important to identify the arch and its branches as well as the ligamentous arteriosum. The ligamentum is then doubly ligated and divided, taking care not to injure the recurrent
laryngeal nerve. In certain circumstances the aberrant subclavian artery need surgical intervention. Some surgeons detach the retrooesophageal aberrant right subclavian artery and reimplant on the aortic arch, while most simply divide this vessel and allow the distal portion to retract across the mediastinum from behind the esophagus.27

**ESOPHAGEAL STRICTURE SECONDARY TO FOREIGN BODY**

Foreign bodies can cause esophageal injury, which can lead to esophageal stricture. These injuries are much more likely from sharper foreign bodies including detachable pop-tops used on aluminum drink cans.30 These objects are often nearly radiolucent; hence the diagnosis is made late. The usual presentation is with obstructive symptoms. In recent years the ingestion of disc batteries is causing an alarming concern (Table 31.6).31,32 These batteries may produce esophageal damage by one or all of the three mechanisms: diffusion of alkali from the battery causing caustic injury, low voltage mucosal burns from the electric current generated by the battery that is not fully discharged and/or local pressure necrosis

**Physical Examination**

- Signs of esophageal perforation:
  1. Subcutaneous emphysema
  2. Hamman's sign (mediastinal crunch)

- General signs and symptoms of sepsis:
  1. Tachycardia
  2. Increased respiratory rate

**Radiographic Identification**

- **Ap projection— double density shadow (bilaminar structure)**
- **Lateral projection— step off at junction of anode or cathode**
- **Both AP and lateral projection views necessary to distinguish it from coin**

**Complications of Esophageal Impaction**

1. Trachea-esophageal fistula
2. Esophageal burn without perforation-esophageal stricture
3. Aorta-esophageal fistula
4. Perforation

**Management**

- **Emetics:** Emetics are contraindicated as they can cause retrograde impaction in esophagus or airway (the battery already in lower end of esophagus or in the stomach). Esophageal impaction has greater potential for serious consequence because of cumulative effect in localized area (no dilution of chemical and electric effects provided by gut secretions)
- **Removal:** Blind removal has high potential for esophageal perforation, also the direct visualization of burns is impossible. Endoscopic removal is best, tight adherence to esophagus requiring considerable care in removal. Subsequent management is on the line of caustic esophageal burn without perforation. Nasogastric stenting and feeding is instituted till another esophagoscopy after 2-3 days. In the waiting period adequate observation should be undertaken looking for signs of esophageal perforation or generalized sepsis.

**Esophagoscopic findings**

- **Signs of full thickness esophageal burns:**
  1. Edema
  2. Tight adherence to mucosa
  3. Visible mucosal defects
  4. Intra-esophageal bubbling on ventilation

**Indications for simultaneous bronchoscopy**

1. Impaction of more than four hours
2. Full thickness injury to anterior wall of esophagus
(Table 31.5). There is also a risk of systemic toxicity from batteries containing mercury. It is believed that the dead batteries produce less injury. Although there is suggestion that batteries that are 22 mm or larger in size range are dangerous, the potential for injury depends upon the size of the esophagus and the ability of the battery to pass into the stomach. The batteries can some time be mistaken for an ingested coin (Fig. 31.11). A careful look at the anterior-posterior X-ray for a small discontinuity in the outer radius of the image is diagnostic. It is always safer to have a lateral view, which demonstrates a stepping (Fig. 31.12), which confirms the diagnosis. The distinction between a battery and coin is important for the above-mentioned reasons. Greater damage is caused by 3-V lithium batteries than 1.5V alkali battery. Maximal injury occurs on anode side of battery (Fig. 31.13). Esophageal mucosal damage can occur within one hour of the ingestion of the battery and damage to all muscular layers can happen within 4 hours (Fig. 31.14). Batteries in the esophagus for a period of days have produced extensive tracheoesophageal erosion. This type of injury is reminiscent of a caustic agent, because after removal of the foreign body and presumed interruption of the pathology, progressive injury has continued in severe instances. A catheter or a magnetic device under radiological control can accomplish the removal of battery from the esophagus.

During a 7-year period, 2382 cases of battery ingestion were reported to a national registry set up in USA for battery ingestion. Button cells were ingested by 2320 of these patients; 62 patients ingested cylindrical cells. These cases are analyzed to reassess current therapeutic recommendations, hypotheses
about battery-induced injury, and strategies for prevention and intervention. Overall, 9.9% of patients were symptomatic. Two children experienced severe esophageal injury following the ingestion of large diameter cells and required repeated dilatation. Outcome was influenced by chemical system. Lithium cells, with their larger diameters and greater voltage, were associated disproportionately with adverse effects. Mercuric oxide cells were substantially more likely to fragment, compared with other chemical constituents of batteries. No clinical evidence of mercury toxicity occurred in this series, although one patient demonstrated minimal elevation of blood mercury levels. A current management protocol is advocated by the registry, advocating a non-invasive approach for most cases of button cell ingestion where an esophageal position is excluded. Manufacturers are urged to provide more securely fastened, child-resistant battery compartments on hearing aids as well as other battery-powered products in household use.

**FUNCTIONAL ESOPHAGEAL DISORDERS**

Diffuse esophageal spasm is an uncommon condition. The original description of this lesion is very complete. A spastic pain usually occurs in the esophagus accompanied by dysphagia. Since this early description, the pathology of diffuse esophageal spasm has been designated as being circular muscle hypertrophy primarily in the lower two thirds of the esophagus. The etiology is unknown.

**SCLERODERMA**

Scleroderma is an uncommon collagen disorder in children. The distal two thirds of the esophagus, which has smooth muscle, may have its normal peristalsis impaired in the patient with scleroderma. Gastro-esophageal reflux is almost universally present. Esophagitis sometimes progressing to stricture of the esophagus occurs quite commonly in scleroderma. Fundoplication has resulted in clinical improvement in many patients despite the fact that the underlying systemic illness and the disordered peristalsis remains unchanged. A scleroderma like disorder of the esophageal motility and poor lower esophageal sphincter pressure has been recently described in breast fed children of mothers who had silicone breast implants. There has, however, been no evidence presented as to the cause and effect.

**CORROSIVE STRICTURES**

Ingestion of corrosives is a major health problem in children. The tragic consequences of ingestion of corrosive and various treatment schedules have been well summarized by Tucker et al. We will not go into the details of the initial management and diagnosis...
and restrict the discussion to the treatment of established strictures. Once the stricture is demonstrated on contrast radiography done around day 10-14 after the injury, a program of dilatation is commenced. Various methods can be used ranging from mercury filled bougies, flexible-graded bougie dilatation, guide wire directed systems (Eder-Puestow) or balloon dilatation. Corrosive strictures can be successfully dilated, however the dilatation should be done with great care. The initial dilatation should never be done blindly. In the presence of several strictures and or problem with direct vision, it is much safer to place a transesophageal string. The string is later on used to guide the dilators prograde (through the mouth) or retrograde (through the gastrostomy). The trans-anastomotic string is achieved by first passing a soft tipped flexible guide wire into the distal esophagus via a gastrostomy. An endotracheal tube advanced through the gastrostomy up toward the lesser curvature can help in this. A general anesthetic is essential for satisfactory dilatation. It is good to repeat dilatation every week for it to be effective. As a practical tip the dilatation should be commenced with dilator two French size smaller than the estimated size of stricture. It should be stopped at two sizes larger than the size that met initial resistance. Nutritional support is a must during the dilatation and healing phase. This can be achieved by nasogastric feeds, gastrostomy or jejunostomy feedings. In strictures that are resistant to the treatment with dilatation GER should be suspected. Gastro-esophageal reflux should be managed surgically if necessary before embarking upon major surgery for these strictures. One study in children has shown that the adjunctive steroid injection into the scar made dilatation treatment more lasting. Localized strictures can be resected with end-to-end anastomosis. The fibrotic injury can be more extensive than seen by contrast swallow hence a good endoscopic assessment is a must before undertaking the process of resection with end-to-end anastomosis. The problem with this approach to corrosive structure is that if the esophagus continues to be used as a conduit for food during the course of years squamous cell carcinoma develop at the site of injury. Any dysphagia 20-40 years after the dilatation of the caustic strictures should be taken seriously and this fact should be passed to the patient’s relatives before discharging them to the care of adult surgeons. Investigation reveals squamous cell carcinoma at the site of the major burn injury usually at the level of the aortic arch. As compared with other patients who have carcinoma of the esophagus, the lesion in this group of patients are more resectable and the patients have a better prognosis probably because dysphagia is apparent earlier because of the esophagus being less distensible. The cicatrix in the esophageal wall may also prevent early local spread of the tumor due to obliterated lymphatics.

**ESOPHAGEAL REPLACEMENT**

The basic principles of esophageal replacement are:

1. It is generally regarded that the patient's own esophagus is the best conduit but there are exceptions to this.
2. The surgeon must weigh the pros and cons of replacement before undertaking this procedure with informed consent.
3. These patients need long-term follow-up.

**PEPTIC STENOSIS**

Strictures of the esophagus secondary to GER are severe. They are late complication of GER. These strictures are secondary to severe esophagitis and are accompanied in some instances by Barrett’s esophagus. In established strictures the basic tenets of therapy are operative correction of GER (for the oesophagitis to heal) and dilation of the stricture. In general dilations of strictures secondary to GER are ineffective until the reflux is controlled. After the intraoperative dilation, a standard Nissen fundoplication is performed. Postoperative dilations, using the string-guided technique, are used as and when required. In the overwhelming majority of reflux strictures in children, the use of antireflux operations and dilations are successful. Only in rare instances is resection required. When given a choice between fundoplication and repeated dilatation or a primary esophageal substitution procedure, fundoplication appears to provide better results and fewer long-term complications. Rarely a patient with epidermolysis presents with esophageal stricture. These patients require esophageal substitution because the underlying disease process does not allow dilatation of the esophagus without complete destruction of the mucosa.
A large number of reports confirm the effectiveness of omeprazole in the treatment of esophagitis in children.\textsuperscript{63-65} Omeprazole may eventually have a role in managing established reflux strictures, but no reports on its efficacy in this regard have appeared so far. Although its effectiveness in esophagitis is apparent, its success in truly advanced esophagitis is not as impressive; less than half of grade 4 esophagitis healed with omeprazole.\textsuperscript{63} Recurrence seems to be inevitable when the drug is stopped.

ESOPHAGEAL ACHALASIA

The etiology of achalasia is unknown. Achalasia is primarily a disease of older people whose symptoms do not begin until adulthood. A congenital etiology is therefore unlikely. Achalasia can occur in a familiar pattern and in such situations pyloric stenosis has been noted.\textsuperscript{66} The symptoms can present from childhood. Gastroesophageal reflux can produce spastic reaction in the lower esophagus resembling a clinical and radiological picture of achalasia, hence some surgeons recommend pH monitoring in all the suspected cases of achalasia of the esophagus. A frequent cause of the delayed diagnosis of achalasia is because of its confusion with the symptoms of gastroesophageal reflux.

A barium examination of the esophagus is diagnostic as it reveals a large proximal esophagus with imperfective peristalsis and a bird beak deformity of the distal esophagus. This radiographic picture is classical of achalasia. A manometry can be undertaken to confirm the diagnosis, which reveals non-peristalsis in the body of the esophagus with little or no relaxation of lower esophageal sphincter.\textsuperscript{67,68} The treatment is surgical, although calcium channel blockers (Nifedipine) have been shown to reduce the lower esophageal sphincter pressure in children with demonstrated achalasia. The effect is usually transient.\textsuperscript{69} Most of the literature dealing with achalasia is found in the adult literature, however the management is similar in children.\textsuperscript{70} Bouginage or balloon dilatation sometime produces good symptomatic relief although in adult literature it is associated with a perforation rate of up to 12%.\textsuperscript{71} Successful balloon dilatation can result in symptomatic gastroesophageal reflux in a significant number of paediatric patients.\textsuperscript{72} The standard accepted surgical treatment for achalasia is esophageal myotomy. This was proposed by Heller 80 years ago. It can be undertaken by thoracic or abdominal approach. The basic principle is to incise both the longitudinal and circular muscle layers of the esophagus down to the submucosa as done in pyloromyotomy. A better resolution of symptoms is reported with abdominal myotomy combined with fundoplication as compared to thoracic myotomy with or without fundoplication.\textsuperscript{73} We believe that esophageal myotomy coupled with fundoplication is the ideal procedure for achalasia.

SUMMARY

Esophageal strictures in children are a challenging problem. Prevention is better than cure. An early diagnosis and prompt treatment can save a child’s own esophagus. Each case deserves individualized management to prevent complication (Table 31.7).

REFERENCES

40. Yeung CK, Spitz L, Brereton RJ, Kiely EM, Leake J. Congenital esophageal stenosis due to tracheobronchial...
Esophageal replacement remains a challenging operation to pediatric surgeons and required significant expertise and experience in the field. Various options available for replacing the esophagus are; colon, gastric tube, stomach, jejunum, bridge gastric tube and bridge colonic segment. The choice, however, depends upon the age of the child, the initial pathology and also the surgeon’s preference. Though most surgeons would prefer to wait till the child has gained adequate weight, the authors have performed an early replacement even in the newborn period for complicated cases of esophageal atresia.  

The indications for esophageal substitution are:
1. Failed primary anastomosis in esophageal atresia necessitating diversion.
2. Long gap isolated esophageal atresia (EA).
3. Wide gap esophageal atresia and tracheoesophageal atresia (EATEF).
5. Severe esophageal trauma.
6. Peptic esophagitis.  
7. Candidiasis.
8. Scleroderma.

Most esophageal replacements are required either for complicated TEF (wide gap, long gap and major leaks) or the postcorrosive esophageal injuries (alkali and acid ingestions).

Table 32.1 Enumerates the authors’ experience in this field.

Criteria for an Ideal Esophageal Substitute are
1. Efficient conduit to supplement the nutritional needs of the child.
2. The conduit should grow with the child and should last for life-long.
3. The surgical technique should be simple, safe and adaptable to small children.
4. Gastric acid reflux into the conduit should be minimal, and if reflux occurs, the substitute should be resistant to acid damage.
5. The presence of the conduit should not impair respiratory or cardiac function.
6. The conduit should not produce any external cosmetic deformity.
7. Postoperative complications if any, should be manageable easily.

TIMING FOR ESOPHAGEAL REPLACEMENT

For the TEF Group

Though the esophageal replacement for esophageal atresia can be performed as a primary procedure in the neonatal period, most of the time it is performed after the diversion (esophagostomy and gastrostomy) has been done, and at a time (6 months to 1 year of age) when the child has gained enough weight and can sit and eat by him/herself.

**For the Corrosive Group**

The ideal time for operating upon a child with post-corrosive esophageal stricture is at least six months after the insult and after sufficient number of dilatations have been tried and failed (normally at least 6 months of trial). The frequency of dilatation depends upon the length of the stricture, the tightness of the stricture and the pliability of the stricture. The dilatation may be begun 3 weeks after the insult starting at a frequency of twice weekly and then gradually reducing the frequency to fortnightly and then once in 3-4 weeks. If the dilatation is required at an increased frequency than planned and if the size of dilator required is less than the previous size used for dilatation, then there would be a need for esophageal replacement. Some authors have taken the criterion for esophageal replacement as recurrence of the stricture within 3 weeks of the previous dilatation.4

**Routes of Esophageal Replacement**

The common routes for performing esophageal substitution are either retrosternal or the transhiatal mediastinal route (Figs 32.1A to D). Rarely a retrohilar route has been used creating a neohiatus to the left side of the natural esophageal hiatus in the diaphragm along the costal margin to gain access to the thorax. The subcutaneous route was measured as 1.8 cm longer than the retrosternal route that was 1.9 cm longer than the mediastinal (orthotopic) route on autopsy studies.7 The difference between the subcutaneous and the orthotopic route was 3.7 cm.7 The subcutaneous route that was used in adults in the past was just in front of the sternum. The advantage was that the food contents could be pushed down manually by the patient himself. However, it was ugly as the movement of the food bolus was visible on the surface. This route has not been used in children, though anecdotal excellent long-term results have been reported using this route.

---

**Fig. 32. 1A to D:** Outlines of the various routes in the chest for esophageal replacement. A. Retrosternal B. Transhiatal mediastinal, C. Retrohilar mediastinal D. Various levels of the opening in relation to the diaphragm
**Retrosternal (Substernal)**

This route is directly behind the posterior sternal surface. It is important to create adequate space for the graft to be housed comfortably at the xiphisternal level, behind the sternum and at the thoracic inlet. The sternal head of the sternomastoid muscle, the sternohyoid and sternothyroid muscles may have to be detached from the bony attachments with the sternum, to prevent compression of the graft and its delicate blood supply specially in the neck region.

**Advantages of the retrosternal route are:**
1. It is technically simple, safe and very easy to create in children.
2. There is no pulmonary or cardiac compression by the interposed segment.
3. There is less chance of damaging the recurrent laryngeal nerve, trachea and major thoracic vessels, especially in the presence of a scarred mediastinum with old surgery.

**Disadvantages:**
1. It is the longest route
2. Chances of kinking of the conduit while coursing over the left lobe of the liver.
3. While creating the space, the pleura may be injured causing pneumothorax, unilateral or bilateral.
4. There is a narrow space between the manubrium and clavicle and the scalene muscles. This may compromise vascularity and may also cause obstruction unless mobilized adequately.

**Transhiatal (Mediastinal) Route**

This is the route, most commonly utilized in newborns, infants and children after the native esophagus has been removed. It is the normal route for esophageal replacement. It uses the normal esophageal hiatus in the posterior mediastinum, thus maintaining the natural route. There is also no risk of kinks and curves using this route. However, the disadvantages are;
- Technically difficult, especially in cases with a scarred posterior mediastinum.
- Chances of damage to the trachea, major vessels and recurrent laryngeal nerve.
- Risk of pulmonary compromise due to compression.
- May need an additional thoracotomy, to remove the esophagus and also to create the enough space for this route.

**Retrohilar Route (Waterston operation)**

This route initially described by Waterston, is no more used, though it is the shortest of all the three routes. In this procedure, the colon is used from abdomen to the neck with the transthoracic-retrohilar route. A thoracotomy is performed through the left 6th intercostal space. The diaphragm is incised along its attachment with the costal margin just to the left of the original esophageal hiatus. The middle colic artery is divided on the lower border of the pancreas close to its origin, preserving the ascending branch of left colic artery and inferior mesenteric vein. The isoperistaltic colonic segment is then brought into the chest through a small incision in the diaphragm postero-lateral to the esophageal hiatus and passing behind the tail of the pancreas and stomach. Colon is finally brought in the neck through the retrohilar route and the apex of the pleura, anterior and medial to the left subclavian vessels. In the original Waterston operation, the lower esophageal stump was mobilized and anastomosed to the colon, preserving the gastroesophageal junction. This carries the risk of injury to the major vessels in the neck with the rare possibility of the catastrophic hemorrhage from subclavian vessels. An inadequate space at the thoracic inlet may also cause compression effect. This operation is now used only very infrequently. The only use may be for a case with left esophagostomy and in which the lower stump has been preserved and also if the mediastinal and the substernal routes are not available. Even with the left sided esophagostomies done earlier, the author’s preference has been to mobilize the esophagostomy well and use either the retrosternal or the mediastinal route.

**COLON INTERPOSITION**

Colonic interposition is the most commonly used procedure to replace the esophagus in the pediatric age group, preferred by most pediatric surgeons around the globe. The procedure is reported to have minor complications in the long-term and less of major complications as compared to those seen with the gastric transposition ($P = .001$).

**The Advantages of Colonic Interposition Include**
1. Reliable vascular pedicle due to the marginal artery of Drummand.
2. Length of the graft is no problem.
3. Can be used as a conduit in any direction—Iso or antiperistaltic.
4. Easy coursing over the liver edge, with due precaution and hitching the liver properly.
5. Relatively safe and easy to perform, even by the beginners.
6. Postoperative complications are infrequent and less serious.

**Preoperative Work Up**

1. Barium enema for rotational abnormalities of the colon if any and to rule out pouch colon and any intrinsic diseases of the colon like polyposis.
2. Assess cardiac status
3. Build up the nutrition to ensure good healing and endurance of anesthesia
4. If the child is on gastrostomy, ensure sham feeding has been continued to develop taste at least for salt and sweet.
5. If the child is on oral liquids following corrosive stricture, assess the status of the lungs and flow across the pylorus.
6. Good colon preparation using polyethyleneglycol (PEGLEC), rectal washes and oral antibiotics.

**Technical Aspects**

Colon has rich blood supply supplemented well by various named vessels arising from the ileocolic, middle colic and left colic blood vessels, all making a network in the mesocolon to form the reliable marginal vessels running all along the length of the colon. This arrangement makes it feasible to shape the colon graft for any length so as to reach even the highest point in the neck to be anastomosed even with the pharynx.

**The Options while using the Colon Conduit are**

1. The right colon and the transverse colon can be used as the conduit, based on the middle colic artery. Though, it would be anti-peristaltic but this is of no significance.
2. The transverse or left colon can also be used as the iso-peristaltic conduit, based on the left colic vessels. It is preferred over the right colon because it is less bulky and the blood supply is also more reliable. The middle colic is a major vessel and bifurcates in the right and the left branch to anastomose freely with the adjoining vessels to supply the right, transverse and the left colon. Normally, it is the left branch which is more prominent and supplies the larger segment of the transverse colon. However, in about 25% cases, it is the right branch that is more prominent. This is important before deciding as to which branch needs to be preserved so as to maintain a rich blood supply to the colonic graft. Figure 32.2 outlines vascular supply of the colon with implications for using the right or the left colon. A temporary clamp or bulldog may be tried on the proposed branch to be divided, to check the reliability of the vascular supply to the graft so planned.

Any of the isoperistaltic or anti-peristaltic colonic segment may be used. An isoperistaltic orientation is theoretically ideal although this has not been clearly
demonstrate. The colonic flexures should be mobilized, temporarily clamping of the ascending branches of ileocolic artery and the left colic artery to check the adequacy of vascularity.

An interposition of the transverse colon may be maintained by a double vascular pedicle based on the left colic vessels and the marginal paracolic arcade. The omentum is also detached from the transverse colon. Liver is hitched with the cut end of the round ligament behind the xiphisternum so as to allow the graft to have smooth course over the liver edge. The length of the colonic segment should be assessed by measuring the required length with a tape so that it is adequate, also keeping in mind that the colon graft shrinks after it has been transacted at either ends. The colon is transacted between clamps for the desired length (Fig. 32.3).

The isolated colonic segment should be cleaned on table with normal saline to remove the residual peglec solution or the fecal matter (Fig. 32.4). The adequacy of the length of the colon segment is reassessed and the colon is placed in the desired place without any tension or obstruction in its route (Fig. 32.5). Any redundancy is trimmed. The colon graft on its pedicle is passed behind the stomach through the gastro-hepatic ligament to take the desired route; a retrosternal or the mediastinal.

The excess of the pulled colon, if any, is trimmed and the vascularity at the edges is reassessed. A wide and single layer end to end (rarely end to side if the vascularity is in doubt) esophagocolonic anastomosis is performed, using absorbable interrupted sutures. Colon is fixed with the prevertebral or deep cervical facia to prevent its sagging.

The distal end of the graft is anastomosed to the anterior wall of the stomach in the body or near the antrum, in two layers. Few sutures are placed at the

Esophageal Replacement with Colon

angle of the stomach with the colon to incorporate the antireflux mechanism at the gastrocolic junction.

The ends of the divided colon are approximated and anastomosed in two layers, in front and inferior to the pedicle of the isolated colon graft (Fig. 32.6).

Pyloromyotomy or pyloroplasty is performed only if the vagus has been damaged. Multiple relaxing incisions can be given on the Taenia coli to elongate the graft, if the need be to avoid a tension.11

Neck wound is closed with a soft drain around the anastomosis (Fig. 32.7). The native diseased and strictured esophagus in patients with corrosive injuries should preferably be removed (Fig. 32.8).

Colon should be decompressed with a nasogastric tube and left open to the atmosphere to avoid acute dilatation and also to drain the swallowed saliva. The retrosternal route is preferred by most authors.8,12,13 A retrosternal route should however be avoided if the liver is large. Few authors however, perform thoracotomy for doing an esophagectomy under vision. In the authors’ experience, it has always been feasible in almost all cases without the need for a formal thoracotomy except in one case with severe periesophagitis following corrosive injury. In another case, the esophageal wall was densely adherent and while mobilizing it, while the esophageal mucosa could be removed completely the muscle wall was left behind. It is acceptable as it is the diseased esophageal mucosa which is prone to turn malignant and not the muscle. This may be advantageous to utilize the transhiatal approach in children with the past history of major leaks or the scarred mediastinum due to peri-esophagitis.14
Recent Alterations
Hadidi et al, ligated the trunk of the middle colic artery supplying the transverse colon at the time of doing the gastrostomy operation. This was attempted with an idea to increase the blood supply to the transverse colon through the left upper colic and marginal vessels. They have reported excellent results after colonic interposition based on left colic branch, with only one out of 11 cases, developing stricture in the neck requiring revision. The well thought procedure has however, not been accepted by the most others. Moreover, the colon has a reliable marginal artery and the chances of graft loss are uncommon. Surgeons have achieved equally good results in large series even without the ligation of the middle colic artery.

Contraindications for use of the Colon as an Esophageal Replacement are

i. Incomplete marginal arterial arcade. It may be absent in around 3% of normal individuals.
ii. Associated high anorectal malformation, specially the pouch colon (relative contraindication)
iii. Any other associated colonic disease, polyposis coli, ulcerative colitis.

COMPLICATIONS OF COLON INTERPOSITION

Early Complications

1. Necrosis of graft: Tension at the anastomotic site because of inadequate length of colon can predispose to ischemic graft necrosis (Fig. 32.9). Ischemia can usually be identified at the time of anastomosis. To meet this challenge, an alternate interposition can be constructed in place of the ischemic segment. Short cut can also be planned in the Taenia coli if the ischemia is limited to the terminal end for a few cm only. Graft necrosis can be suspected in the postoperative period by the presence of fever, a dark serosanguinous drainage in the NG/mediastinal drain, crepitus, pneumothorax, sepsis or shock. A fibre-optic endoscopy can confirm the diagnosis. Prompt re-exploration with removal of the gangrenous graft is mandatory necessitating diversion in emergency. Subsequently, gastric tube or stomach pull up can be considered to replace the esophagus.

2. Anastomotic leak: Leakage from the proximal esophageal anastomosis is common. This may vary from 20-50%. Leak could be major or minor, with or without symptoms. Ischemia, tension, technically faulty suturing and presence of the esophageal fibrosis at the anastomotic site are the usual reasons for the leak. Majority of the leaks would heal spontaneously provided an adequate drainage has been ensured. Antibiotics and proper nutrition is to be continued. The leak may present as an esophagocutaneous fistula.

3. Gastric outlet obstruction, colonic leak, peritonitis.
4. Mediastinitis, pneumothorax, empyema.
5. Operative mortality ranges from 1-10%.

Late Complications

1. Anastomotic stricture is frequent and is seen in 20-30% cases. The proximal anastomosis is commonly involved. Most strictures respond to dilatation. Lower end strictures are less common and usually require surgical revision, as blind dilatation of the lower anastomosis is hazardous.
2. Obstructive symptoms due the kinking of the lower end of the esophagus over the liver (Figs 10A and B).
3. Redundancy of colon or upper esophageal pouching. Mild redundancy of the colon may
Esophageal Replacement with Colon

389

not necessitate revision of the colonic conduit if there is no dysphasia. Redundancy may lead to food stasis, recurrent regurgitation and aspiration. The dilated graft may also cause pulmonary compression. Surgical revision may be required if the patient is symptomatic (Figs 11A and B).

4. Halitosis.

5. Acid reflux: There is no clear difference in the degree of reflux between a direct cologastric anastomosis or if the anastomosis of the colon has been made to the lower esophageal stump.

8. Inflammatory colonic polyps.

10. Pulmonary symptoms due to chronic acid reflux and aspiration

11. Intestinal obstruction due to adhesions

12. Dumping syndrome.

13. Late graft stenosis.

THE WORLDWIDE EXPERIENCE

Corrosive strictures are common in many countries, e.g. Egypt, Poland, Romania and Turkey, due to the accidental ingestion of washing soda liquid that is used liberally in households (as the milky white fluid kept in drinking water plastic or glass bottles for washing clothes). However, Egyptians possibly have the largest personal and collective experience of over 1200 cases of esophageal replacement using colon. Their postoperative complication rate is also low. Ala Hamza et al reported an experience with more than 850 cases of esophageal replacement over the last 30 years. Complications in the last 475 cases included 10% cervical leakage, 5% proximal strictures, 2% postoperative intestinal obstruction, 1% mortality, and 0.6% late graft stenosis.

Colonic replacement of the esophagus was felt as the ideal treatment in cases of caustic esophageal strictures after failure of dilatation. The posterior mediastinal route was preferred as it is shorter, and in long-term follow-up results show improved evacuation and less reflux than with the retrosternal route.

The Factors for this Success could be

1. Referral of most such patients to major centers to be operated upon by the experienced faculty interested in the field.

2. Use of end to side (instead of end to end) and a tension free anastomosis in the neck, reducing the incidence of postoperative leak and the stricture.

3. Exactly measuring the segment of the colon to be used to replace the esophagus.

4. Ensuring good blood supply at either end of the segment of the colon.

5. Removing the native diseased esophagus and placing the colon through the transhiatal route.
6. Using the iso-peristaltic left colon based on the ascending and the descending branches of the left colic artery.
7. Draining the colon in the postoperative period to avoid distension.
8. Incorporation of the valvular mechanism at cologastric junction to prevent reflux.
9. Check endoscopy for early detection of the strictures in the neck and institute dilatation program if the need be.
10. Follow-up with endoscopy to assess for development of any malignancy in the long-term.

FOLLOW UP
Patients who undergo esophageal replacement should be kept under regular follow up not only for assessing their growth and development status but also to monitor the complications if any. Colonic interposition is one of the safest and best alternatives to the normal esophagus, with minimal short and long-term complications. Patients develop normal eating habits and catch with the height and weight. Postoperative stricture rate is around 10% in experienced hands, mostly managed with dilatations. Half of these may need surgical correction. Moreover, even if the complications develop; these are not serious and easily manageable with the medical or rarely the surgical interventions. Similarly, cologastric reflux and peptic ulcer disease are uncommon. Redundancy may be noted in over 5-10% cases but surgery is indicated only if the patients develop vomiting and dysphasia. In a long-term follow up series of 51 patients reported by Mitchell et al with a mean follow-up of 14 years, reported that almost all the patients were able to eat a normal diet and only 5% had poor results. However, most of these patients were below the 25th percentile for their weight and height. Stone et al reported 86% good results in 37 patients followed up for a mean period of 9.7 years with excellent weight gain and growth development.

REFERENCES
In the last 20-30 years there have been no publications on the topic of esophageal surgery in childhood, without mentioning the well known postulate: “The best esophagus in children is his/her own esophagus.” Truly a rare operation in childhood, esophageal replacement is still mandatory in cases of extensive damage of the esophagus, mainly due to caustic injuries and in a few cases of long gap esophageal atresia (EALG). Several techniques are commonly used: colonic graft, gastric tube (GT) and gastric transposition are the most popular techniques, depending on the experience and preference of the surgeon. Other options of esophageal replacement or reconstruction have been published, but only small series, with a few cases and lack of long-term follow up: colonic patch, small bowel and sigmoid transposition with microvascular anastomoses, different types of small bowel interposition. At present the long-term results and the quality of life in young adults, after esophageal replacement performed in childhood have been published, many with very good results and a normal life. This chapter is devoted to the gastric tube esophageal replacement (GTER) in children.

**HISTORY**

Esophageal replacement by GT is undoubtedly connected with the personality of Prof. Dan Gavriliu, general surgeon in Bucharest, Romania (Fig. 33.1).

He was the first to perform the reversed gastric tube in adults; in 1951, he published his first series of 21 cases. He has positioned the tube initially presternally, then retrosternally and never used the intrathoracic or posterior mediastinal route. In the original technique he recommended an associated splenectomy to facilitate the tailoring of a tube long enough to easily reach the neck and wrapped the tube with omentum. In 1957 he published a book about surgery of the esophagus and over a long and brilliant carrier he performed close to 1000 GTER and popularized the technique in Romania, Europe and then in North America. In an interview he declared performing more than 5000 GTER (!) for all indications, including children with EALG. In the new world the technique is known as Dr.Heimlich’s operation. Dr Heimlich from Ohio, without knowing of D Gavriliu’s work, described the same technique and published his first short series in 1959. The first GT performed in Canada was by Dr James Fallis, but S Ein has extensively used the GT in Children and published long-term results.
In fact, the history of GT is a bit different: Several well known surgeons in Europe and Northern America, at the end of 19th century and beginning of 20th suggested and did experimental work on esophageal replacement with the stomach (D. Biondi 1895, Gosset 1903, Hirsch 1911, Carl Beck and A. Carrel). In 1969 P Orsoni wrote a very comprehensive monograph in French: “Esophagoplasties”. In his book, an extensive review of the true history of esophageal reconstruction is presented and he restored the true “paternity” of GTER. Prof Amza Jianu, professor of General Surgery in Bucharest, Romania had been the tutor of Prof D Gavriliu at the beginning of his surgical training. In between 1910-1936 he imagined, proposed and did many experimental works on animals on GTER. He performed the experiments together with Dr D Gavriliu but Amza Jianu never performed his operation on humans; Dr D Gavriliu was the first surgeon using the technique in patients. Over time several modifications of the original technique were published: Transhiatal esophagectomy (Denk, 1913, Turner, 1936, Orringer 1978), which later was combined in a one stage operation with colonic graft (B M Rodgers and all 1981). In the last decade the most utilized procedure for pediatric esophageal replacement is a combination of transhiatal esophagectomy and the placement of the substitute graft (colon, small bowel or gastric tube) through normal, posterior, mediastinal route, in a one stage operation: For gastric tube it was first published in 1985.

JD Burrington (1968) and JC Pedersen (1996) presented a short series of GTER for EALG performed very early, even in the neonatal period. A very attractive technique has been recently published and experimentally documented, which uses an isolated pediculated gastric tube interposition as esophageal substitute, especially in cases of esophageal atresia long gap. The technique claims some interesting advantages but needs bigger series and long-term results.

SURGICAL ANATOMY—PRACTICAL CONSIDERATION FOR GTER TECHNIQUE

When performing any type of esophageal replacement, retaining a well vascularized graft is the main concern. There is no series on esophageal replacement without a few cases of graft failure and necrosis of vascular cause (thrombosis, poor vascular perfusion, compression/twisting of the main pedicle). A few surgeons for improving the graft perfusion, combine vascular grafts (colon, small bowel) with additional blood flow, via micro vascular anastomosis at the level of cervical anastomosis (with facial, internal mammary, or even external carotid artery).

It is unanimously accepted that the stomach has an excellent, rich vascular network, with multiple anastomosis and low septic risk, due to acid secretion. As the vast majority of surgeons use the reversed gastric tube for esophageal replacement (RGTER), the interest is focused on blood supply of the great curvature of the stomach. The great curvature is bordered by the gastroepiploic arcade (gastroomental), resulting from the direct anastomosis of the right (originated from left gastric artery) and left (originated from splenic artery) gastroepiploic vessels. Numerous collateral vessels spread within the great curvature wall where they make large loops with rich anastomosis. In many cases the gastroepiploic arcade is incomplete for 2-7 cm, raising concern in the mind of the surgeon on the quality of blood supply within the gastric tube (30% of cases in my personal series of 107 RGTER). Study on microvascular anatomy has demonstrated an excellent vascularity within the wall of great curvature in all cases, unrelated with a complete or incomplete gastroepiploic arcade. In surgical practice an incomplete arcade is not a contraindication for utilization of GT. Studies published recently on the vascularity of the stomach show that the fundus of the stomach is less well vascularized than the vertical part of the stomach and the antrum; consequently, at least theoretically, an isoperistaltic tube, based on right gastroepiploic artery, will have less perfusion in the end part of the tube than a RGT which is brought up to the neck for anastomosis (Fig. 33.2).

Experimental work of Schilling MK et al 1997 on blood perfusion in different types of GT, based on Doppler flowmetry, proved that the best flow was found in the fundus tube, based on lesser curvature vessels (fundus rotation gastroplasty). They also demonstrate by the same technique that dissection of gastrocolic ligament and vascular disconnection when the tube is made, reduces the blood flow along the great curvature. They recommend intraoperative utilization of Doppler flowmetry which might prevent
ischemia-induced anastomotic breakdown. In 2006 Nishikawa K et al. presented their experience with intraoperative thermal imaging in esophageal replacement; they measured the surface temperature of the intact stomach, devascularized stomach and the GT and clearly demonstrated a lower surface temperature in the proximal part of the GT. They conclude that intraoperative thermography is a non-invasive, reliable method and recommended to be used when the GT is made. Lazar G et al. 2003, in a genuine experimental work, proposed utilization of thoracic epidural anesthesia, to improve the gastric microcirculation when a GT is made. All the above methods to document the satisfactory perfusion of GT are non-invasive procedures, not time consuming and could be used intraoperatively; the author has no personal experience with them.

A previous gastrostomy, incorrectly located on the great curvature and interruption of the gastroepiploic arcade could be a contraindication for gastric tube; in my series 2 cases presented with gastrostomy on the great curvature and vascular arcade compromised; one case has been converted in colonic graft with excellent result the other had an atypical gastric tube involving the posterior wall of the stomach at the level of the gastrostomy and finally a complete necrosis of the tube occurred.

In conclusion, the great curvature of the stomach offers an excellent, well vascularized structure for esophageal replacement, with a low risk of vascular graft failure, compared to colon interposition or small bowel.

**INDICATIONS FOR ESOPHAGEAL REPLACEMENT**

Esophageal atresia long gap and extensive esophageal stricture postcaustic ingestion are the most common indications for esophageal replacement in children. The Foker’s technique of rapid esophageal elongation, together with various procedures of delayed esophageal anastomosis, almost eliminates the need for replacement in EALG. The complete failure of end-to-end anastomosis after primary, delayed or secondary surgery for EALG is a very rare condition which still may require an esophageal replacement.

The correct aggressive treatment of caustic injury with corticoids, early dilatation and eventually endless-loop bougienage in cases of moderate stenosis but resistant to intermittent dilatations significantly reduces the number of cases who need esophageal replacement.

Occasionally, for isolated cases of severe esophageal stricture in patients with epidermolysis bullosa, achalasia, long esophageal duplication, or infectious strictures of the esophagus a replacement of the esophagus could be indicated. The choice of the type of replacement mostly depends on surgeon preference. Interestingly Harmel performed esophageal replacement on two siblings with epidermolysis bullosa; his comment was that the GT was easier and performed in shorter time than the colonic graft, but with very good results in both cases. In the past the GT replacement has been used in desperate cases of uncontrollable bleeding due to esophageal varices.

In some cases the GT, colonic graft or gastric transposition have specific indications or cannot be used: In VATER syndrome, esophageal atresia associated malrotation, congenital megacolon, congenital short colon, premature with previous episodes of NEC, multiple intestinal atresias syndrome the colonic graft is contraindicated. Very small stomach as in type I esophageal atresia, gastric scars from caustic ingestion, especially strong acids, inappropriate site of gastrostomy on the great curvature makes the GT unsuitable for replacement.
Gastric transposition, although a very popular and safe operation, should be cautiously used in childhood, only as a last resort, if the other types of replacement are not possible.

Finally it should be mentioned that the GT has occasionally been utilized for other indications such as drainage for the ventricular shunt (ventriculo-gastric shunt), for biliary atresia as gastro-portostomy, via a short isoperistaltic tube (China) and in adult surgery for continent, tubeless gastrostomy in cases of unresectable esophageal cancer.

**OPTIMAL TIME FOR ESOPHAGEAL REPLACEMENT**

The optimal time for esophageal replacement depends of many factors: primary disease, co-morbid pathology, the level of intensive care unit for safe postoperative care, often an arbitrary decision of the surgeon (i.e. not earlier than 1 yr, 6 or 8 kg). For esophageal atresia there is a general agreement for an early repair/replacement of the esophagus as soon as possible, even in neonatal period, to achieve the oral feeding.

All types of replacement (gastric tube, colonic graft and gastric transposition) have been performed successfully in neonatal period or early infancy and can be safely done if the mandatory conditions for a successful GT replacement are achieved (see below).

In case of severe strictures, not responding to dilatations, the replacement should be done after all methods of dilatation have failed. In the author’s experience the endless loop dilatations performed over a long time (1-3 years) is an excellent method which, if it is used correctly, could avoid the replacement. The advantages of the method are that it is done daily or twice a day at home, by family (sometimes by the patient if older), no need of anesthesia, very safe, with minimal complications (nasal, choanal, soft palate ulcerations, granuloma, stenosis) and allows concomitant oral feeding. The disadvantages are: presence of the loop, need of a gastrostomy and is difficult to accept by family and patient, mainly for psychological reasons (Fig. 33.3).

Some authors recommend early replacement based on a non-documented idea that the mediastinal fibrosis increases over time and the removal of the damaged esophagus will be difficult and more prone to complications. They recommend the replacement-if needed—at 6 months postingestion of the caustic substance. If the posterior mediastinal route is used, previous mediastinitis from the caustic or iatrogenic perforation, then a long interval is recommended (minimum 1 year) since the complete healing of mediastinitis. In these cases the retrosternal position of GT could be a better option. The damaged esophagus should finally be removed as a separate operation or in one stage. The replacement for esophageal atresia should be performed on baby in good health, with a documented big gastric reservoir, on well accepted “sham feeds”; majority of these cases have their replacement performed between 8-14 months. For caustic strictures the replacement has never been done earlier than 1 year from ingestion in most of the cases (mean 16-24 months).

**CHOICE OF ESOPHAGEAL REPLACEMENT: COLONIC GRAFT, GASTRIC TUBE OR TOTAL GASTRIC TRANSPOSITION**

The literature regarding the “best esophageal replacement in children” is abundant; almost every year 1 or 2 articles try to answer this question better. Based on a large series and comparing the long-term results, the first option is equally divided between colonic substitution or gastric tube, followed by total gastric transposition. The other substitution as small bowel, different other
gastric tubes from fundus or lesser curvature, Scharli’s operation included should be regarded as isolated indications and their utilization should be based on the real contraindications for gastric tube or colonic substitution.85,86

**PREOPERATIVE PREPARATION FOR GASTRIC TUBE ESOPHAGEAL REPLACEMENT**

Esophageal replacement is a major surgery in pediatric patients; postoperative morbidity and even mortality are still recorded in many series. A few cases of failure of any type of esophageal grafts are noticed in most of the series. It is recommended to have implemented a nationally accepted protocol for 1-3 tertiary centers of excellence, with experienced surgeons in esophageal pediatric surgery and high level PICU. In several countries patients who eventually need esophageal replacement are taken over early by a multidisciplinary team to insure best care (pediatric gastroenterologist, nutrition, pneumologist, experienced endoscopist, stoma care, experienced surgeon, anesthesist even psychologist for family or older patient support (teenagers with suicide attempts, interruption of school, stress due to multiple dilatations, etc.).

There are several mandatory conditions that should be fulfilled for a successful GTER:

1. The decision for GTER should be a well planned operation.
2. The best time for safely performing the GT has been discussed. Many of these patients, especially with plurimalformative syndromes or postcaustic injury present with severe malnutrition. Improving the nutritional status is an intimate part of the preoperative preparation; this can take months.
3. Most of the patients who underwent esophageal replacement have a preoperative gastrostomy. The Stamm gastrostomy is most commonly used by pediatric surgeons but often the gastrostomy has been performed elsewhere and could be inappropriate as site or of poor quality (leaking, inflammation, erosions due to gastric juice). In a few cases a new gastrostomy with closure of the old one could be the only option. The surgeon who performs the initial gastrostomy must write detailed notes about the gastric vascularity and if a further gastric tube is possible. Some surgeons prefer a feeding jejunostomy instead of gastrostomy with the reason of having “a stomach free of previous surgery” at the time of replacement. The gastrostomy is a mandatory preliminary step before gastric GTER not only for feeding but for creating a big gastric reservoir. After several months of feeding jejunostomy, the stomach becomes very small and the GT is no longer possible. If the patient is referred with a jejunostomy already in place, before GTER the jejunostomy should be closed and the patient must have a gastrostomy performed. Feeding should be given as large bolus and the gastric capacity should be at 250-750 ml, depending on age (Fig. 33.4).

The big gastric reservoir is a major problem in type I esophageal atresia; in these cases initially the stomach is so small that even placing a gastrostomy tube could be a problem. A well established protocol for gastric enlargement, but bigger and bigger meals allows the stomach to reach a normal volume in 3-6 months (Figs 33.5 to 33.9).

In cases of EALG a program of “sham feeds” is mandatory. The “sham feeds” should be implemented immediately in neonatal period. For patients with end or lateral esophagostomy it is easy to perform but for patients without esophagostomy, under continuous pharyngeal suction for months, the swallow can still be achieved using an empty bottle.
Preoperative contrast study of the stomach and colon are recommended by some surgeons; in the author’s experience these preoperative studies are not necessary. In immediate preoperative period, total bowel preparation with Golytely or Clean prep should be carefully performed, if intraoperative the replacement should be switched from colon to gastric tube or vice versa, depending on abnormal vascular findings. The author would also like to mention that the “Informed consent” signed by parents must always include all 3 options of replacement.

**OPERATIVE TECHNIQUE OF GTER**

Majority of surgeons, including the author routinely use the reversed gastric tube; this technique is presented as: “How do I do the reversed gastric tube esophageal replacement in children? “There are several differences in between the replacement for EALG and the one for caustic stricture or diseases which require concomitant esophagectomy.

Broad spectrum antibiotic prophylaxis is given 0.5 hr before surgery and an antibiotic treatment is
maintained 3-5 days, until any septic complication is ruled out and feeding through gastrostomy is initiated. Good venous access is provided, better by a double lumen central vein line. The left side of the neck from above the angle of the jaw, the whole chest and abdomen are meticulously prepared, sterile and covered with cutting through Opsite. In adult surgery the operation is performed by two surgical teams: one abdominal, building up the tube, another operating on the neck; in children the operation is performed by only one team.

**Gastric tube esophageal replacement for Esophageal atresia**

The gastrostomy tube is pulled out and the site of gastrostomy is separated from the abdominal wall; this first step could be done before or after laparotomy. The author does the gastrostomy separation as initial maneuver. Through a midline supraumbilical laparotomy, the stomach is approached and inspected. The left triangular liver ligament is divided and the lower esophageal stump prepared as for Nissen fundoplication. The vagus nerves are identified and separated from esophagus; often the posterior nerve is not clearly visible and its identification is abandoned. No upward dissection of lower esophageal stump is performed now, to avoid, an incidental pneumothorax or worse, bleeding from mediastinum, at the beginning of a long operation.

In the original Gavriliu’s description of the GT, he recommended mobilization of the splenic angle of the colon “en bloc” with the spleen, even splenectomy. All of these maneuvers are not recommended or necessary. The stomach is inspected, the place where the GT will be created is marked with transfixed sutures and the length of the tube is approximated with a feeding tube which goes from mid part of great curvature till the left mastoid process; that is the necessary length of the further gastric tube. Usually the proximal end of the GT starts 2-5 cm far from the pylorus, on the antral segment. The gastro-epiploic vessels are identified and followed towards the left but not yet divided; still either tubes, isoperistaltic or reversed could be decided. The gastro-colic ligament is progressively divided from right to left, the great omentum left attached to the colon and the gastro-epiploic arcade to the stomach. The width of the GT is very important; this should be more or less of the same caliber as the native esophagus (Fig. 33.10).³⁷

For modeling the GT the author uses a chest drain tube CH 10-14 for babies and 18-22 for older children. The GT is then separated from the great curvature. The reversed or isoperistaltic GT must be decided now and the gastroepiploic vessel ligated and divided at the right or left end of the gastroepiploic arcade (Figs 33.11 and 33.12).
The GT could be made in two different manners:
1. Manually, by hand suturing.
2. Mechanically, with staplers suture.

A 2 cm transverse incision is made on the antrum at the chosen level; the chest tube is inserted retrograde within the stomach and placed close to the great curvature. For preventing unnecessary blood loss during separation of the GT, pairs of transfixed sutures are placed over the vessels with a big straight needle. The GT is divided in between the sutures with sewing progressively (P Orsoni’s recommendation). The first 3-5 cm of the GT should be larger than the rest of the tube and made funnel shaped, for a good cervical anastomoses.

The initial 97 GT of the authors series were all hand made. The first 3-5 cm of the GT are made with interrupted double layer sutures of resorbable stitches (Vicryl, PDS, Monocryl 3/0-5/0) and the rest of the tube and stomach by continuous, running, double layer sutures. Then the gastrostomy tube is replaced, most commonly through the same site or a new one. Often the gastrostomy could be comfortably included in the long suture line which closes the new great curvature. The GT has to be made water proof and checked by injecting saline solution under moderate pressure. In babies the author prefers the hand made tube which takes 20-40 min to be done.

The last 10 GT (since 1993) have been done by mechanical suture with staplers (Ethicon, Johnson and Johnson, linear cutter of 55 or 75 mm.) This is a very fast and easy technique, which takes 10 to 15 min. for a very long tube. At the chosen level on the antrum, a complete transverse division is done, the chest tube is inserted in the same manner and the linear cutter is placed as close as possible near the tube. The division is bloodless. In older children the size of the staplers should be quite big (11-14 mm). The risk of a leak due to default staplers could generate life threatening complications (one personal case complicated with mediastinitis). A safe and wise maneuver is to over sew the mechanical suture line with a continuous suture of PDS 3/0-5/0 all along the tube and gastric suture. The water proof should be also checked carefully. At the end of gastric tube suture (manually or by staplers) the long suture line could be sealed with a biological glue (Tisseel or other glues) to decrease the risk of minimal leaking. Without prospective study performed or published the author has used routinely the sealing of the GT with Tisseel, with a real benefit.

After the GT is made, the transhiatal route for the passage of the GT is performed. The technique is well known and common for all types of esophageal replacement in adults and children. By digital dissection the tunnel is progressively made upwards. The dissection should stay at all times strictly in front of the vertebral body. The cervical esophagostomy is mobilized and a retrotracheal digital dissection is gently directed downwards, within the posterior mediastinum. The transhiatal and cervical operator’s finger should get together and finalize a wide and comfortable passage. The remnant lower esophageal stump is removed with a cut of the linear cutter. A big Nelaton catheter is passed down through the posterior

mebooksfree.com
route and brought to the abdomen. The GT, protected with a finger glove is attached to the catheter and pulled up gently, under direct vision, within the neck. The long suture should be kept in the anterior position. About 2-5 cm of the length of the GT should be left in the abdomen as is the normal anatomy of the esophagus. The intra-abdominal segment of the GT prevents gastro-tube reflux. Together with the GT, a strong no. 1 silk stitch is brought through the posterior mediastinum which will be used to correctly place a long 6-16 mm J-vac drain in the mediastinum. The drain is pulled out by a small separated incision on the neck with its distal end just above the diaphragm.

The cervical anastomoses is the most delicate part of the operation. The GT is trimmed of 1-2 cm and checked for a good vascular supply. Usually there is no problem with the color and the bleeding from the GT. If the GT brought to the neck is blue or with obvious ischemia, the vascularity must be checked all along the tube, identifying the cause (kicking, compression, torsion, damage to the arcade, etc.). In very rare situations a tube with compromised vascularity should be removed and another option of replacement utilized, in the same operation or later (no case in my series). It is crucial to have a long GT; often, after trimming a few cm the GT shows an excellent blood flow. The anastomoses is made end-to-end, one layer, interrupted suture of 5/0 resorbable material. The operation ends by repositioning the gastrostomy in the same place and closure of the abdomen. The duration of the procedure is usually between 1 ½ to 3 ½ hours.

Gastric Tube Esophageal Replacement for Esophageal Stricture and Other Diseases

The removal of damaged esophagus is mandatory. Several cases of malignant transformation of the old esophagus have been published. In Gavriliu’s series 3 patients died due to cancer of the remnant esophagus. Peptic ulcer, severe bleeding and cystic transformation of the diseased esophagus–esophageal mucocelle have been reported (one case in my series) (Figs 33.13 and 33.14).

The esophagectomy can be performed as a separate operation, by right or left thoracotomy, or as a transhiatal esophagectomy, by blunt digital dissection or stripping, without thoracotomy, performed concomitantly with the esophageal replacement. The combination of the 2 operations into a one stage operation is today “the golden standard” for the majority of pediatric surgeons.

Preoperative preparations are the same for GTER as for EALG. The operation starts by left cervical approach of the esophagus which is dissected and separated from the trachea. Left recurrent and vagus nerves should be identified and protected. It is recommended to insert a very big intraesophageal

Fig. 33.13: Mucocele of the damaged esophagus left in situ. A metallic ring retained within the cystic transformation of the esophagus. The child presented in emergency with life-threatening respiratory distress syndrome due to tracheal compression

Fig. 33.14: Same case as in Fig. 33.13: The damaged esophagus was removed by right thoracotomy. The ring is visible in the lower esophagus
tube, pushed down up to the level of the stricture. By this maneuver the level of esophageal transection is precisely decided with no risk of missing a loose stricture (3 cases in my series, with total gastric transposition performed elsewhere, had the anastomosis with the stomach done below an unrecognized stenosis within the esophagus). Some surgeons prefer to do a preoperative endoscopy on the table. A vascular loop or a soft tube is placed around the esophagus to facilitate the manipulation during dissection. As for the transhiatal esophagectomy, the mediastinal dissection should not be performed initially, to avoid complication at the beginning of a long operation (injury of the trachea, main neck vessels).

The gastric tube is fashioned as previously described. The transhiatal ophagectomy is done by digital dissection upward from the abdomen and downward from the neck. The esophagus is manipulated by the 2 loops surrounding it in the neck and abdomen. Keeping very close to the esophagus, gentle but firm, the dissection is quite uneventful in many cases and surprisingly with minimal bleeding. The most common complication is a pneumothorax–right or left- which will require at the end an ICD. Sporadically injury of the aorta, trachea, main bronchus, main thoracic duct or pericardium, have been reported (none in the author’s series of 107 cases). In case of major hemorrhage the surgeon should not hesitate to control the hemorrhage by open thoracotomy. At the end of mobilization the esophagus should move easily up and down. In several cases of teenage patients, the digital dissection is limited, but not complete. In these cases—as in adult surgery—the stripping of the esophagus becomes necessary. The author has performed the stripping in 3 cases with an ordinary varices stripper and the removal of the esophagus has been complete. Then the GT is brought up to the neck through the bed of the removed esophagus and an end-to-end anastomoses is performed (Figs 33.15A and B).

In cases with documented history of severe mediastinitis due to perforation (pleural effusion, empyema, mediastinal drainage for pus collection) the blunt esophagectomy should be avoided. Sophisticated preoperative imaging such as: spiral CT, MRI, MRA cannot predict the risk of catastrophic complications. Two options should be considered:
- One stage operation with esophagectomy performed by open thoracotomy, followed by esophageal replacement via transthoracic or mediastinal route;
- Retrosternal positioning of the gastric tube, followed several months later, by open esophagectomy. This second option is preferred by the author (Fig. 33.16).

**Reversed gastric tube vs. isoperistaltic gastric tube**

There are still a few surgeons performing the isoperistaltic gastric tube (IGT) based on a false idea...

---

**Figs 33.15A and B:**

A. Severe stricture of the esophagus. During dilatation a perforation with mediastinitis occurred.

B. Excellent result with GT in retrosternal position

**Fig. 33.16:** Complete obstruction of the whole esophagus post-caustic injury (left). Result of RGTER with esophagectomy and GT positioned in the posterior mediastinum (middle). General view of GT and the stomach which retains a good capacity (right)
of better passage of the foods through the IGT. Two published series, one in adults, another in children prove the opposite; heavy complications, even mortality; in long-term some patients needed secondary gastro or jejunostomy for feeding (Fig. 33.17). In the author’s series 2 cases were performed in the isoperistaltic manner at the beginning of experience with GT, due to apparent better vascularity of the GT. Both cases had anastomotic fistula which closed spontaneously in one case and by redo-anastomoses in the second (Figs 33.18A and B).

In one case severe a dumping syndrome persisted for several years due to rapid passage of the food through the antrum and pylorus. In both cases repeated video recorded barium swallow and follow through did not show any regular peristaltic waves, only some autonomic motility as in the reversed GT. The isoperistaltic GT should be an exceptional indication based on serious anatomic reasons. Otherwise, compared to the RGT has only disadvantages:

1. The IGT is less well irrigated in the distal end which is anastomosed with the cervical esophagus.
2. The IGT should be made much longer than the RGT.
3. To bring up the IGT to the neck, the duodenum and the stomach should be extensively mobilized by a Kocher maneuver, unnecessary in RGT.
4. There is no proof of better motility in the IGT compared with the RGT.
5. In many cases of IGT the stomach is in fact bypassed by food and may generate dumping syndrome.

**Pyloroplasty: is it necessary?**

Most of the authors who use total gastric transposition associate a true pyloroplasty or just an extra mucosal pyloromyotomy with the reason to avoid delay in gastric emptying. In the author’s experience the drainage procedure is unnecessary in GTER and often can cause negative effects on gastric emptying; none of 107 cases of RGTER had a drainage procedure.

**Pharyngo-esophageal replacement with gastric tube and duodenum.**

In several cases of extensive esophageal strictures, due to strong caustic agents, the pharynx is also involved or completely destroyed. Most common the hypopharynx, but often the oropharynx are excluded. On video recorded study the contrast material is instantly regurgitated through the nose. All these cases (3 in my series) had concomitant laryngeal injury and a tracheostomy was already in place. The multiple stages of repair of these complicated cases (initial pharyngeal reconstruction with skin flaps or free graft of colon or short sigmoid segment, etc.), followed by a type of esophageal reconstruction is not discussed in this chapter. There is a general agreement on very poor results, a few patients being finally able to return to oral feeding.

Concomitant pharyngeal and esophageal reconstruction in such cases can be achieved by an original procedure; one stage pharyngo-esophageal reconstruction with first part of the duodenum (PERDGT)
and a long gastric tube, associated with transhiatal blunt esophagectomy (Fig. 33.19).

The main steps of the operation are the same with the one stage RGTER for caustic stricture with several modifications. The first approach is on the neck with a long vertical or transverse incision identifying the remnant pharyngeal pouch. Intra-oral maneuver with a finger pushing down the pharynx by an assistant facilitates the preparation of the site for the further anastomoses; if possible, the anastomoses is placed on the posterior and lateral pharyngeal wall and the anastomoses should be as wide as possible. Then the neck is temporarily sutured and the procedure continues intra-abdominal. The first part, mobile of the duodenum is prepared as for a gastric resection. The vascular arcade is meticulously preserved and the duodenum is transected as distal as possible. Through the duodenum, a chest drain tube CH 18-22 is placed and pushed retrograde within the stomach close to the great curvature. On the antrum, 2-3 cm far from the pylorus a linear cutter 75 mm is placed and the first fired for the gastric tube is performed. Often a very long tube is needed to reach the pharynx and the tube goes up to the upper part of the fundus (the longest tube in my series measured 54 cm (21.5 inches). By duodeno-gastric anastomoses the G-I continuity is restored. After the blunt transhiatal esophagectomy, the long tube is pulled through the posterior mediastinum to the neck. Pharyngo-duodenal anastomoses is a real difficult task and can take a long time. As the patients are intubated through the tracheostomy, intraoral maneuver could facilitate the anastomoses. Oral feeding rehabilitation requires patience and time, with involvement of the speech therapist. An amazing finding has been seen in all 3 cases: on video recorded barium swallow the pylorus, which is now in the position of pharyngo-esophageal sphincter keeps its function intact and opens intermittently. All 3 cases achieved impressively good oral feeding for liquid and solid feeding, but in one case rehabilitation lasted 2.5 months of intensive work. Two patients have excellent long-term results; one died in obscure conditions 2.5 years from operation, due to tracheostomy complications.

**POSTOPERATIVE CARE**

Most of the cases have a smooth postoperative recovery; the ventilatory support is needed for only a short period (1-2 days). There is no need for postoperative TPN. Frequent pharyngeal suctions of saliva are necessary in the early postoperative period. In cases with the GT in the retrosternal position, suction is mandatory for 2-5 days; in the mediastinal position of GT there is often no need for pharyngeal suction. The mediastinal drain is removed in 2-5 days after 24 hours of “nothing coming out”. Continuous enteral feeding is initiated through the gastrostomy tube as soon as the bowel movements return to normal. In cases with uneventful course, on day 7 postoperatively the permeability of the GT is checked with a colored cold drink which should flow easily and quickly through the gastrostomy tube. Liquid, then loose and finally soft diet is given progressively. Most of the cases, especially older children are able to eat normally 2-3 weeks postoperatively. The gastrostomy tube is still kept for 1-3 months for safety, in case of eventual stenosis of upper anastomoses.

For GTER performed in early infancy, on babies with serious co morbid problems, oral feeding could be delayed for weeks or months under intensive rehabilitation.

**Postoperative dilatation: Yes or No**

The GTER has only one important problem which is the risk of progressive narrowing of esophagus-gastric tube anastomoses. Routine postoperative dilatations are not recommended. A strict follow-up by clinical examination, contrast study (better video
recorded) and endoscopy should be done monthly (for the first 6 months), for early detection of anastomotic stenosis which requires regular dilatations. In my series, 40% of cases had 1-6 dilatations. The wire guided dilatations are preferable to balloon dilatations which can cause more damage. A long-term follow-up is mandatory in all cases with esophageal replacement in childhood.

COMPLICATIONS OF GTER

Early Postoperative Complications

Except of a pneumothorax or serious bleeding which are immediately recognized and treated, there are several specific complications to GTER.

1. Anastomotic breakdown or leaking anastomosis is the most common complication of GTER. The frequency of this complication in large series goes from 66-13% (in author’s series) with a mean of 50%. The leaking anastomosis presents various degrees of severity, from a minor leak which closes spontaneously in 10-14 days without stenosis, to complete disruption of anastomoses due to limited ischemia of the GT. The fistula of upper anastomoses is significantly more frequent in cases of retrosternal position of the GT than for posterior mediastinal route. In the author’s series of 107 cases of RGTER, 9/19 (37%) of cases performed through retrosternal route vs. 7/88 (6%) cases performed through mediastinal route developed a fistula. Most of the cases which develop an anastomotic leak would be candidates for stenosis; all these cases should be strictly followed and require esophageal dilatations. In a few cases a surgical revision of anastomosis was necessary (3 cases in author’s series) (Fig. 33.20).

2. Necrosis of gastric tube: This is a very rare but possibly lethal complication. The cause is always vascular and in most of the cases is due to the stubborn decision of the surgeon to keep a GT which is blue and with poor bleeding when brought to the neck. The partial or total necrosis of the tube is an early complication and the only treatment is emergency resection of the necrotic graft. For the GT in the mediastinal position, severe mediastinitis is often the cause of death (one case in our series); for GT in the retrosternal position the complication is less serious. All attempts to save a compromised tube end up as a failure and delays the removal of the GT (one case in author’s series). Removal of a necrotic graft will be followed by a new substitution, performed months later (colon or small bowel segment) with the graft placed retrosternally. The problems of failed esophageoplasty is the subject of several articles.

3. Mediastinitis without compromised graft: This is a serious challenge of treatment and the true viability of the graft should be proved early by redo operation. Correct drainage, effective antibiotic-therapy, multiple support could not prevent a high mortality. The most common cause of mediastinitis is a leak from the long suture line; when performed with mechanical staplers the risk is even higher.

Late Complications of GTER

In the literature sporadic cases of rare complications are reported as: broncho-gastric tube fistula, stricture within the tube evolving to complete obstruction, perforation of acquired diverticulum, mucocelle on the old esophagus left in situ (one case in our series), sporadic cases of peptic ulcer within the GT, majority successfully treated with modern antacid drugs. Gastric reflux within the GT was noticed in many contrast studies but asymptomatic in most of the cases. The reality of the reflux has been demonstrated in author’s series by 24 hr pH metry on
the GT (10 cases all presenting different grade of reflux). In a few cases (3 cases in author’s series) the reflux manifested at night, by unpleasant return in the mouth of gastric content or food. The semi-fowler position partially resolved the symptomatic reflux, which in all cases improved spontaneously over time. Perhaps there is an etiologic relation between the presence of chronic reflux and peptic ulcer within the GT.

H Lindahl and Bornon J have mentioned the presence of “Barrett’s esophagus” in mucosal biopsies of the esophagus above the GT esophageal anastomosis.80,91 If true, a high risk of malignancy is possible early in life.98 In fact both authors have found gastric cells migrated within the esophagus which is not the known “Barrett’s esophagus”. In our series 32 patients had endoscopic examinations, with multiple biopsies and none presented with this abnormal histology.

Finally the most common complications of the GT are related to the esophagus-GT anastomoses: fistulae and stenosis. The role of accurate technique, well vascularised GT and utilization of mediastinal route, significantly diminished the rate of these complications (from 37-6% with a mean of 13% in author’s series).

DISCUSSION

A comparison between the most popular techniques of esophageal substitution in children is not the purpose of the author. The author’s personal experience of 28 years of esophageal replacement (1975-2003) includes: 107 gastric tubes and 6 colonic grafts (transverse and left colon, 2 retrosternally and 4 transmediastinal).

Brief presentation of personal experience. Indications for GTER: 21 cases EALG, 86 caustic strictures. Type I GTER: 19 cases (56): retrosternal route, no concomitant esophagectomy: Rate of fistulae 37% (7 cases). GT dilatation–3 cases; stricture–3 cases (Fig. 33.21).

Type II: 88 cases: posterior mediastinum, transhiatal esophagectomy, no pyloric surgery, mechanical suture 10 cases; rate of fistulae 6% (7 cases). All but 2 cases had reversed gastric tube esophageal replacement.

Comparing the 2 techniques, type II has shown significant advantages:

- Significant decrease of anastomotic fistulae;
- No GT dilatation;
- No stasis within the GT;
- Shorter GT;
- Easy access to postoperative endoscopy.

Most of the complications of the series were already presented. To summarize: gastric graft failure: 2 cases, one death. Anastomotic stricture 5 cases with surgical revision in 2 cases; postoperative bowel obstruction: 5 cases. Peptic ulcer: 2 cases, one Zollinger-Ellison syndrome.

Mortality in the whole series: 7 cases (6.5%) but 5 cases were before 1982 and unrelated with the technique (poor postoperative ventilatory support–4 cases) and 1 case sudden infant death syndrome. Two deaths were related to GTER: necrosis of the graft 1 and mediastinitus 1. The series has a very good follow-up: 88 patients have been reviewed periodically in 1991, 1996, 2001 and 2003. In 2007, 35 cases of adults with GTER done in childhood were assessed for quality of life.99 Majority of them have a normal professional, social and familial life; 8 of the work outside of their native country.

In long-term follow-up sophisticated methods of evaluation could be used, but finally a good history, clinical examination, contrast study and eventually endoscopy allows an objective assessment of patients.

An encouraging fact is that after 6-8 months postoperatively, the GT no longer changes its anatomy as for the colon substitution (redundancy, stasis of the graft, dilatation with enormous loops). An interesting...
aspect of GTER was the lengthening or “growing” of the tube through teenage and adolescent period: GT “grows” harmoniously with the body growth, about 1 cm per year for both segments thoracic and intra-abdominal (Fig. 33.22).

The advantages of the gastric tube esophageal replacement and esophagectomy in one stage operation, without thoracotomy can be summarized:
1. The gastric tube has an excellent blood supply.
2. The gastric tube presents a very low septic risk due to acid secretion.
3. The gastric tube in most of the cases is an easy operation if performed by an experienced surgeon and utilization of staplers.
4. The gastric reservoir as well as the gastric and pyloric function is fully preserved; this advantage is most probably a crucial advantage of GT and the colonic graft substitution.
5. Performed by an experienced team, in a well equipped tertiary hospital, the operation has a very low rate of morbidity and mortality (Fig. 33.23)

Several critics are formulated for the GT:
1. After GTER the stomach is small and lacks capacity.
2. GTER could have as side effect a megaloblastic anemia resistant to treatment.
3. In a few cases “Barrett’s esophagus” has been demonstrated within the cervical esophagus with a theoretic risk of malignancy.
4. Some patients complain of “vagotomy-like” symptoms or real dumping syndrome.

In fact most of the disadvantages of GTER were already commented and none were really identified in our series. Complaints of dumping syndrome are mostly related with the isoperistaltic GT.

There is only one problem with the GTER and that is the esophageal anastomoses. With a meticulous good technique, strict follow-up in the early postoperative period, eventually several dilatations, the problem related to the upper anastomoses can be well controlled.

Although a rare operation in childhood, esophageal replacement represents a major procedure which requires expertise, experience, modern technology and a multidisciplinary team at a specialized center. Total gastric transposition is a very safe procedure, very popular in most of the countries but with major long term negative side effects due to complete or partial suppression of the gastric reservoir. The colonic replacement and gastric tube are the only 2 procedures recommended in childhood for preserving the gastric reservoir with all its physiological functions, crucial for further growth.

REFERENCES

84. Gupta DK. Primary and secondary esophageal replacement by gastric pull-up, experience over 27 years. Long gap esophageal atresia symposium, Mannheim, Germany, 2007.

There is no ideal substitute available till date to replace the esophagus. However, the choice revolves around the one which is simple and safe to perform and conforms to the function and anatomy to match the original esophagus. The child should have the ability to swallow and enjoy the taste of the normal food. The operative procedure should have minimal or no short and long-term postoperative complications. In addition, the children should continue enjoying the same for long in their life ahead.

The indications and routes for esophageal replacement have been discussed in the previous chapter of "Esophageal replacement with colon interposition". This chapter entails to gastric transposition.

WHY STOMACH?

Gastric transposition was first done in children only about 3 decades back. Though, organ most commonly used to replace the esophagus in the past has been colon, stomach has been used as gastric pull up in adults with carcinoma esophagus with satisfactory results. The colon interposition was also associated with many complications; like redundancy, reflux, stricture and the graft loss, albeit rarely. This has compelled the surgeons to find an alternate procedure. While colon graft maintained a reasonably good vascular supply on its vascular pedicle, however, the problem was faced if the colon was either not available (polyposis coli, pouch colon, ulcerative colitis) or its vascular arcade was not found satisfactory. Gastric transposition is however, not favored in patients with high pharyngeal strictures.

The authors developed interest in this technique during the past 15 years or so, after having an unpleasant experience with the use of colon in one of their patients who lost graft in the immediate postoperative period. Though, this could actually be considered due to the technical fault as the colon graft had been taken and interposed under tension. This single disaster in our series, prompted us to consider using stomach for the purpose of esophageal replacement. Similarly, the authors had been routinely using the antiperistaltic gastric tube (based on fundus) in children with corrosive injuries. However, the mediastinal leak and the osteomyelitis of the sternum that had followed, from the leak from the suture line of the gastric tube in one of the patients, was very discouraging. Thus, the need for the use of stomach as an alternate to the established procedures of colon interposition and the gastric tube.

The procedure was first performed in few children and our initial results were published in 1997. Subsequently, impressed with the outcome and the ease of the procedure of gastric transposition, the scope and the indications were expanded even in the newborns. Our recent experience with the use of stomach to replace the esophagus not only in children but also in the newborns was published in 2003 and 2007 as an alternative procedure to the colon interposition.

Stomach was considered as the best option available in the newborns requiring esophageal replacement. This was because the vascular supply to the colon and the jejunum is very precarious. This not only limits the length of colonic and jejunal segment to reach the neck without tension, but also remained
quite risky to use these segments in the neonatal period, specially if there had been major esophageal anastomotic leaks with ongoing infection in the mediastinal region. Also, the size of the stomach in newborns and the infants less than 6 months of age, is too small and unfit for preparing the gastric tube. Moreover, the blood supply to the stomach is rich. The gastric wall is also quite muscular to withstand the mediastinal infection if any. Thus, gastric transposition was considered and it remained the only option to replace the esophagus in the neonatal period. It was tried and also found quite feasible in the newborns who required esophageal replacement following postoperative major leaks and also with the long or wide gap esophageal atresia and tracheoesophageal fistula (EA/TEF) in our set up.2-4

Recently, there has been an interest seen with the use of stomach to replace the esophagus. Thus, many surgeons switched over from using colon interpositions to gastric transpositions for esophageal replacement in children.5,6

The gastric tube has been preferred by others. However, though the gastric tube has a thick muscular wall and a reliable vascular supply, it has a long suture line and any leak from it may prove very serious. Each procedure for esophageal replacement has its merits and demerits and the choice should be that with which the surgeon is most familiar and most appropriate for age and the indication.7

The esophageal lengthening procedures using Scharli’s technique of the division of the stomach on the lesser curvature, in which the upper part of the stomach remained in the chest while the lower half remained in the abdomen, has still not become popular. The procedure is associated with high rate of complications like ischemia, leak and even the graft loss.8,9 The procedure is also considered un-physiological as part of the stomach in the chest and part of in the abdomen, results in paradoxical inflation of the thoracic stomach with the each act of inspiration.4 The placement of the esophagogastric suture line in the chest may also be risky and any postoperative leak might prove disastrous.

The credit for popularising gastric transposition as the primary procedure for replacing the esophagus goes to Prof. Lewis Spitz, from Institute of Child Health, Great Ormond Street, London, who after noting the unacceptably high complication rate with the use of colon interposition in children, started using stomach, since then, many series have appeared reporting satisfactory and early and long-term results in the newborns, infants and children.1-4,6,10-16

**AGE FOR GASTRIC TRANSPPOSITION**

Traditionally, replacement of the esophagus is performed when the child can sit and eat by him/herself. However, with due precaution, the replacement can be done at any time if the condition so demands. Gastric transposition is now generally carried out by most surgeons at around 6-12 months of age, but can be performed even in the newborn period or anytime thereafter when the baby is fit for tolerating the major surgical procedure and the anesthesia. The procedure has been done successfully in childhood and the long-term results including the complications are available.16,17

Major postoperative leak following EATEF repair has been correlated with the increased mortality and morbidity in neonates.18 Colon and jejunum should not be preferred due to delicate arcades. Gastric tube can not be fashioned as the size of the stomach is too tiny. Moreover, the stomach is much smaller in newborns with EA to be housed very well in the mediastinum. However, the smaller sized stomach in EA has never posed a problem for a primary anastomosis to be performed with the esophagus in the neck. The important factor being that in the neonatal stage, the tunnel in the posterior mediastinum is created very easily as compared to that in older children with previous history of thoracotomy and mediastinal leaks. Thus, neonatal gastric transposition has been recognized as the only option of saving the lives of these patients as it can even be performed in the presence of pyothorax and septicemia following the major anastomotic leaks.1 The advantages of performing the gastric pullup in the newborns are that the procedure of gastric transposition takes only a little more time than performing the diversion procedures (esophagostomy and gastrostomy) in the newborn period. The blood loss is also minimal (10-30 ml only) and the operating time is not much (less than 2 hours). Needless to emphasize that it required expertise and the dependable intensive care facilities for postoperative monitoring, prolonged ventilation, offering the
antibiotics, pain relief and central venous access for long-term nutritional support.

**ADVANTAGES OF GASTRIC TRANSPOSITION FOR ESOPHAGEAL REPLACEMENT**

1. It is a technically easier procedure.
2. The stomach has a thick muscle wall and maintains reliable vascular supply.
3. Adequate length is possible for anastomosis without tension.
4. The fundus being the highest point can reach for the anastomosis in the neck.
5. A single anastomosis is required in the neck.
6. No thoracotomy is required.
7. There is no suture line in the chest, except for the closure of the esophagostomy site and possibly the gastrostomy site also (if the same had been done in the past).
8. It is also an option in patients with pouch colon or where it is risky to use the colon due to precarious blood supply.
9. The gastric transposition procedure has the least short-term morbidity and mortality as compared to the other alternative procedures.

**Advantages of Neonatal Gastric Transposition**

1. It is the best option available for newborns. Colon and jejunum should not be used due the precarious blood supply especially in the presence of sepsis or pyothorax due to salivary leaks.
2. It avoids the need for a diversion in the neonatal period with the known morbidity and even mortality associated with gastrostomy and esophagostomy.
3. There is no suture line in thorax thus free from the risks of a leak in the chest.
4. Neonatal gastric pullup can be performed even in the presence of sepsis as the stomach being very vascular and muscular, can withstand the sepsis and the local salivary leaks well.
5. This offers the definitive surgery at birth itself and avoids repeated visits to the hospital.
6. Gastric pullup can be performed even in emergency without the need for any preparation.
7. The success rate is quite high even in very sick newborns.

**DISADVANTAGES OF GASTRIC TRANSPOSITION**

1. Bulk of stomach in mediastinum/thorax can cause respiratory distress and may decrease venous return. It seemed more theoretical rather than seen in practice.
2. Reflux in the bulky stomach is common and can cause aspiration pneumonitis.
3. As vagotomy is part and partial with the procedure, gastric emptying may be delayed despite pyloromyotomy.
4. As the reservoir function of the stomach is lost, there may also be rapid gastric emptying leading to dumping.
5. The loss of gastric reservoir function also affects the growth and development of the patient.

**ROUTE FOR TRANSPOSITION**

1. Transhiatal route is feasible in most children. It is feasible even in the newborns as there are no mediastinal adhesions in the newborn period. Moreover, the stomach is very small and transhiatal route is quite short.
2. Substernal route is preferred after infancy, though this is little longer than the mediastinal route. Care should also be taken not to prefer this route if liver is large likely to obstruct the stomach during its course.

**GASTRIC TRANSPOSITION—SURGICAL PROCEDURE**

It may be done as a staged procedure following the initial diversion (with cervical esophagostomy and gastrostomy) that had been done or also as a primary procedure in cases with complicated EA/TEF group (long gap EA without fistula, wide gap EA/TEF not amenable for primary anastomosis and following the major anastomotic leaks after primary anastomosis, if the same is not manageable with other popular methods). The procedure of gastric transposition can be performed either in routine or even in emergency. It does not require any preoperative preparation unlike the colon.

**Staged Procedure**

With the gastric transposition or even gastric tube in mind in future, the gastrostomy should be sited at the
anterior stomach surface well away from the greater curvature with the aim to preserve the gastroepiploic arcade. Sham feeding should be encouraged to develop taste for sweet and sour and also to avoid feeding problems later on.

**Operative Technique**

The patient in the supine, a folded towel is placed under the shoulders of the patient to extend the neck and expose the esophagostomy site (Fig. 34.1). The cervical esophagostomy is mobilized placing an elliptical incision around it in the neck, detaching it carefully from the sternocleidomastoid muscle. Care is also taken not to injure the esophagus wall and preserve the recurrent laryngeal nerve during its mobilization. Esophagus is mobilized for 2-3 cm and the terminal few mm of its wall are freshened to resect the skin edges. The blood supply to this part of the esophagus is submucosal and does not pose any ischemic threat even after its extensive mobilization in the neck.

An adequate space is created at thoracic inlet with sharp and blunt dissection which would accommodate the fundus of the stomach easily. Cervical facia and sternohyoid muscles may have to be detached from their bony attachments with the manubrium or the clavicle to create enough space at the thoracic inlet. In the authors view, this is one of the most important aspects of the successful surgery to avoid any vascular compression on the major vessels once the stomach is pulled up and housed in the neck.

The abdomen is opened with a supramucosal midline incision that may extend up to few cms below the umbilicus if the need be. The gastrostomy, if present, is taken down. Invariably, there are dense adhesions between the stomach and the liver. These are separated carefully with sharp and blunt dissection. The left lobe of the liver is freed from its attachment with the left hemidiaphragm, folded on itself and retracted to the right side by an assistant. An access is gained to the gastroesophageal junction. The peritoneum is incised transversely in front of the abdominal esophagus and the lower esophageal segment is freed from all around. With a ribbon tape around the gastroesophageal junction, the esophagus is mobilized. It comes out easily without any blood loss and is usually 3-5 cm long (Fig. 34.2). Both, the anterior and the posterior vagus nerves have to be invariably sacrificed while delivering the esophagus in the abdomen.

The operative steps have been shown in Figures 34.3A-F.

The stomach is mobilized, starting through the gastrocolic ligament. The right gastroepiploic vessel, the gastroepiploic arcade and the right gastric vessels are preserved. The 4-5 short gastric vessels running between the stomach and the spleen are either cauterized or ligated. Authors prefer to ligate these individually to avoid any vessel spasm or even thrombosis. With the use of the diathermy while handling these vessels, the authors have noted that

*Fig. 34.1:* A follow-up case of esophageal atresia, now 1 year of age. The esophagostomy and gastrostomy had been performed in the neonatal period

*Fig. 34.2:* The mobilized stomach with the gastrostomy site. Fundus is shown with a white arrow marking the highest point for anastomosis in the neck. The lower esophageal stump held in the artery clamp, is excised at gastroesophageal junction and sutured in two layers.
the upper half of the stomach becomes bluish, flabby with comparatively ischemia, possibly due to vascular spasms, hence it is better to avoid the use of diathermy.

The stomach is now pulled toward the left and the left gastric vessels are identified and ligated securely close to their origin. Kocherization of the second part of duodenum is performed to gain length and bring the duodenum and the pylorus in a straight line. Spleen is preserved in all.

The esophageal stump is transected from its junction with the stomach and the defect is closed in 2 layers. The site of the gastrostomy is also closed in
two layers. Two stay sutures are applied in the highest point in the stomach, e.g. the fundus, for taking the same up in the neck for the anastomosis.

Attention is now given to choose the route. If the mediastinal route is to be used, the feasibility is checked. The esophageal hiatus is stretched and the tunnel is created blindly with the finger in the mediastinal route between the membranous posterior wall of the trachea and the prevertebral facia, reaching up to the neck, and making sure it is adequate and without any obstruction in its path. No thoracotomy is performed. This route is quite feasible and rather preferred in all neonates. If the creation of the tunnel is found difficult due to previous thoracotomy adhesions, the attempt is abandoned and the substernal route is favored. In that case, the hiatus will be closed with a figure 8 suture. The substernal route can be created easily by a blunt finger dissection starting just behind the xiphisternum.

Pyloromyotomy, (rarely, the pyloroplasty if the need be) for about 2 cm, starting from the normal stomach to just proximal to the duodenum is performed as a drainage procedure. Then the stomach is pulled up through the tunnel with the help of a red rubber catheter fixed to the fundus with the help of silk stay sutures marked on right and left corners, ensuring that no torsion of stomach occurs during the procedure.

A single layer esophagogastric anastomosis is made in the neck using 5/0 absorbable interrupted sutures. The anastomosis is constructed above the level of the aortic arch so as to decrease the chances of gastroesophageal reflux.

The pyloric antrum is fixed to the diaphragmatic edges at the hiatus (Fig. 34.4). The stomach is also hitched to the prevertebral fascia to prevent any tension on the anastomosis. A soft glove drain is used to drain the neck wound. The stomach is decompressed with a nasogastric tube the tip of which is carefully placed in the mid thoracic region.

A feeding jejunostomy is optional and is reserved for critically ill patients who might take longer time to recover from surgery and require nutritional support. This may also be added later on if the need is felt in the postoperative period due to delay in the institution of normal feeds. Total parental nutrition (TPN) is a good alternative but for short-term only. The TPN related cost and the risk of infection, both need serious considerations, especially in developing world providing free services.

The indications for esophageal replacement in the newborn period are mainly due to the complicated cases of EA and TEF (e.g. major leak to avoid diversion, long gap with isolated EA or cases with the wide TEF, not suitable for primary repair) (Fig. 34.5).

The operative procedure for gastric transposition in the newborns are essentially the same (Figs 34.6A - E). However, it requires safe anesthesia for the sick newborns, a close monitoring of vital signs including the insertion of a CVP line. Postoperative elective ventilation is mandatory at least for first few days after surgery. This provides effective oxygenation and stabilizes the patients comfortably. Patients should preferably have an epidural catheter for the morphine infusions for the pain relief. Plasma (and or blood) infusions should be transfused in the first few days to maintain hemodynamic stability and tissue perfusion. A urinary catheter for assessing the urine output is essential.
Postoperative care is important and includes

1. Strict monitoring of the respiratory and cardiac status.
2. Elective ventilation with paralysis is helpful.
3. Large bore nasogastric tube to prevent acute gastric dilatation and aspiration.
4. Adequate sedation and relief of postoperative pain by morphine infusion, caudal blocks or epidural catheter. Muscle relaxation may be provided by infusion.
5. A skiagram chest in the immediate postoperative period to look for any pneumothorax or acute gastric dilatation. Insertion of the chest tube in case the pneumothorax is detected.
6. Early institution of drip-in feeds to maintain nutrition. Oral clear liquid feeds are started once the general condition is better or the contrast study performed at postoperative day (POD) 7-10, shows no evidence of anastomotic leak.
7. Small frequent feeds orally and a head up position at an angle of 45 degrees all the time during nursing and sleep.

**POSTOPERATIVE COMPLICATIONS (TABLE 34.1)**

1. Compression of major vessels in the neck, resulting in decreased venus return. An adequate dissection in the neck would prevent it.
2. Twist of the stomach while pulling the same into the chest. Careful handling and placing the identification sutures on either end of the fundus before pulling the same would avoid the complication.
3. Perforation while performing pyloromyotomy. A proper identification of the same and repair would avoid its consequences.
4. Leak from the closure sites of the native esophagus and the gastrostomy. This is not a common problem with the experienced hands.
5. Bleeding while mobilizing the stomach from the liver surface, short gastric vessels, gastroepiploic vessels. Adhesions with the liver are notorious and may bleed while dissecting the stomach off the liver. With patience and careful sharp and blunt dissection, it can be achieved, though may be time consuming.
6. Ischemia of the fundus of the stomach, if the diathermy has been to divide the short gastric vessels. However, it is never significant enough to cause graft loss. Still, the short gastric vessels should better be ligated to avoid spasm of the vessels.
7. Respiratory and vascular compromise due to the presence of the unusual bulk in the thoracic cavity. As the stomach gets elongated during its pull, the bulk does not cause respiratory compromise. However, it is best to avoid gastric pull up in patients with large and bulky stomach. In such cases, a gastric tube or the colonic interposition may be a better choice.
8. Acute dilatation of the stomach, if the same has not been decompressed well. To have good postoperative gastric decompression, a nasogastric tube must be left in midthorax and allowed to drain freely. It should be checked for patency from time to time.
9. Vomiting, aspiration pneumonia due to stasis of food in the stomach. As vagotomy is invariably performed with gastric transposition, an upright position and avoiding the fatty and large meals just before going to bed may help. An endoscopy...
Figs 34.6A to E: Gastric transposition in a newborn following major leak after EA/TEF repair. 

A. The esophagostomy has been mobilized with an elliptical incision in the neck. The stomach has also been mobilized with a midline incision in the abdomen, based on right gastoepiploic vessels and right gastric artery. Thoracotomy incision is not required. The mobilized stump of the lower esophagus seen in the picture, is yet to be resected and suture closed. The fundus of the stomach is the highest point (and not the esophagus stump) and used for making the anastomosis with the esophagus in the neck.

B. The newborn on postoperative day 3. Abdominal and neck wounds are seen. The chest tube seen in the picture is from the previous thoracotomy while trying an unsuccessful primary repair of the EA and TEF at day 2 of life. Baby is still on elective ventilatory support.

C. Postoperative barium study on day 9 showing thoracic stomach. No anastomotic leak was detected. Oral feeds resumed slowly the next day.

D. Same newborn baby on postoperative day 10, is off from all monitoring devices, IV fluids, ventilatory support, CVP line and the epidural catheter. Now only on oral feeds and ready to be discharged once the daily intake is ensured after gastric transposition.

E. Same baby with the mother at 6 months of age, with normal feeding pattern and catching up with the growth and development.
may also be performed to check for the mechanical block.

10. Intestinal obstruction subsequent to laparotomy.
11. Neck or abdominal wound infection.
12. Leaks: Postoperative leaks from the anastomosis in the neck are not uncommon with an incidence of 6-33%. This may result from ischemia, tension on the pulled stomach or due to the technical fault while making the anastomosis. Leaks may be minor, detected only on barium study, or major manifested by salivary or milk leakage from the wound site. Most leaks would close spontaneously without any intervention. The collected material should be drained out freely from under the skin and muscles, removing the skin sutures appropriately.

**FOLLOW-UP**

The barium study is performed usually on postoperative day 7-10, when the patient has already stabilized, with most catheters and devices are out. The bowel sounds have returned and the wounds are healing (Figs 34.7A-C).

Gastric clearance function tests with the barium swallow and the milk feed mixed with Tc99 colloid scan in the sitting position, and the HIDA scan to evaluate the presence of the duodenogastric reflux (DGR) are performed around day 10 and then at follow up of three months.

**Fig. 34.7A-C:** Follow up barium studies in different patients showing a near normal contoured thoracic stomach that has adapted as the esophagus in each case.
The barium study should be performed first in the lying position and then in the sitting position. The follow up studies show a near normal contour of the thoracic stomach that adapts itself as the esophagus.

**PRECAUTIONS**

A close watch has to be kept in the immediate postoperative period for pneumothorax and acute gastric dilatation (Fig. 34.8). As neonates demonstrate an accelerated gastric emptying and the presence of the duodenogastric reflux in the immediate postoperative period, a careful feeding and nursing in an upright position (preferably at 45 degree angle from the bed) is essential to prevent aspiration pneumonitis.\(^4\)

Anastomotic leaks in the neck are not uncommon but most of them are minor and resolve within few days.\(^17,19\) Even in the presence of ongoing leak in the neck, the clear water or even milk feed can be initiated. This would help in clearing the tract and provide nutrition. Acidic gastric juice worsens the leak. The pH is monitored. It is usually around 2.5 despite vagotomy. Major leaks result in strictures thus a close watch is needed in the follow up, including the endoscopy at regular intervals. Most of these (50-80 \%) respond to dilatation.\(^17,19\) Only rarely is the revision needed.\(^5\) Anastomotic strictures have been reported to be more common in patients having previous caustic esophageal injury.\(^16\)

Gastric transposition for esophageal substitution has been associated with a mortality rate of 5% of patients in the best hands.\(^16\) However, this was the experience reported in higher age group and not that in the neonates, in whom a higher operative mortality is expected. Most of the deaths in children (67\%) have been reported in the early postoperative period.\(^16\) The causes of death in the early postoperative period include ongoing sepsis and congenital heart disease besides aspiration that is preventable with close monitoring (Table 34.2).

In the authors’ experience with 51 cases of gastric pull ups till date, there has been no graft loss. Other large series have reported similar results.\(^16\) However, in our series, there were 5 deaths of 51 children undergoing gastric transpositions, 31 of these have been done in the neonatal period most of whom were usually very sick and on ventilatory support as well. These deaths were in the neonatal period, due to ongoing lung collapse and sepsis in 2, serious congenital heart disease in 1, and multiple anomalies in another. There was possibly one procedure related death in our series due to vascular compromise at the level of thoracic inlet. This patient had very large liver that bled to touch. He also developed swelling of the face within 3-4 hrs after surgery. Patient collapsed before he could be opened up to relive the possible compression. Since then, the authors are very careful

while making either the tunnel or the space in the neck, before attempting to pull and house the stomach up at the thoracic inlet. Death has been reported a year following the procedure, due to respiratory arrest following aspiration at home.17

Difficulty in establishing oral feeds in the early postoperative period is common. Short-term support with total parental nutrition may be provided. However, jejunostomy may be a better option and should be considered to bypass the upper gut and provide nutrition. Vomiting and aspiration is also seen frequently.

Redo surgery may be required for the stricture in the neck, mechanical obstruction in its course, jejunostomy related complications besides the intestinal obstruction due to adhesions.17 A mechanical obstruction may be caused by the compression of the large lobe of the liver on the stomach during its course.

Symptoms mimicking obstruction have been reported due to stasis of food in the thoracic stomach (functional obstruction due to vagotomy) without any evidence of mechanical obstruction.4 This needs careful assessment for the need of jejunostomy to provide nutrition. It may also lead to aspiration pneumonia during sleep.

**POSTOPERATIVE RESULTS**

**Feeding**

Gastric transposition re-establishes effective gastrointestinal continuity with few complications.5 In a large series of 173 children reported by Spitz et al,16 the most common indications included failed repair of different varieties of esophageal atresia (127), caustic injury (23), and peptic strictures (8). In more than 90% of these, the outcome was considered good to excellent in terms of absence of swallowing difficulties or other gastrointestinal symptoms. Many, however, preferred to eat small frequent meals. The authors also have similar experience during the follow up studies of patients who had undergone gastric transposition 10 year back or more. Majority of the patients learned the acceptable habit of eating and swallowing in due course of time.20 There has been no deterioration in the function of the gastric transposition in those patients followed up for more than 10 years. Poor outcome may be associated with multiple previous attempts at esophageal salvage.16

**Pressure Profile and Manometry Studies**

The thoracic stomach does not have peristalsis but responds well to the food bolus. The manometric studies performed after gastric pull up documented mass contractions without any propulsive or peristaltic waves. The baseline pressure was little higher in newborns as compared to that in children. Also, the pressure increased by over 120% both in newborns and children in response to the food bolus.21 The response was irrespective of the age at surgery and the route adopted (Fig. 34.9).

**Growth and Development**

It has now been shown that gastric transposition is compatible with normal life, though the growth and development remained subnormal in children followed up for 5-10 years in some series. The height has been calculated as 80-90% of 50th percentile in the authors’ series.21 The average weight was subnormal in most of the patients up to 60-70% of the expected weight. Anemia has been found in 70% of the cases during long-term follow-up.20

**Quality of Life**

In our experience, about two-third patients showed normal gastric clearance on barium or nuclear scanning. One-third of these either showed an obstructed flow (> 20 minutes) or even a rapid clearance (< 2 minutes) from the thoracic stomach. These findings did not change either with the age at surgery or the type of the route used for the gastric transposition. Similarly, a duodenogastric reflux was demonstrated in 67% patients following the gastric transposition in the postoperative period. The values decreased to 40% at 1 year follow up. It was surprising that only a few of them were symptomatic and had bilious vomiting. The significance of positive duodenogastric reflux is yet not clear but may lead to biliary gastritis in the long-term. In our series, a follow up after 10 years with endoscopy and biopsy from the gastric mucosa did not reveal either biliary gastritis or atrophy of the mucosa in the transposed thoracic stomach.20

The authors’ have noted the decreased functional capacity of the lungs in patients with gastric pull up. This was much more in group of patients who had
undergone previous thoracotomies. This may be secondary to the pulmonary compression or recurrent aspirations.20

The quality of life for patients with esophageal atresia was generally unimpaired by any side effects of gastric transposition.15 Patients undergoing gastric transposition as a primary procedure experienced fewer disease-specific symptoms in the medium term compared with patients who had undergone previous unsuccessful attempts at reconstruction or replacement of their esophagus.15

Colonic interposition is the most commonly used procedure to replace the esophagus in the pediatric age group, preferred by most Pediatric Surgeons around the globe. Tannuri et al recently published their 27 years experience with the use of colon as well as stomach, with postoperative merits and demerits of each procedure.22

The authors feel that “Gastric transposition is a satisfactory means of esophageal substitution and "probably the best" of all the available options especially for patients with esophageal atresia”.19 Its role in neonates for replacing the esophagus for complicated EA and TEF as an emergency procedure, is unsurpassable with any other procedure.23 For post-

Acidity

Following the vagotomy, which is invariably performed, a rise in the pH is not troublesome even if noticed.4 Our children, the 24 hr pH study performed during follow up of more than 5 years after the surgery, have shown a pH between 1.7 - 3.6 (Fig. 34.10). Though, it is contrary to the reports mentioning high pH after gastric transposition, it may be a good sign not to have achlorhydria and subsequent chances of malignancy developing later in life.

Intrathoracic stomach apart from facing a vagotomy and elongation, may also have a decreased blood supply to the tune of 20%. The consequences of all these need to be monitored in the long-term.

Rare Serious Complications

Carcinoma: A carcinoma developing at the esophago-gastric junction in the neck has been mentioned in an adult who had gastric pull done for the corrosive stricture (Egyptian experience as mentioned by Dr Alla Hamza). However, whether it was due to the abnormal mucosa left in the esophagus, is difficult to assess.

Gastric perforation: A 13-year child who had undergone gastric pull in infancy, presented with scant fresh bleeding by mouth. While undergoing an endoscopic examination in emergency, there was gush of blood in the mouth. An emergency sternotomy was done to locate the site of bleeding. The source was found to be directly from the heart. As the endoscopist was quite a known expert in the field, the iatrogenic injury was ruled out. The bleeding was purported to have resulted from the perforation of the gastric ulcer.

in to the heart, leading to the gastrocardiac fistula, severe hemoptysis and death, (personal communication).  

In other series with long-term follow-up, such serious problems have not been reported so far.

Jejunal Interposition as a Substitute of Esophagus

Kohei Hashizume, Antonio Dessanti

When the esophagus is congenitally defected or severely damaged after birth because of causative agents or other reasons, substitution of esophagus becomes necessary. It has been controversial what to use as a substitute of the esophagus in infants and children. Organs used as a substitute of the esophagus are stomach, gastric tube, colon, and jejunum. Necessary characteristics of the substitute of the esophagus should be, (1) the operation is simple and easy, (2) it should have good peristalsis and good transportation ability, (3) it should not dilate once positioned in the thorax or mediastinum, (4) symptoms caused from the deficit of the organ itself should not severe.

The usage of the jejunum as a substitute of the esophagus is not very popular. It is because the operation is believed to be cumbersome and time-consuming and there is necessity of discarding some length of jejunum to make a sufficient length of vascular pedicle. However, the most important point is not the duration of the operating time but the quality of life of the patient who should live more than 50 years after the operation. So the disadvantage of longer operation time is easily compensated by the better quality of life of the patients, if the function of the jejunum is much better than the other substitutes of the esophagus. The authors believe jejunum is the most appropriate substitute of the esophagus in infants and children, and present here the technical points of the operation and also the results of the operation.

TIMING OF OPERATION

It is controversial when the operation of the reconstruction of the esophagus should be done. The point is not the problem of handling the jejunum. Many pediatric surgeons have the experience of operating on the small intestine in babies who weigh less than 1000 grams. However, it is not advisable to perform jejunum interposition in neonates. The severest and disastrous complication of this operation is total necrosis of the interposed jejunum, and it should be prevented at all costs. The main reason of this complication is vascular insufficiency, i.e. arterial thrombosis or venous occlusion. In neonates the mesenteric arteries and veins are very friable, and are liable to be torn, and also the scarceness of mesenteric adipose tissue makes the veins vulnerable to bending and occlusion. So the babies should be grown enough at the time of the operation by enteral feeding through gastrostomy or by parenteral nutrition. The authors think 6 months of age and/or 6 kg of weight is adequate. After 6 months of age, it is rather difficult to start oral feeding even if the resumed continuity of the esophagus is perfect, because the critical period of learning of oral intake is before that time.

TECHNIQUE OF THE OPERATION

The operation needs 2 incisions, right thoracotomy and laparotomy. The patient is placed in semi-left-lateral position and all the upper body is cleaned and draped from axilla to inguinal region (Fig. 35.1). With this positioning, and some rotation of the operation table one can easily perform preparation of jejunal loop through laparotomy and anastomosis of esophagus with jejunum through right thoracotomy. First, the abdomen is opened for the preparation of the jejunal loop. The authors prefer an upper midline incision, as it is much easier to approach the esophageal hiatus with this incision compared to transverse incision.

After opening the abdomen, the intestine is thoroughly inspected for any anomaly such as
malrotation and Meckel’s diverticulum. The vasculature of jejunum may be variable, but usually has the configuration shown in the figure. The first jejunal artery with accompanying vein is preserved. The second and third jejunal arteries are usually ligated and cut near their origin, and the fourth artery is preserved and is used as the part of vascular pedicle of the jejunal loop. With these procedures, you can get adequate length of the vascular pedicle, which consists of the fourth jejunal artery and the vascular arcade from the point of the confluence with the first jejunal artery to the point of the confluence with the fourth jejunal artery (Fig. 35.2). The vascular arcade is ligated and divided between the first and the second jejunal artery, and corresponding part of the jejunum is divided. The distal side of divided jejunum is then placed on the anterior chest wall to ensure that this part can be brought to the level of the place designated for the upper anastomosis. Usually one can get adequate length of vascular pedicle and the jejunal loop is easily brought to the upper part of the chest wall (Fig. 35.3). If it is clear that the length of the vascular pedicle is adequate, the arcade is ligated and divided just distal to the point of the confluence with the fourth jejunal artery. The length of the jejunal loop prepared is usually too long for the interposition between the proximal and distal esophagus, and there will be a possibility of interposed jejunum becoming redundant and tortuous in the thorax. So the redundant part of the jejunum, i.e. the distal part should be resected. However, one must be very careful not to resect too much length of the jejunum, it may jeopardize the later anastomosis. The continuity of the jejunum is restored by the anastomosis between the oral and anal ends of the jejunum. The jejunal loop prepared is brought to the upper abdomen through a small hole in the mesocolon. Concerning the route to the thoracic cavity, if the length of the lower esophagus is long enough to permit the lower anastomosis done
in the right thoracic cavity, the loop should be brought anterior the stomach and through a hole in the diaphragm. However, if the length of the lower esophagus is not adequate enough and the anastomosis should be done in the abdomen, the jejunal loop should be brought to the right thorax thorough retrogastric route and through esophageal hiatus. Maximum precision is necessary to avoid a kinking and torsion of the vascular pedicle.

The level of right thoracotomy depends on the length of the upper esophagus, but usually fifth intercostal space is used. The anastomosis of the upper esophagus and the jejunal loop may be end-to-end or end-to-side. Usually, however, the end-to-side anastomosis is better to avoid undue tension to the vascular pedicle. After the oral anastomosis the length of the remaining jejunal loop is estimated, and if it is too long, additional part of the anal end of the jejunal loop should be resected. By this procedure, the interposed jejunum becomes straight and stasis of food in the interposed jejunum is avoided. During this procedure, however meticulous procedure is needed to avoid injury to the vascular pedicle. This can be accomplished if the resection of the redundant jejunum is done as near the jejunum wall as possible. The anastomosis of the interposed jejunum and the lower esophagus is accomplished by end-to-end fashion. If the lower esophagus is very short and the only remnant, the jejunum may be anastomosed to the stomach directly. A drain is inserted in the right thorax and the thoracic wall is closed, and then the abdomen is closed with a penrose drain near the esophageal hiatus.

After operation, thoracic and abdominal drain should be observed carefully for is any drainage of saliva or intestinal contents. When there is small amount of drainage, if the general condition of the patient has not deteriorated and CAP is not very high, wait and watch policy is the best. After one week the patient is brought to the radiology department, and upper GI study is done. If there is no leakage, oral intake should be started. If it is the first oral intake for the patients they cannot cope with oral feeding at first. Usually several weeks or even months are necessary for them to adapt. If there is a leakage, patient should be on parenteral nutrition, enteral feeding through a gastrostomy, or enteral feeding through an enteral tube inserted through a gastrostomy, depending on the size of the patient and the size of the leakage. Usually the leak will heal spontaneously after 2 weeks of conservative treatment.

**LONG-TERM RESULTS**

Comparing the results after the reconstruction of esophagus using colon, the long-term results of jejunal interposition is extremely good. The reasons for that are as follows: (1) The possibility of stricture formation at the anastomotic site is less probable. (2) The peristalsis of jejunum is much better than that of colon. (3) There is less tendency of dilatation after some years. (4) There are much fewer intrinsic problems compared to colon such as diverticulum formation and development of adenoma. The patients have few problems, and they show normal growth. Thus, the influence of resection of redundant part of the jejunum on growth is nil or minimum.

The follow-up upper G-I contrast study films are shown in Figure 35.4. One can notice almost normal sized jejunum in the right thorax and normal mucosal folds. The jejunum is straight or some redundancy with L-shaped configuration is seen in few cases, but the peristalsis is good and the flow of the barium from upper esophagus through interposed jejunum to the lower esophagus is very good.

![Fig. 35.4: Upper G-I study during follow-up—The interposed jejunum is not tortuous and shows no dilatation. Also peristalsis is normal and transition time is almost normal](image-url)
REFERENCES

Early in this century ingestion of caustics was common and resulted in dense strictures for which methods of dilation were advised. As obstructions usually recurred, bypass operations were common with conduits of skin or segments of the gastrointestinal tract. Recently when intensive steroid therapy were used, usually it prevented all but localized areas of stricture. In case of short stricture, different kind of procedures has been advocated for treatment. If the stricture is longer or resistant to dilation, it can be managed by incision and insertion of a colonic patch with excellent long-term results.

Extensive review of the medical literature disclosed the original description of colon patch by Hecker, Hollmann, Biemann Othersen and others in the pediatric series. The concept of incision of an esophageal stricture and insertion of a patch was originally reported for the cervical and also the terminal esophagus. Not until Hecker and Hollmann’s work was applied even to the thoracic esophagus.

In 1986, Biemann Othersen reported a 10-year experience with the use of the vascularized colic patch in the management of esophageal strictures in children to overcome redundancy and stagnation in the interposed colon often associated with marked growth retardation, with satisfactory long-term results. Biemann Othersen extended his work and demonstrated the effectiveness of this technique in a series of children in 1997.

**ADVANTAGES**
- Retains continuity of esophagus
- Less injury to vagus nerves
- Permits re-epithelialization and scar regression in the surrounding esophagus
- Preserves the lower esophageal sphincter in most cases.

**DISADVANTAGES**
- Formation of pseudodiverticulum, if redundant
- Long intrathoracic suture line
- Difficult access to approach the abdomen and the chest simultaneously to carry the colon patch anastomosis in the neck
- Risk of the retained strictured mucosa of the esophagus with the possibility of development of malignancy later.

**PREOPERATIVE PREPARATION OF THE PATIENT FOR COLON PATCH**
- Programmed esophageal dilatation is accomplished through the use of Savary bougie dilators. Stricture is dilated under general anesthesia with no fluoroscopy control. The dilatation is guided by visual monitoring of the guide wire to confirm its presence in the stomach. This type of dilatation was continued for at least one year before considering failure.
- Bowel preparation with cololyte started 24 hours prior to surgery and continued hourly until clear out put obtained.
- The patients are covered by Gentamicin in combination with second generation cephalosporin and Metronidazole.
Colon Patch Esophagoplasty

SURGICAL TECHNIQUE

Many surgical techniques developed for esophageal replacement are still in use. The technique of colon patch as described by Drs. Hecker and Hollmann with a few modifications was used in our institute.4,8

The patient is placed in semilateral position so as to have an adequate access to the upper abdomen and also to the right side of the thorax. Two separate incisions were used in all but one child. A midline upper abdominal incision and another on the right side through the 5th intercostal space, exposes the stomach, colon, diaphragm, and the entire length of the esophagus in the chest. We have used transpleural approach. The segment of colon used is based on the middle colic or the left colic artery. Careful measurements determine the length of the colon segment needed. The esophageal stricture is incised longitudinally until the normal esophagus is reached at either end of the stricture.

A template of the patch size required is then made. The colic segment is selected so as to have enough length of the pedicle on the marginal arcade. The colon is cleaned and opened on its anti-mesenteric border. The colon patch is fashioned while still in the abdomen. If the segment of colon is first brought into the chest and then trimmed, its location deep in the thoracic cavity makes control of hemorrhage more difficult. The colic segment is more accessible in the abdomen. The colo-colic anastomosis is made of the remaining colon.

When the patch has been fashioned, it is passed behind the stomach and through a hole in the right diaphragm. The patch should fit without tension or the redundancy and is sewed into place using the continuous sutures. The excess of the colon is excised leaving only a patch (adjoining the mesentery) necessary to bridge the elliptical defect so created in the longitudinal wall of the strictured esophagus.

Instead of passing the patch through the hiatus, we pass it through a small cut in the diaphragm to the right side of the chest. Boix-Ochoa fundoplication was our procedure of choice in the four patients and a Nissen type fundoplication had already been done in another institute. Two chest drains, one anterior and one posterior are used.

Postoperative Care

- Total parenteral nutrition is started 24 hrs post-operative.
- Opacification of the new esophagus is done 5th - 7th day postoperative using non-ionic dye.
- Feeding is started after bowel function has started and the patient’s condition gets stabilized.
- The follow up visit is usually every month for a few months and then 6 monthly for the first 2 years.

THE AUTHOR’S SERIES (TABLE 36.1)

Total of five patients have had colon patch performed in our institute. Four patients had extensive caustic strictures and one had a stricture after a failed esophageal atresia repair in the past. All the five patients were males. The age of patients at surgery was around 4 years for the caustic injury patients and 13 years for the one with stricture post-tracheo-esophageal fistula. The site of the stricture was mid esophagus in three, upper two-third in one and lower esophagus in one. The length of stricture varied from 5 -12 cm. Three patients developed anastomotic leaks which were treated conservatively. It subsided in two

Table 36.1: Summary of colon patch esophagoplasty (Author’s series)
and one was managed by a postoperative fundoplication 10 days postcolon patch esophagoplasty (Fig. 36.1). The first patient operated in this series developed patch diverticulum, which was resected 12 years after colon patch esophagoplasty with no intra or postoperative problem regarding the vascularity of the patch. All had pre-, intra- or post-colon patch fundoplication.

The follow-up period ranged from one month to 20 years. All the patients are eating and growing normally after surgery. None have developed respiratory symptoms and there is no malignant change in the older patient.

**DISCUSSION**

The colic patch currently offers advantages that outweigh any disadvantages. When the patch is perfectly tailored to the defect, no bulging or redundancy is found. It is easily constructed and, with a good marginal artery, can be carried high into the chest. The patients do not require close postoperative follow-up.

The only problem has been that a considerable amount of colon must be discarded to obtain adequate length of the pedicle, but the same amount of bowel would be used as well if the colon interposition is planned.

Our second case with partial anastomotic disruption and prolonged postoperative course, make us suggest that fundoplication should be done simultaneously with the colon patch if it has not been done pre-operatively. The need of fundoplication has also been clearly shown by others.5,9

The third case in our series with post TEF repair stricture, the leak stayed long but in our opinion that was because he has been left with severe stricture for 13 years with many trials of dilatation and including the laser therapy in another institute. He was living on liquid and semi liquid diet only. His weight was 17 kg at the time of surgery. The upper pouch pre operatively was filled with turbid fluid which was coming out of his chest drain postoperatively. He was eating for the first time in his life after colon patch procedure (Fig. 36.2).

The current alternative operations for the esophageal strictures are either esophageal replacement using colon, stomach or the small intestine. The entire stomach, when brought up to the proximal esophagus, refluxes and occupies a large space in a small chest.

The gastric tube also allows reflux of acid secretions and may not easily reach high enough. The reconstructed gastric tube is adjacent to the major vessels and organs such as the heart, aorta and trachea, and ulcers if any, occurring in the tube, carry the risk of perforation into these structures. Though the incidence is low, the development of such perforations can cause serious, life-threatening complications.10
Small intestine lacks a marginal artery and has a tendency to be redundant. Swallowing is a slow process when food must traverse an interposed piece of small intestine. If the scared esophagus is bypassed, it may accumulate secretions and eventually perforate or carcinoma may develop in the retained scar.

There have been reports of carcinoma developing years after a chemical burn but the average time from injury to carcinoma is 30-40 years with a frequency of 1.2-2.6%\(^8\). Carcinoma has also been reported in anterothoracic dermatoesophageoplasties. In our patients who have had interposition of a colic patch, the scar in the esophagus has become much more pliable as the tension is relieved after insertion of the patch. Portions of the esophagus, which prior to the patch contain scar epithelium and granulation tissue, eventually become covered with esophageal mucosa. Endoscopic evaluation after patching showed good epithelial covering of the area of previous stricture with improved pliability of the esophageal wall. The patch is easily identified on endoscopy\(^4,6\). The possibility of carcinoma developing in some of our patients does exist but the risk is presumably minimal.

Originally, it was thought that the length of the stricture may limit the use of the patch technique. We performed colon patch esophagoplasty to more than four inches strictures with good outcome. The gastero-esophageal junction was included in one of cases with very good result (Fig. 36.3). None of the patients have had any respiratory or growth problem.

These good results were published by others as shown in Table 36.2. Immediate postoperative leak and the late stricture can be managed conservatively. Tendency of the patch to bulge, producing a pseudo-diverticulum might need a second thoracotomy and repair by plication or excision\(^8\). The postoperative functional results were good.

Biemann Othersen used a free patch of small intestine anastomosed by microsurgical techniques to the vessels in the neck because the neck anastomosis was thought to be difficult to be treated with a colon vascularised patch.

Recently, we have used the colon patch in one of our cases with very long stricture extending from the neck to the lower-third of the esophagus. The patient had a very short esophagus with a pulled intra-thoracic stomach (Fig. 36.4). The colon patch was interposed on its vascular pedicle in front of the stomach and the duodenum, into the cervical esophagus extending to almost the whole of the esophagus with some tension. Repair of hiatus hernia was more accessible through the thoracoabdominal approach. The free patch worked well (Fig. 36.5) though the patient developed significant wound disruption on the fifth day, requiring re-closure of the main abdominal and the thoracic wound.

Table 36.2: Outcome of colon patch esophagoplasty by different authors
This patient continued with bile stained high gastrostomy output and the dye study confirmed the obstruction at the last part of the duodenum. This required abdominal exploration. The pedicle of the colon patch was found traversing in front of the duodenum and the stomach causing obstruction. A gastrojejunostomy with jejuno-jejunostomy was found necessary to bypass the obstruction and avoid any injury to the pedicle supplying the patch. The graft in this case had been passed to the thorax through the hiatus and this might have contributed to the tension on the vascular pedicle. This was possibly avoidable, had an enough length of the pedicle been planned.

CONCLUSION

Colon patch esophagoplasty for short and long esophageal stricture has been used in the past. In the author’s series, the immediate postoperative leak from the long suture line has been managed conservatively with good outcome. Our second case with partial anastomotic disruption and prolonged postoperative course make us suggest that fundoplication should be done simultaneously with the colon patch if it has not been done preoperatively. The need of fundoplication has been clearly shown by others in the patients with poor colon patch result. In the third case in our series with esophageal stricture post-tracheoesophageal repair, the leak stayed for long although he has had antireflux surgery. This was possibly due to the fact that he had been left with esophageal stricture for 13 years with many trials of dilatation and laser therapy in another institute. He was living on liquid and semiliquid diet only. The upper pouch was filled with turbid fluid which was coming out of his chest drain postoperatively. He was eating for the first time in his life after the colon patch esophagoplasty.

SUMMARY

The surgical treatment of strictures has been greatly facilitated by the use of the colic patch in which the interposed segment can be tailored to match the gaping defect after a longitudinal esophagotomy through the stricture. The esophagus is not resected from its bed and its nerve supply is not interrupted. Colon patch esophagoplasty is prone to complications, which can be overcome. Fundoplication should be done simultaneously. Colon patch esophagoplasty is worth considering in benign esophageal strictures, including long gap ones. Our result is encouraging to use colon patch as an alternative to esophageal replacement even for the entire scared esophagus.

There is admittedly no substitute for the damaged and scared esophagus, but of the available conduits, the colic patch has been most satisfactory in our limited
experience. We believe it will become the preferred method of treatment of esophageal strictures especially for patients who are difficult to be followed closely in the postoperative period.

ACKNOWLEDGEMENT

The author’s would like to acknowledge Dr Reijo Luoma who introduced colon patch esophagoplasty technique in the author’s institute.

REFERENCES

Esophageal perforation is one of the alarming emergencies in pediatric surgery. It is the most rapidly fatal and most serious perforation of the gastrointestinal tract.\textsuperscript{1} The incidence of esophageal perforation is noted to be rising, probably due to increasing endoscopic manipulations and aggressive neonatal resuscitation. The incidence in adult perforations is also increasing; Sawyers et al reported an upward trend from one in 20,000 admissions to one in 8,000 admissions.\textsuperscript{2}

Fifty-sixty years ago, the disease was always deadly; some believe that it had claimed the life of an ancient great warrior: Alexander the great.\textsuperscript{3} In 1947, Barret reported the first surgical intervention for this disease, he repaired a spontaneous rupture of the esophagus by simple suture repair; since then, the management of this emergency condition has evolved rapidly.\textsuperscript{4} At present, despite improvement in mechanical ventilation, hemodynamic monitoring, total parentral nutrition, interventional radiology and more effective antibiotics. This condition continues to be associated with significant morbidity and mortality.

A collective review of the world literature reveals a mortality rate of 18-29%.\textsuperscript{5} Higher incidences were even reported. In a collective review of 50 cases of neonatal esophageal perforation from 15 series Mollitt et al reported a 30% mortality; another author reports a mortality rate of 65%, mortality rate is lower in children; one author reported a rate only 4%.\textsuperscript{6-8} Several factors affect the mortality rate. One of the most important is the time elapsed between injury and intervention. A report showed that if treatment was delayed for more than 24 hours, mortality rate jumped from 13-45%; other factors are the age of the patient, the cause and site of perforation.\textsuperscript{9,10}

**ETIOLOGY**

**Intraluminal Causes**

1. Instrumentation: Endoscopy, dilatation, intubation (nasogastric or sengstaken tube, sclerotherapy.\textsuperscript{11-15}
2. Foreign body, particularly alkaline batteries.
3. Caustic ingestion.\textsuperscript{16,17}

**Extraluminal Causes**

Nasogastric tube, penetrating wounds, blunt trauma operative injuries and fracture spine.\textsuperscript{13,18-21}

- Spontaneous perforation (Boerhaave syndrome).\textsuperscript{22}
- Perforation associated with pre-existing esophageal disease as tumor or esophagitis.\textsuperscript{23,24}

In a study by Attar et al the most common cause of perforation was due to instrumentation, 37.5%; among those cases, perforation due to endoscopy was the commonest 54.2%.\textsuperscript{9}

In neonates, esophageal perforation is relatively rare.\textsuperscript{25} It may be spontaneous, but most commonly traumatic resulting from oropharyngeal suction, passage of nasogastric tube or endotracheal intubation.

**PATHOLOGY**

Perforations occur either as an immediate total breach of the esophageal wall or as a mucosal laceration that is followed by intraluminal abscess formation and subsequent mural rupture. Thus there may be an interval of many hours between the endoscopy and the appearance of the signs and symptoms of overt perforation. Sharp foreign bodies may perforate immediately, but blunt foreign bodies will sometimes
cause pressure necrosis and delayed perforation. An immediate chemical then bacterial mediastinitis occurs which may proceed to empyema, sepsis and multiple organ failure. Mediastinal emphysema occurs early and the characteristic sound can be auscultated over the pericardium. This sign is commonly known as Hammond’s crunch. The emphysema can be seen on X-ray films in the mediastinum, or when it dissectsfar enough superiorly, as it commonly does, it may be palpated subcutaneously above the clavicles. Pneumothorax and pleural effusion may occur. Rupture through the pleura occurs, either immediately or later, as a result of the intense inflammatory response. Rupture into the pericardium has also been reported. The pleural fluid will show a significant amylase activity, thus causing possible confusion with another diagnostic possibility, acute pancreatitis; but serum amylase activity is not elevated in patients with perforation.

Incomplete rupture may occur in some cases; the tear may affect the mucosa only as in Mallory-Weiss syndrome. Continued vomiting and retching may cause the mucosa to become lacerated and a small false lumen of the esophagus to be formed; the lumen may dissect for some distance or remain localized. After severe vomiting, intramural hematoma may result and may dissect and encase the entire esophagus.

CLINICAL FEATURES

In neonates, the most common sign is difficulty in passing a nasogastric tube; the differential diagnosis would be other causes of obstruction as esophageal atresia. The most common symptom is respiratory distress due to pneumothorax, and the presence of increased oral secretion or drooling. There are also difficulties with feeding: vomiting, cyanosis, coughing and/or choking.

In neonatal Boerhaave syndrome, the predilection is to present as a right pneumothorax as opposed to rupture into the left pleural cavity most commonly found in adults, this difference is explained by the close adherence of the aorta to the left side of the esophagus. Dyspnea followed by cyanosis may occur shortly after birth, but usually delayed to six-thirty hours; both are relate to tension pneumothorax. If perforation remains undiagnosed, respiratory distress worsen with the first feeding. Vomiting, coughing, choking episodes and mild hematemesis have been observed. Thoracocentesis may reveal serosanguineous or grossly bloody pleural fluid as well as the contents of the previous feeding. If a chest tube is placed for reduction of the tension pneumothorax hydropneumothorax, formula may reappear immediately following feeding. times, pleural fluid may contain fibrin.

In older children there is pain in the neck, chest or epigastrium, depending on the site of perforation. Pain is increased by movement of the head or by swallowing when the perforation is cervical. There is also dysphagia and odynophagia. Palpable subcutaneous emphysema in the neck, due to migration of air upward, may be present. The air trapped in the mediastinum causes a crunching sound on chest auscultation (Hammond’s sign). However, these are not frequent in children as they are in adults. Tachycardia, fever, leucocytosis, shock and sepsis may be also present.

Perforation of abdominal esophagus from operation or instrumentation may present with both generalized peritonitis and mediastinitis with transit of contaminants through the esophageal hiatus into the mediastinum. If perforation is due to external trauma, the nature and extent of associated injuries to the blood vessels, other mediastinal organs or intra-abdominal contents will determine the presentation. Thus, clinical manifestations of the esophageal injury may be obscured by the concomitant injuries.

INVESTIGATIONS

Plain X-ray

Pneumomediastinum is the abnormality seen most often on plain films and loss of the contour of the descending thoracic aorta due to density seen in the left cardiophrenic angle. In cases with delayed intervention, pleural effusion, pneumothorax, hydropneumothorax mediastinal abscess, mediastinal widening sometimes associated with fluid levels and subcutaneous emphysema might be seen.

In cases with suspected perforation in which plain X-ray is negative, a contrast study using diatrizoate meglumine (gastrograffin; Schering Health Care) or iopamidole (Gastromiro; E Merck Pharmaceuticals), which may show a leak; if there is no leak detected, a major perforation is not usually present; and if perforation is still highly suspected, then a barium study could be done safely. Barium is more likely to
detect small perforations due to its greater radiographic density and better mucosal adherence.49

**CT Scan**

The study may reveal loculated mediastinal fluid collections, loculated pleural fluid collections, pneumothorax and pneumomediastinum and pulmonary infiltrates. The exact site of perforation can not be assessed by CT, but it may: (1) Determine the presence and extent of mediastinal and pleural involvement initially, and maps the area of surgical drainage, (2) Enables good evaluation of the efficacy of surgical drainage, (3) Gives excellent information about the position of the drainage tube. (4) Shows lesions not seen on the chest X-rays, such as anterior pneumothorax, lung perforation by chest tube, pleural effusion, and pulmonary infiltrates.50

**TREATMENT**

**Conservative Management**

Mediastinal tissue seems more resistant and esophageal perforation appears more contained in children than adults. When the perforation is restricted to the mediastinum with adequate drainage into the esophageal lumen, only local esophageal suction drainage is necessary. If perforation extends into the pleural cavity, usually on the right side, a thoracic drain is introduced. In case of delayed treatment with formation of intrathoracic abscess, thoracotomy is performed with drainage of the abscess, and when a prolonged period of esophageal obstruction is expected, gastrostomy is performed. Esophagograms are repeated after 10 days. If no perforation can be detected any longer, oral feeding is resumed. Otherwise, drainage is continued for another 10-day period until perforation has disappeared. Suture repair is indicated only in the case of large tear, in which spontaneous healing can not be expected.51

Cameron et al6 made four criteria for conservative management: (1) Esophageal disruption should be well contained within the mediastinum or between the mediastinum and visceral lung pleura, (2) the cavity should be well drained back into the esophagus, (3) minimal symptoms should be present and (4) minimal evidence of clinical sepsis.

Other authors restrict conservative management: consisting of broad-spectrum antibiotics and nasogastric tube for feeding; only to infants with submucosal perforation. Intrapleural perforation can be treated with tube thoracostomy.

Operative management is indicated for massive intrapleural spillage and/or inability to control leakage or pneumothorax with tube drainage and for deterioration of clinical condition or development of complications that warrant surgical exploration.52

**Operative Intervention**

Large tears and massive uncontained perforations require surgical intervention. Many authors prefer to intervene surgically in almost all perforations when diagnosed early, within 24 hours of injury, as the success rate of such interventions is high.9,53

**Primary Closure and Drainage**

This modality is indicated in early cases of perforation, before infection sets in. The perforation is closed with single layer of running absorbable suture (5/0 vicryl). Silk should be avoided as it is thought to excite inflammatory reaction and persists in tissues as a nidus for infection; monofilament sutures are less reactive, but is difficult to handle and the knot may not be secured. A swaged-on needle with suture material that is smooth and thick enough to avoid tearing through tissues is used. Stitches are meant to coapt the edges of the tear without the tension, which may cause necrosis of the suture line and a leak.54 When repaired early, success rate is 81-87%.9,53

**Primary Closure with a Buttress**

Buttressing the closure with a graft strengthen the suture line and act to minimize the probability of leak, particularly if repair was delayed. Several methods were suggested: pleural patch overlay or intercostal muscle flaps; or pedicled pericardial flap.55,56

**Debridement and Drainage**

In late intervention, tissues which have been bathed with saliva and possibly gastric juice becomes very friable and can't hold sutures. Instead of immediate primary repair, local drainage coupled with feeding gastrostomy or insertion of a total parental nutrition line may be necessary, forgoing primary suture repair.42
Esophageal Diversion and Exclusion

In late diagnosis, there is usually an intense inflammatory reaction and tissues become very friable, preventing any direct dealing. In such cases, the esophagus is ligated at the gastroesophageal junction using a polypropylene suture snared over a sialastic band and a cervical esophagectomy and a feeding jejunostomy are done.57 The area bearing the infection is thus excluded from function and is given a chance for healing, after which esophagectomy and esophageal replacement are done. Hopefully, this approach is rarely used.

Esophagectomy and Replacement

In cases of perforation associated with severe damage to the esophagus, as occurs in extensive burns after corrosive ingestion; esophagectomy and replacement with stomach, colon or jejunum are done.

REFERENCES

The surgical management of lung abnormalities requires a thorough knowledge of the surgical anatomy of the lung.\textsuperscript{1,2} Though thoracoscopic resections have been attempted by the experts, the principles of surgical resection of the lung remain the same and require experience to deal with the various conditions that may vary from case to case.\textsuperscript{3,4} A thorough planning is essential for a successful outcome. The surgeon should be aware of all the possible common and rare anomalies that may form the differential diagnosis of a particular case before planning surgery. The ray of imaging modalities available today makes it essential to choose the most appropriate modality for a particular case without increasing the risk of radiation exposure to the baby (Figs 38.1 and 38.2). The recent introduction of multidetector row computed tomography scanners has altered the approach to image the pediatric thorax but would be more relevant in cases with malignancy or some other rare diseases.\textsuperscript{5} Bronchoscopy and spiral computed tomography with multiplanar reconstruction is especially useful to identify rare lesions like stenosis of the bronchus.\textsuperscript{6}

**ANATOMY OF THE LUNGS**

A knowledge of the normal lobar and segmental anatomy of lungs and some key anatomic relations to adjacent structures are important for performing a smooth lung resection without inviting any trouble (Figs 38.3A and B).\textsuperscript{7,8}
Each lung is divided into lobes by the oblique fissures on both sides and an additional horizontal fissure on the right side (Fig. 38.3). The right lung is normally larger than the left, with an upper, middle, and lower lobe. The left lung is composed of upper and lower lobes similarly situated, and the lingula is analogous to the right middle lobe. The tracheal bifurcation is at the fourth or fifth vertebral body at the time of birth. The right main stem bronchus is larger, more vertical, and about half the length of the left main bronchus (Fig. 38.4). These features account for the preferential passage of the foreign bodies into the right lung, particularly to the right lower lobe. The right lung has 10 segments and the left lung has only 8 segments as the four segments on the left side are fused into two (Figs 38.5A and B).

Each segment is supplied by one or more branches of the pulmonary artery and is drained by its own veins. The bronchus with its branches is central in location (Fig. 38.6). The arteries tend to occupy a position nearer the center of the segments and the veins lie along the intersegmental planes.

The epithelium of the bronchus is ciliated, pseudostratified, columnar epithelium. Smooth muscle demarcates the basal extent of the mucosa. Mucus-producing glands are apparent in the submucosa. Parasympathetic ganglion cells are abundant. Cartilage is an essential structural element for maintaining expiratory patency of the major conducting airways. Proceeding distally in the tracheobronchial tree, luminal size diminishes, and certain features are lost. In particular, as the bronchus becomes a bronchiole, cartilage is lost, the glands disappear, and the epithelium becomes simple,
columnar, and ciliated. Smooth muscle and elastic tissues remain. More distally, these elements drop out of the terminal bronchiole as the need to conduct large volumes of air diminishes. At the level of the respiratory bronchiole and alveoli, where gas exchange occurs, capillaries and epithelial cells are juxtaposed intimately. Most gas exchange occurs by diffusion across a membrane composed of thin cytoplasmic extensions of the Type 1 epithelial cell and the capillary endothelial cell bound by a common basement membrane that is only nanometers in thickness.

**PULMONARY VESSELS**

The circulation on which respiratory gas exchange depends is derived from the pulmonary artery and its branches. The circulation that provides nutritive support for the lung parenchyma and the bronchi, however, is systemic. Intramural collateral flow from the trachea to the bronchi is derived from the inferior thyroid arteries, which are supplied by the thyrocervical trunks of the subclavian arteries. Venous bronchial drainage is into the azygous and hemiazygous systems. Generally, both arteries and veins follow the segmental and lobar architecture of the bronchi.

**Right Pulmonary Artery**

It courses transversely for a short distance in front of the right main bronchus and reaches the anterior aspect of the upper lobe bronchus where it supplies
its first branch to the upper lobe that soon divides into an apical and an anterior vessel. The main pulmonary artery continues downwards, lying in a groove on the anterior surface to the bronchus below its upper-lobe branch and gives off the posterior segmental branch to the upper lobe. The vessel can be found only by dissection in the depths of the fissure as it enters the lobe beneath the fissure.7

The middle lobe is supplied by two branches of the pulmonary artery, that arise at the base of the confluence of the fissure distal to the posterior segmental branch to the upper lobe and enter the middle lobe - lower lobe segments. The vessel to the superior segment arises after passing downwards and backwards. A spray of vessels then supplies the remaining four basal segments.

**Left Pulmonary Artery**

This is longer than that on the right side. The artery curves upwards and over the main bronchus then gives off the first branch which supplies the apical and posterior segments.7 The vessel then arches behind the upper lobe bronchus, gives off branches to the upper three segments of the lobe. In the interlobar fissure the main vessel gives off a single lingular artery which may be one or may divide into a vessel to each segments of the lingula. The left lower-lobe arteries come from the interlobar part of the main vessel, much as on the right. They come off, more distally, arising close to the bronchi of their segments of supply.

**Pulmonary Veins**

The venous system is similar on both sides. The veins draining the segments converge to form large trunks and end as the superior and inferior pulmonary veins at the hilum of the lung.7 The superior pulmonary vein receives the apical, posterior and anterior segmental veins from the upper lobe and two or more veins from the middle lobe. The inferior pulmonary vein receives the veins from the lower lobe segments. The pulmonary veins are most anterior at the hilum.

**BRONCHIAL VESSELS**

The small bronchial arteries supply nutrition to the lungs. There is usually one main artery to each lung. These arteries (one or two) arise from the aorta just beyond the origin of the left subclavian or they may
come from one of the upper aortic intercostals or from the thoracic aorta. On the left side, the main-stem bronchus and its dependent airways are supplied by two bronchial arteries that arise from the anterior surface of the descending thoracic aorta. On the right side, usually there is a single bronchial artery present and it arises from either the third right intercostal artery or the superior left bronchial artery.

Numerous anastomoses between the bronchial and pulmonary arterial systems are of significance in inflammatory lung disease. Early in the course of inflammatory disease, thrombosis of the bronchial artery branches occurs leading to the progressive enlargement of the bronchial arterial system. Massive hemoptysis is always from enlarged bronchial vessels. Bronchial artery embolization techniques to control catastrophic tracheobronchial hemorrhage require a thorough knowledge of the bronchial arterial supply to each lung and its variations. The intercostals bronchial—vascular interplay supplies reticular branches to the midthoracic section of the spinal cord. It is thus vital to know that paraplegia has occurred following embolization of important spinal branches from the bronchial system.

**POSTEROLATERAL THORACOTOMY**

This is usually planned through the fifth intercostal space as this gives direct access to the hilum of the lung. For lesions in the lower lobe, the 6th intercostal space may also be used, specially in older children. The skin incision is curved with the posterior part being at least 1.5 cm (one finger breadth) below the inferior angle of the scapula. The skin is incised. The subcutaneous tissue is cut and the muscles are incised in the line of incision. The muscles encountered are latissimus dorsi posteriorly and serratus anterior anteriorly. The fifth intercostal space is counted. It is usually just below the space at the tip of the scapula. The skin incision is curved with the posterior part being at least 1.5 cm (one finger breadth) below the inferior angle of the scapula. The skin is incised. The subcutaneous tissue is cut and the muscles are incised in the line of incision. The muscles encountered are latissimus dorsi posteriorly and serratus anterior anteriorly. The fifth intercostal space is counted. It is usually just below the space at the tip of the scapula. The intercostal muscles are incised with a cautery along the upper border of the rib below, until the pleura is reached. The pleura is opened and a Finochietto rib retractor is placed and opened slowly to expose the chest cavity (Fig. 38.7). This gives a direct access to the fissures of the lung. The rest of the procedure depends on the affected lobe and the disease. The lobes of the lung are examined for the extent of the disease. In cases of congenital lobar emphysema, the rounded edges of the affected lung may be appreciated in contrast with the sharp edges of the normal lung (Fig. 38.8A to C). The affected lung is held with the help of a lung holding forceps (Fig. 38.9). The congenital anomalies are usually limited to a particular lobe (Figs 38.10A to C). However, the disease may involve the adjacent segments of the other lobes. Thus, after resection of the affected area, the other areas should also be examined for any residual disease and the further decision is taken accordingly.

**PULMONARY RESECTION IN CHILDREN**

The most common resection performed in infants and children is lobectomy. The pulmonary vessels are large, delicate and thin-walled. These require a different technique than applied to the systemic vessels. Dissection is carried out in a perivascular plane and each vessel should be dissected for a sufficient length, before an attempt is made to pass a right angle clamp behind the vessel. It is preferable to grasp only the adventitia of the vessel. Some surgeons advocate to begin the dissection by encircling the main pulmonary artery proximally with a vessel loop or a blunt angled artery forceps before the more hazardous dissection is started, so that if injury occurs, control is assured. The authors however, do not follow this and feel that a meticulous dissection around the thin walled vessels will prevent any untoward hazard.
Figs 38.8A to C: A. Rounded edges of the affected lung in a case of congenital lobar emphysema. B. These are well appreciated in contrast with the sharp edges of the normal lung. C. An emphysematous bulla may be well appreciated in the affected lobe with congenital lobar emphysema.

Fig. 38.9: The Congenital Cystic Adenomatoid Malformation (CCAM) of the lung involving the right lower lobe. The abnormal lobe has been pulled out of the chest cavity. The large cyst has been decompressed, as marked with arrow. Lung is being held by Duval's lung holding forceps.
Figs 38.10A to C: The resected specimen of Congenital Cystic Adenomatoid Malformation (CCAM). A. Medial view B. Lateral view C. Cut open section, showing the large cyst (marked with arrow) with many other adjoining multiple smaller cysts

Fig. 38.11: The superior pulmonary vein dissected and held between ligatures. An emphysematous bulla (arrow) can be well appreciated
There are several techniques for ligating the pulmonary vessels. Most commonly, the pulmonary vessels are ligated in continuity and then divided (Fig. 38.11). The technique of triple ligation with division of the vessel, leaving two proximal ligatures separated from each other with an adequate vascular stump is commonly employed. Else a transfixation suture may be applied to the proximal vessel after dividing the vessel between the two simple ligatures. The technique of ligating the main vessel proximal to the bifurcation, and severing the vessel distal to the bifurcation, to produce a large cuff from which the ligature is unlikely to escape, is also safe. The authors also feel it safe and wise to ligate the distal end of the vessel including the lung tissue with it, as this would provides enough strength to the vessel for a secure ligation. It is also important to know that the vessels are very thin and are being tackled while the lung hilum has been stretched, so there are high chances of slippage of a simple suture if ample care is not taken. The role of the assistants is also important to provide a stable environment for meticulous suturing.

Thus, the key points for tacking vessels are:
- Vessels should be dissected gently and freed from the investing sheath.
- All vessels should preferably be transfixed and ligated, especially on the proximal side, to avoid slippage of the suture.

Figs 38.12A to D: The branches of the pulmonary artery to the left upper lobe being dissected. A. The main branch of the left pulmonary artery to the left upper dissected for a distance. B. The distal branches dissected and ligated individually. C. The proximal end of the branch secured with double ligatures. D. The branches of the left pulmonary artery to the lingular lobe dissected for a distance and held between ligatures. Care should be taken at this step to preserve the main branch to the lower lobe (arrow).
working with small airways, the difference between an acceptable and compromised residual bronchus can be exceedingly small. In addition, some staples may be too large for the secure closure of an infant bronchus. For these reasons, a carefully hand-sewn bronchial closure is preferable in infants and small children (Fig. 38.13). The bronchus should be sucked clean before suturing, while requesting the anesthesiologist to maintain positive ventilation. The inflation of the residual lung should be checked before cutting the desired bronchus. The bronchus stump is closed by using the non-absorbable interrupted sutures (prolene) of the appropriate size. It should finally be checked for any leak while maintaining a positive airway pressure. The residual lobe should be examined for any evidence of abnormality (Figs 38.14A and B).

**Right Upper Lobectomy**

To access the right upper lobe, the approach is from the anterior side of the hilum.

Two branches of the pulmonary artery and three branches of the pulmonary vein are ligated. The third dorsal branch of the pulmonary artery is ligated. The three bronchial branches and the upper lobe bronchus are then closed.

**Right Middle Lobectomy**

This is usually combined with a right upper lobectomy or a right lower lobectomy. To access the right middle...
lobe, the approach is from the anterior side of the hilum.

The distal branch of the upper pulmonary artery is ligated. The middle lobe bronchus with its two bronchial branches are then encountered that may be clamped and sewn later. The middle lobe artery is then ligated.

**Right Lower Lobectomy**

To access the right lower lobe, the inferior pulmonary ligament is first divided. Two branches of the pulmonary artery and the lower pulmonary vein with its two branches are ligated. The two bronchial branches that are visible after ligation of the pulmonary artery branches are then tackled and closed.

**Left Upper Lobectomy**

To access the left upper lobe, the approach is first the anterior side of the hilum to tackle the vessels one by one. Two proximal branches and two distal segmental branches of the pulmonary artery are ligated. The superior pulmonary vein is then ligated. The upper lobe bronchus is then closed by gaining access through the posterior side of the hilum.

**Left Lower Lobectomy**

To access the left lower lobe, the inferior pulmonary ligament is first divided. Two branches of the pulmonary artery and the lower pulmonary vein are ligated. Two branches of the pulmonary artery are ligated between the upper and lower lobe. The lower lobe bronchus is then closed.

**Pneumonectomy**

For right pneumonectomy, the azygous is ligated first as it crosses below the bifurcation of the right main bronchus. The right pulmonary artery is found just below the right bronchus and ligated at three places and divided between ligatures. The upper pulmonary vein and then the lower pulmonary vein are ligated. The right main bronchus is then suture closed using interrupted sutures.

For left pneumonectomy, the left pulmonary artery, upper pulmonary vein and lower pulmonary vein are ligated in that order from cranial to caudal direction. The left main bronchus is then suture closed.

**MALIGNANCY**

The role of thoracotomy and surgical resection of pulmonary metastasis remains uncertain. A large multicenter review suggested that thoracotomy should
be used cautiously in the management of pulmonary relapse. However, thoracotomy is more appropriate in the management of metastases present at diagnosis that persist after neoadjuvant chemotherapy. Children suffering from cancer are prone to develop systemic fungal infections secondary to the severe immunosuppression caused by the disease itself and the antineoplastic therapy. Intravenous antifungal medications and, when feasible, surgery are used for the treatment of pulmonary aspergillosis. Thoracoscopic resection of metastatic lesions is reasonable for nephroblastoma, but a thoracotomy is suggested for other metastases.

INFLAMMATORY MYOFIBROBLASTIC (PSEUDO) TUMOR OF THE CHEST

Inflammatory myofibroblastic tumors are very rare. These require surgical resection for confirming the diagnosis and providing the only possible effective treatment. A complete resection of the tumor from the chest achieving negative margins, leads to excellent outcome. However, this may not always be possible in all cases as the disease may be fulminant and involve the chest wall and the diaphragm (Fig. 38.15). Various operations performed for this lesion include lobectomy, wedge resections, tracheal/bronchial resections with end-to-end anastomosis and the chest wall resection.

REFERENCES

Infants and children manifest an extraordinary diversity of congenital and acquired abnormalities of the lung, and collectively these lesions have become increasingly important indications for pulmonary resection in childhood. Although the spectrum of lung abnormalities in children encompasses lesions with diverse etiologies, there is considerable overlap in presentation, anatomic variation, and radiographic appearance of chest lesions. The widespread use of prenatal ultrasound in the past two decades, even in uncomplicated pregnancies, in concert with technological advances in imaging technology has resulted in a dramatic increase in identification of these chest lesions and a better understanding of their natural history. Furthermore, this period has also seen the development of the field of advanced fetal interventions.

Surgical treatment was first used in the 1930’s and 1940’s, with Reinhoff successfully excising a unilocular cyst from the right upper lobe in 1933, and Fischer reporting the removal of the right upper and middle lobes for cystic disease in a 1-month-old infant a decade later.

Patients with these chest lesions may be asymptomatic, or critically ill with respiratory insufficiency. Great progress has been made toward a better understanding of the natural history with regard to diagnostic and therapeutic possibilities. An efficient and organized approach for the evaluation of these patients should lead to excellent outcomes, although a definitive diagnosis may not be made until surgery. Recent advances in thoracoscopy and video-assisted thoracoscopic surgery have changed practice and decreased morbidity.

**EMBRYOLOGY**

Lung growth and development begin at approximately 3 weeks’ of gestation and proceed until about 8 years of age. Early in prenatal life, developing of the conducting airways (i.e. trachea through to terminal bronchioles) occurs, while in the late prenatal period (after about 16 weeks gestation), the gas exchange units (i.e. respiratory bronchioles, alveolar ducts and alveoli) form. Early childhood experiences the growth of the lung and the continued formation of alveoli. By approximately 8 years of life, lung development is complete and no new alveoli are formed.

The traditional understanding is that the tracheobronchial tree and proximal gastrointestinal tract arise from common foregut anlagen and thus, the term bronchopulmonary foregut malformation is often used to describe congenital lung cysts.

At the end of the third week of gestation, the laryngotracheal groove can be seen arising as a ventral diverticulum in the embryonic foregut. The laryngotracheal groove elongates caudally to form the primordium of the trachea, which develops two lateral outgrowths, the lung buds. Next, the lateral walls of the foregut, called longitudinal ridges, begin to approximate in the midline, forming the tracheoesophageal septum, which separates the dorsal esophagus from the more ventral tracheobronchial tree. Separation should be complete by the end of the sixth week of gestation. In parallel, the more dorsal aspect of the foregut develops into the primitive esophagus. Also by the end of the sixth week of gestation, the trachea has undergone symmetric distal division into the left and right mainstem bronchi. Progressive bronchial branching continues and by the end of 7 weeks’ gestation, the primitive lung is formed.
with 5 major lobes and three to five orders of bronchi. Mesenchymal proliferation follows in the adjacent mediastinum and gives rise to the lung supporting structures, such as pleura, smooth muscle, cartilage, collagen, and blood vessels. All major bronchial beds are present by 8 to 9 weeks gestation, when closure of the pleural peritoneal canal completes formation of the diaphragm. This process is of profound importance in understanding the physiologic consequences of mass lesions in the fetal thorax.

Recent investigation into the embryology of the foregut in chick embryos has called into question this traditional description. These studies, using scanning electron electron microscopy, have described a paired caudal “lung bud” with no identifiable tracheal primordium. Even more elusive is the developmental program of the lung primordial after separation from the foregut anlagen.

NORMAL ANATOMY

The right lung has upper, middle, and lower lobes and is normally larger than the left lung. The left lung has upper and lower lobes and the lingua is analogous to the right middle lobe. The tracheal bifurcation is at the level of the fourth or fifth vertebral body by the time of birth. The right mainstem bronchus is normally larger, more vertical, and about one-half the length of the left. These anatomic features account for the preferential drainage of endobronchial material or foreign bodies into the right lung, particularly the right lower lobe.

The circulation on which respiratory gas exchange depends is derived from the pulmonary artery and its branches. In contrast, the circulation that provides nutritive support for the lung parenchyma is systemic. The main left bronchus and its dependent airways is supplied by two bronchial arteries arising from the descending thoracic aorta and on the right, a single bronchial artery is typically present from the third intercostals artery or the more superior of the left bronchial arteries. Intramural collateral flow from the trachea to the bronchi is derived from the inferior thyroid arteries. Venous bronchial drainage is to the azygous and hemiazygous systems.

In large airways, respiratory epithelium is ciliated, pseudostratified, columnar epithelium. Smooth muscle demarcates the basal extent of the mucosa. Mucus-producing glands are evident in the submucosa. Parasympathetic ganglion cells are abundant, and cartilage is present. Cartilage is an essential structural element for maintaining expiratory patency of the major conducting airways. Proceeding distally in the tracheobronchial tree, luminal size diminishes, and certain features are lost. In particular, as the bronchus becomes a bronchiole, cartilage is lost and the glands disappear. More distally, smooth muscle and elastic tissue drop out of the terminal bronchiole as the need to conduct large volumes of air diminishes.

At the level of the respiratory bronchiole and alveoli, where gas exchange occurs, capillaries and epithelial cells are juxtaposed intimately. Most oxygen and carbon dioxide diffusion occurs across a membrane composed only of thin cytoplasmic extensions of the type I epithelial cell and the capillary endothelial cell, bound by a common basement membrane. This is only nanometers in thickness.

Mass Lesions in the Fetal Thorax

Increased use of prenatal ultrasound in even routine pregnancies, along with high resolution ultrasonography, has lead to a dramatic increase in the antenatal identification of developmental chest malformations, but definitive diagnosis is not possible. The natural history of developmental lung cysts discovered prenatally demonstrates that some decrease in size, some actually resolve, and some enlarge. All developmental lung cysts may act as a mass in the fetal chest with potential important physiologic consequences both before and after birth. The presence of a mass in the fetal thorax can result in mediastinal shift, hydrothorax, and polyhydramnios. In severe cases, in utero mediastinal compression and displacement can lead to cardiac failure, nonimmune fetal hydrops, and death of the fetus. The mass lesion in the fetal chest may also result in maldevelopment of the lung with the consequence a hypoplastic lung prone to pulmonary hypertension and respiratory insufficiency at parturition. Although the fetal lung mass is typically unilateral, the pulmonary hypoplasia can be seen bilaterally because often associated mediastinal shift affects development of the contralateral lung.

Fetal hydrops is characterized by signs of congestive heart failure, pleural and pericardial...
effusions, and anasarca. The development of fetal hydrops secondary to a developmental lung cyst is believed to be the result of several factors including; increased intrathoracic pressure, obstruction of the vena cava with decreased venous return and marked central venous hypertension, increased lymphatic transudate across the lung due to anomalous arterial supply with systemic pressure, and congestive heart failure from compression, mediastinal shift, and arterial venous fistulae. In this setting, the mortality of a fetus that develops hydrops is reported to approach 100% and selected fetuses may be appropriate for in utero intervention. Furthermore, polyhydramnios and mediastinal shift in utero may induce preterm delivery.

Prenatal intervention is controversial and the potential benefits to the fetus must be balanced against the risks to the mother and of preterm labor and prematurity to the infant. In utero interventions include; aspiration, placement of thoraco-amniotic shunts and the EXIT procedure. Generally aspiration is associated with rapid re-accumulation of the pleural fluid requiring serial procedures. Thoraco-amniotic shunts have been demonstrated to reverse fetal hydrops but complications include; occlusion, displacement or being pulled out by the fetus, and induction of preterm labor. Delivery should be planned in a tertiary care environment able to provide both prompt thoracotomy and multidisciplinary critical care for a newborn or preterm infant.

Physiologic problems after birth fall into two general patterns of presentation; respiratory insufficiency secondary to pulmonary hypoplasia and pulmonary hypertension in infants and recurrent pulmonary infections and persistent radiographic abnormalities in older children.

CONGENITAL DISORDERS

Congenital Cystic Adenomatoid Malformation (CCAM)

Congenital cystic adenomatoid malformation (CCAM) is a term applied to a cystic, solid or mixed intrapulmonary mass that communicates with the normal tracheobronchial tree. These lesions are characterized on pathologic examination by excessive proliferation of terminal respiratory structures (usually bronchioles) forming intercommunicating cysts of various sizes, with an associated suppression of development of the corresponding alveoli. The bronchial (adenomatoid) and alveolar components within the mass can vary considerably, resulting in differences in the ratio of solid and cystic components of a CCAM. The presumed etiology is failure of the bronchial buds to connect to the developing alveolar mesenchyme around 16 to 20 weeks gestation leading to overgrowth of the bronchioles. The cysts are lined by cuboidal or columnar ciliated epithelium and demonstrate a focal increase in elastic tissue. In addition, there is typically an absence of cartilage which may explain the tendency for air-trapping in these cysts. These lesions typically have a normal arterial supply and involvement is generally unilobar, with a predilection for the lower lobes. They are equally distributed between the right and left lobes. There is a slight male predominance, and no racial predilection.

Stocker and colleagues, using pathologic examination, described three subtypes based primarily on cyst size and whether they contained mainly cystic or adenomatoid (glandular) structures. In the Stocker classification, Type I lesions had cysts > 2 cm, Type II lesions had cysts < 1 cm in diameter, and Type III lesions were solid lesions with no cystic spaces. Mucus-producing cells are unique to Type I CCAM. Interestingly, Type II lesions were commonly associated with other severe anomalies including; renal agenesis or dysplastic kidney, syringomyelia, prunebelly syndrome and pectus excavatum.

The increased identification of these lesions prenatally and follow-up with serial ultrasound examinations throughout gestation, has enabled a better understanding of the natural history of CCAMs in utero. Prenatally diagnosed lesions may increase in size, decrease in size, and complete resolution has been reported to occur in about 10-15% of cases. Adzick and colleagues, using prenatal ultrasound, classified these lesions as either macrocystic (> 5 mm cyst diameter) or microcystic (solid or cysts < 5 mm cyst diameter). The characterization is clinically relevant because the natural history for the two subtypes is different. The microcystic lesions are currently believed to be more frequently associated with other developmental abnormalities, and therefore the patients have a poorer prognosis. Associated anomalies, including congenital heart disease, pectus excavatum, renal agensis, skeletal abnormalities, jejunal atresia and others, have been
reported, but the incidence is low. The micocystic CCAMs may be seen in association with developmental airway obstruction due to bronchial atresia or stenosis. The pathologic features are consistent and demonstrate focal areas of increased bronchiolar proliferation, variable alveolar development and regional displacement of the unaffected lung parenchyma. Lesions of great size, particularly those that are microcystic or solid in composition, are potentially associated with in utero mediastinal, hydrops fetalis, and fetal death. In less dramatic cases, the micocystic lesions are associated with lung maldevelopment resulting in pulmonary hypoplasia and respiratory distress at the time of delivery. In contrast, macrocystic lesions are rarely associated with the development of pulmonary hypoplasia or fetal hydrops. They are often asymptomatic at birth and generally have a favorable prognosis.

Adzick and colleagues suggested that the appearance of anasarca or fetal hydrops in fetuses with microcystic CCAMs is an indication of impending fetal demise; they have reported neonatal survival after fetal lobectomy in a small number of highly selected patients. The natural history of in utero macrocystic lesions appears less threatening, and although some have been managed with prenatal thoracoamniotic shunting or aspiration, most of these infants can be successfully treated after delivery at term. In addition, it appears that as many as one-third of macrocystic lesions diminish in size during fetal development. This is an important area of active investigation, with lung volume compared to thoracic volume as a ratio emerging as a potentially quantifiable measure to identify fetuses at high risk.

Most CCAMs are easily identified on plain chest radiographs. Larger lesions typically appear as sharply outlined, irregularly shaped, radiolucent areas of multiple sizes. Other consistent findings on plain chest radiographs are atelectasis in the surrounding adjacent lung, mediastinal shift, depression of the ipsilateral hemidiaphragm. In older infants and children, who have infectious complications, air-fluid levels may be present. Micocystic CCAM lesions appear more homogeneous and solid on radiographic imaging. It may be difficult to distinguish CCAM from other chest lesions, particularly pneumothorax or CDH, on plain film. Passage of a nasogastric tube into the stomach or an upper or lower gastrointestinal study may be definitive to diagnose congenital diaphragmatic hernia.

Clinical presentation for CCAM lesions, similar to other congenital lung malformations, is variable. One important factor dictating the mode and time of presentation is the degree to which communication with the tracheobronchial tree leads to air-trapping, progressive lung hyperinflation, and respiratory distress. The majority of CCAMs not diagnosed prenatally are diagnosed in early infancy and respiratory distress is the most common presenting symptom. The severity of symptoms is variable ranging from mild dyspnea and tachypnea to severe respiratory insufficiency. Occasionally, severely affected infants may have all the ventilatory instability of newborns with congenital diaphragmatic hernia. This includes the potential need for conventional mechanical ventilation, high-frequency or jet ventilation, or extracorporeal life support.

Smaller lesions followed antenatally are often asymptomatic at birth and frequently undetectable on plain chest radiograph. A CT scan should be performed at about 3 weeks of age and will almost always demonstrate the lesion. In older infants and children, infectious complications of these lesions secondary to inadequate clearance mechanisms predominate and presentation is typically due to acute or chronic recurring pneumonia.

The principal goal of treatment for CCAM is to resect the area of abnormal lung promptly. Operative management is typically lobectomy. In asymptomatic infants the procedure is generally performed between 3 and 6 months of age. Rarely, cases of multilobar involvement or infectious complications may require pneumonectomy. CT scans are generally obtained to provide anatomic detail and plan resection (Fig. 39.1). Rarely, ventilation-perfusion scan may provide helpful information in planning parenchymal-conserving operations in complicated cases such as multilobar or bilateral involvement. Segmental resection may be appropriate for smaller lesions and has been reported, but data suggest that complications may be higher with no demonstrable long-term benefit with this approach. Pneumonectomy is required in as many as 15-20% of affected patients to achieve complete resection of a complex, multilobar CCAM.
Thoracoscopic and minimally invasive techniques are currently being used for wedge resection, segmental resection, and lobectomy in selected patients depending on the experience and skill of the surgeon. The use of stapling devices has improved the ability to perform lung segmental and wedge resections without increased risk of postoperative air leak.

Outcome after surgical resection for infants and children is good with survival between 80-100% in modern series. Adzick and colleagues reported survival in four of 6 selected fetuses with microcystic CCAM after in utero thoracotomy and lobectomy between 24 and 32 weeks’ gestation. The potential complications of lobectomy are similar in incidence as for other lesions and long-term pulmonary function is excellent.

Malignancy in CCAM

There are over two hundred reported cases of malignancy identified in association with developmental lung lesions. Bronchoalveolar carcinoma of the lung has been reported both many years after lobectomy and within a CCAM. In addition, embryonal rhabdomyosarcoma and squamous cell carcinoma have also been demonstrated in association with these lesions.

Congenital Lobar Emphysema

Congenital lobar emphysema (CLE) refers to the abnormal postnatal collection of air within a lobe of the lung that is otherwise anatomically normal. There are a many etiologies which can result in CLE; the unifying theme is partial bronchial obstruction. Mechanisms resulting in CLE include bronchomalacia due to a developmental defect resulting in the absence of cartilage from a bronchus, intraluminal bronchial obstruction (secretions, mucus plugging), infection damaging alveoli, developmental abnormalities of alveoli, and pulmonary alveolar hyperplasia or polyalveolar lobe. In the classic form, the lobar overinflation is a form of bronchomalacia secondary to a developmental deficiency of cartilage within the bronchial wall that causes focal bronchial collapse during expiration. The cartilaginous deficiency presumably causes the affected bronchus to act as a ball-valve mechanism that permits inflation and expansion of the lobe but not deflation. This specific defect can be demonstrated in about one-half of surgically resected lobes. Endobronchial lesions that may cause CLE include viscid secretions, mucous plugs, or granulation tissue. CLE can also result from external compression of the bronchus including; enlarged heart chambers associated with congenital heart disease, anomalous pulmonary vessels or a large ductus arteriosus, mediastinal lymphadenopathy, vascular rings, and mediastinal bronchogenic cysts. CLE is associated with congenital heart disease or abnormalities of the great vessels in approximately 15% of infants. For this reason, screening echocardiography prior to surgery is appropriate in all affected infants.

CLE is an uncommon lesion and demonstrates an approximately 3:1 male predominance. Interestingly, almost all infants are white and CLE is generally a disease of early infancy. Typically a single lobe is involved. The left upper lobe is most frequently affected (40-50%), followed by the right middle lobe (30-40%), and the right upper lobe (20%). Involvement of the lower lobes or multiple sites is rare. The clinical course of congenital lobar emphysema is as varied as the numerous etiologies, with some infants having mild symptoms that remain stable and others demonstrating rapidly progressive respiratory failure. Respiratory symptoms are nonspecific; tachypnea, dyspnea, wheezing, and cyanosis. The normal
responses in infants to respiratory distress and hypoxemia (agitation, crying, tachypnea) exacerbates the process and a vicious cycle ensues. While more than half of patients become symptomatic in the first few days of life, others do not become symptomatic until 1 to 4 months late and some remain asymptomatic. In general, the earlier the onset of symptoms, the more likely the progression of disease with deteriorating lung function and a worsening of respiratory symptoms.

This lesion has significant potential for dramatic and rapid physiologic decompensation in the newborn infant. The lobar overdistension causes compression of adjacent normal lung tissue and mediastinal displacement with herniation of the emphysematous lobe to the contralateral chest (Fig. 39.2). Predictably, the problem may be escalated by intubation and positive-pressure ventilation. In these cases, emergency thoracotomy is necessary and life-saving. This challenging clinical scenario can also occur during preoperative endoscopic evaluation, necessary to eliminate reversible obstructing endobronchial lesions as an etiology for the lobar emphysema, and the surgeon and OR personnel must be prepared to decompress the thorax by emergent thoracotomy and then proceed to definitive lobar resection.

Physical findings in CLE may include an asymmetric thorax, a shift in the apical cardiac impulse to the contralateral side, and focal hyperresonance and diminished breath sounds on the involved side. The plain chest radiograph findings in CLE typically include; lobar hyperinflation, contralateral shift of the mediastinum and trachea, compression and atelectasis of adjacent lung, and flattening of the ipsilateral hemidiaphragm (Fig. 39.3). The differential diagnosis includes pneumothorax, giant cystic adenomatoid malformation, and a pneumatocele. The clinical and radiographic appearance can mimic that of tension pneumothorax, and differentiating CLE from this condition is essential: a tension pneumothorax is characterized by a collapse of the entire affected lung into the hilum; in contrast, in CLE, the adjacent compressed lung can almost always be seen on radiography. In stable patients, computed tomography (CT) and magnetic resonance (MR) imaging can provide helpful anatomic detail, particularly to identify thoracic mass lesions that may be causing extrinsic bronchial compression.19

The classic congenital form of CLE is rare in preterm infants; however, an acquired form of the disease has been identified. This acquired form of pulmonary emphysema is more recently described, in the 1970’s by Cooney, and is characteristically seen in preterm infants in association with bronchopulmonary dysplasia.20 The presumed etiology is a combination of barotrauma from positive-pressure ventilation in

Fig. 39.2: Skiagram of a 5/12 month baby with recurrent URI. The baby had congenital lobes emphyseme of the right upper lobe.

Fig. 39.3: Skiagram chest showing imphysemetous left lobe with flattening of the diaphragm and mediastinal shift.
the noncompliant immature lung and oxygen toxicity. In contrast to the congenital form of CLE, the acquired form is seen in older infants because it develops in a time-dependent manner on mechanical ventilation. The hallmark pattern is not unilobar in distribution, but rather, multiple areas of focal hyperinflation and interstitial emphysema and the middle and lower lobes are most commonly involved. Many of these lesions will resolve spontaneously. Occasionally, if a mass effect persists and produces some of the same clinical symptoms of compression of the normal lung and mediastinum seen with other chest lesions, surgical intervention may be indicated. In this setting, outcomes following resection are predictably less optimal than with resection for other lung cysts because often there is little residual normal lung for gas exchange.

Another form of neonatal pulmonary emphysema is focal pulmonary hypoplasia or polyalveolar lobe. This term describes a condition in which a 3 to 5 fold increase in the number of alveoli present results in lobar or segmental emphysema. This condition represents about one-third of cases of congenital lobar emphysema.

The treatment of CLE is lobar resection. Because the causes of CLE are structural, improvement is rarely seen with supportive treatments such as oxygen inhalation, airway humidification, suctioning or antibiotic administration. Medical therapy alone is associated with an early mortality rate of > 50% and 75% of survivors had persistent lobar emphysema.

A period of expectant management is acceptable for the largely asymptomatic lesion, however, complete resolution of the radiographic findings is rare, and for this reason surgical resection is indicated.

Surgical resection enables complete expansion of the normal lung and eliminates concerns for potential interference with compensatory lung growth and chronic infection from retained secretions. As noted previously, pre-resection endobronchial evaluation is important to identify reversible causes of bronchial obstruction which can be corrected without parenchymal lung resection. CLE resulting from extrinsic bronchial compression is associated generally with a focal cartilaginous defect of the affected bronchus that is not adequately relieved by simple decompression without lobectomy.

Clinical results of lobectomy in infants and children for this lesion are generally excellent. Poor results with reconstructive procedures, such as bronchoplasty and segmental bronchial resection and anastomosis, make these procedures inadvisable. Outcomes after thoracotomy and lobectomy for symptomatic infants are excellent and not different than for lobectomy for other lesions discussed in this chapter. Older children without respiratory symptoms severe enough to warrant pulmonary resection demonstrate normal pulmonary function results in long-term follow-up. In addition, adults who underwent neonatal lobectomy for CLE were demonstrated to have equal ipsilateral and contralateral lung volumes despite the previous lobectomy and this appeared to be related to compensatory tissue growth rather than distension of residual lung parenchyma.

Pulmonary Sequestration

Pulmonary sequestration is a mass of nonfunctioning lung tissue which lacks normal communication with the tracheobronchial tree and has an anomalous systemic arterial supply. Two forms of pulmonary sequestration have been described; extralobar sequestration (ELS) lies outside the normal lung tissue and is invested with its own visceral pleura, and intralobar sequestration (ILS), in which the abnormal pulmonary tissue is incorporated within the visceral pleura of the normal lung.

The precise etiology of the embryologic origin of pulmonary sequestration is unknown. Several theories exist including; formation of an accessory lung bud that becomes an accessory lung mass, embryonic adhesions between the pulmonary bed and the adjoining tissue separates the sequestration from the primary developing lung bud, and persistence of the early embryonic splanchic blood vessels producing traction on tips of the bronchial tree resulting in separation of the tissue from its “parent lobe”. The most widely accepted theory is failure of the pulmonary artery to develop fast enough to supply the whole of the growing lung leading to formation or persistence of systemic arterial supply from the aorta.

Sequestrations represent about one-third of congenital lung lesions in most reported series and
the male predominance is as high as 3:1, particularly for extralobar sequestration. Although there is wide variation in reported series, ILS appears to be more common with a ratio of 3 to 1. Extralobar sequestrations demonstrate a more variable occurrence pattern in the chest or beneath the diaphragm, but most frequently are basilar, located on the left side at the costophrenic sulcus in the posterior mediastinum, adjacent to the esophagus. Other rare locations for ELS include within the diaphragm and even within the pericardium. ILS is most common within the posterior and basal segments of the lower lobes and more often on the left side. Upper lobe involvement is seen in only 10% to 15% of pulmonary sequestrations and bilateral involvement is rare. None of the postulated embryologic origins for pulmonary sequestration can explain the predilection of ELS for the left side.

On pathological examination, sequestrations tend to be more solid than cystic and demonstrate parenchymal abnormalities similar to microcystic (type II) CCAMs. In extralobar sequestration, the arterial blood supply typically arises directly from the aorta (lower thoracic) and an infradiaphragmatic source is demonstrated in up to 20% of the patients, often passing within the inferior pulmonary ligament. In some large intralobar sequestrations, hemodynamically significant arteriovenous fistulas can be formed and congestive heart failure has been reported. In addition, the abundant blood supply within an intralobar sequestration can occasionally lead to recurrent or massive hemoptysis, spontaneous intrapleural hemorrhage, or massive hemothorax. Venous drainage is variable, but typically is through the pulmonary veins to the left atrium for intralobar lesions and the azygous or hemiazygous system for extralobar lesions. Venous drainage through esophageal or subclavian intercostals and infradiaphragmatic connections to the adrenal or portal vein are reported. As with other congenital lung lesions, many variations in arterial supply and venous drainage combinations have been described.

Coexisting congenital anomalies are common with extralobar sequestrations (> 50%), particularly congenital diaphragmatic hernia, but rarely seen with intralobar sequestrations. Other anomalies seen in association with extralobar sequestrations include; chest wall and vertebral deformities, hindgut duplications, tracheoesophageal fistula and esophageal duplication and congenital heart disease. Pulmonary sequestrations, similar to other congenital lung lesions, demonstrate a broad spectrum of clinical presentation. Prenatal diagnosis is common, particularly for ELS, and the characteristic appearance is a posterior mediastinal or infradiaphragmatic solid mass. The anomalous arterial blood supply is pathopneumonic on color-flow Doppler ultrasound. Large lesions can be associated with the same physiologic problems described for other mass lesions in the chest. ELS has been associated with severe hydrothorax and fetal hydrops. Because these are often small lesions not typically associated with mediastinal shift and cardiac compression, other etiologies include obstruction of the vena cava or increased lymphatic transudate from abnormal lymphatics within the sequestration in association with systemic pressures.

After parturition, many sequestrations are asymptomatic. The pattern of clinical discovery is different for ELS compared to ILS. Extralobar sequestrations are recognized most often in infancy as incidental findings on chest roentgenograms, particularly in association with diaphragmatic hernia. Other presentations include; respiratory distress, pneumonia, feeding intolerance, hemorrhage, and arterial-venous shunting leading to congestive heart failure.

In contrast, the primary symptoms for ILS are chronic, recurrent respiratory infections with cough, fever, and pleuritic chest pain. The nonspecific nature of the complaints with ILS frequently leads to a delay in diagnosis. The pulmonary infection is introduced through communication with the adjacent lung through alveolar spaces and poor ventilation and inadequate clearing mechanisms facilitate progression of the infection. Because the infectious complications typical of ILS evolve in a time-dependent manner, < 10% of cases are diagnosed in children under one year and only one-third are diagnosed before 10 years of age. The classic presentation of ILS is recurrent pneumonia in the same bronchopulmonary segment, usually lower lobe, in a child > 2 years of age. Recurrent or persistent focal pneumonias, lung abscess, chest pain and hemoptysis are all common.

The radiographic appearance for pulmonary sequestration is nonspecific. Common findings on plain film include; an incidental posterior mediastinal mass low in the chest, lobar atelectasis and pneumonia, and occasionally an air-fluid level. Ultrasound with
Doppler blood flow imaging, contrast enhanced CT, and MR imaging and MR angiography are all helpful diagnostic adjuncts that provide excellent anatomic detail in select patients. Contrast enhanced CT scan and MR angiography has replaced angiography for the evaluation of the arterial supply to pulmonary sequestrations because they provide equally reliable anatomic detail with less potential morbidity than angiography.

The anomalous arterial supply in pulmonary sequestration is elastic and these vessels undergo early cystic or fibrous degeneration. These characteristics in conjunction with inflammatory changes can make control of major vessels challenging during resection. Because of the foregut derivation, occasional communication with the esophagus or stomach occurs and this possibility should be investigated either intraoperatively or preoperatively by axial imaging or contrast studies of the gastrointestinal tract. In particular, an ELS that presents as pulmonary infection should raise suspicion for possible communication with the GI tract.

The standard treatment for both intralobar and extralobar sequestrations is surgical resection. Preoperative imaging typically is CT or MRI. The standard procedure is lobectomy through a traditional thoracotomy incision. For extralobar sequestrations, preoperative imaging is critical to evaluate for possible lesions located below the diaphragm. With extralobar sequestrations, resection does not involve removal of normal lung parenchyma. Although extralobar resections are frequently asymptomatic, resection is recommended for definitive diagnosis and to avoid the risk of hemorrhage, infection, and malignancy. Squamous cell carcinoma, adenocarcinoma, and embryonal rhabdomyosarcoma have all been reported in pulmonary sequestrations. Many surgeons now use thoracoscopy and video-assisted minimally invasive techniques and report equivalent results to open thoracotomy, while avoiding the morbidity associated with thoracotomy.

In both intralobar and extralobar forms, a careful search of the thorax must be undertaken prior to resection to identify and control the aberrant systemic arterial blood supply. The aberrant arteries are elastic in type and frequently have atherosclerotic changes, making them extraordinarily friable. The systemic arterial inflow to the pulmonary malformation is multiple in 15% of cases.

As with other pulmonary resections in infants and children, outcomes following resection of pulmonary sequestrations are excellent and survival approaches 100% in the absence of serious co-morbid conditions. In cases of extralobar sequestration, no functioning lung tissue is resected. Morbidity and postoperative complications should be minimal and are not different than for other pulmonary resections. Long-term pulmonary function is expected to be excellent.

**Bronchogenic Cysts and Lung Cysts**

Bronchogenic cyst is a term which collectively describes congenital cysts located along the tracheobronchial tree or within the lung parenchyma. These cysts are believed to arise as a result of abnormal budding of epithelial cells from the primitive tracheobronchial tree. Other malformations included with bronchogenic cysts due to their shared embryology include enteric duplication cysts and neuroenteric cysts. Maier and colleagues classified bronchogenic cysts into five groups based on location: paratracheal, carinal, paraesophageal, hilar, and miscellaneous (pericardial, cervical subcutaneous, and abdominal). About two-thirds of bronchogenic cysts are located peripherally in association with the intraparenchymal bronchi.

Bronchogenic cysts are typically solitary, spherical, unilocular cystic structures that are filled with mucus or fluid (Figs 39.4A and B). They are often attached to but do not communicate with the tracheobronchial tree. Histologically these lesions demonstrate elements consistent with their airway origin including; cartilage, smooth muscle, mucous glands, and respiratory epithelium. Hyaline cartilage plates must be present for this diagnosis and bronchial-type glands generally are present. They typically have a normal bronchial arterial blood supply.

Cystic lung lesions that result from abnormal development of the more distal airways, alveoli, or pleural or lymphatic tissue are termed true lung cysts.
Lung Anomalies

(Figs 39.5A and B). They constitute a heterogeneous group of parenchymal lung cystic lesions that even collectively are rare. Differentiation of the tissue of origin is of pathologic interest but generally does not affect presentation or clinical management. One important exception is when the lesion is lymphatic in origin and the result is pulmonary lymphangiectasis. This malformation is typically characterized by diffuse bilateral pulmonary cystic disease, and the outcome is often lethal.

Bronchogenic cysts, similar to essentially all congenital lung cysts, may be discovered incidentally on plain chest radiographs or present with symptoms. The majority of bronchogenic cysts remain asymptomatic and many are first recognized in adults. An exception are bronchogenic cysts in a parabronchial location which often result in progressive air-trapping from partial bronchial obstruction.

Symptomatic presentation is also analogous to other chest cysts including; compression of adjacent hollow viscera, such as the airway or esophagus, or with infection from inadequate drainage of secretions. The most consistent presentation is infection or nonspecific respiratory symptoms in early childhood, such as cough, stridor, or wheezing from airway compression. Symptomatic presentation in infancy is uncommon; however, with mediastinal cysts, partial bronchial obstruction with air-trapping can produce...
radiographic findings identical to CLE with the potential for acute respiratory distress.

The classic appearance on a plain radiograph of a bronchogenic cyst is that of a smooth, roughly spherical, pratracheal or hilar solid mass without calcification (Figs 39.6A and B). Displacement of the adjacent airway and distal air-trapping are frequent findings, even in asymptomatic patients. The presence of air or an air-fluid level within the cyst suggests communication with the tracheobronchial tree or foregut, and this is a particularly likely finding in the presence of acute infection. Larger lesions can be difficult to distinguish from a lung abscess or macrocystic CCAM on chest radiograph. As with other thoracic mass lesions, CT scan and MR imaging can often provide helpful anatomic detail. Compression of the trachea or esophagus may also be demonstrated on endoscopy or esophogram.

Resection is the standard treatment for virtually all bronchogenic and lung cysts, even in asymptomatic patients because of the risk of infection. This scenario can lead to presentation indistinguishable from a cavitating pneumonia or lung abscess. Persistence of the intraparenchymal cystic abnormality following resolution of the inflammatory process is characteristic. Resection of these well-circumscribed lesions is generally straightforward and in the case of mediastinal cysts, does not require parenchymal lung resection. Occasionally, limited local lung resection or rarely lobectomy may be required. Preoperative antibiotic treatment is necessary for infected lesions. As with many thoracic lesions, thoracoscopic resection of bronchogenic and lung cysts is emerging as a popular approach in selected patients.

**Pulmonary Agenesis, Aplasia and Hypoplasia**

Pulmonary agenesis, aplasia, and hypoplasia are a constellation of lung malformations characterized by underdevelopment of the lung. In pulmonary agenesis, there is no development of the bronchial tree, pulmonary tissue, or pulmonary vasculature, whereas in pulmonary aplasia, there is a rudimentary bronchial pouch. In pulmonary hypoplasia, there is a decrease in the number and size of the bronchial Airways, pulmonary alveoli, and pulmonary vasculature. Other congenital malformations are frequently associated with these conditions.

Pulmonary agenesis is the complete failure of development of both the lung parenchyma and tracheobronchial tree. Bilateral pulmonary agenesis is exceedingly rare and incompatible with survival; there are several hundred cases of unilateral pulmonary agenesis reported in the world literature. The embryologic defect is failure of bronchial budding from the trachea in early organogenesis resulting in absence of one or both mainstem bronchi. In the absence of bronchial development, the lung also fails to form. Unilateral pulmonary agenesis is frequently (> 50%) associated with other severe developmental anomalies. Most commonly, these include elements of the VACTERL association (e.g. vertebral, anorectal, cardiac, tracheoesophageal, renal and limb), with cardiac lesions predominant. Pulmonary aplasia is
similar with one normal bronchus and a small, blind-ending nub on the opposite side with no or incomplete lung on the affected side.31,32

There are several patterns of discovery for patients with pulmonary agenesis; patients without symptoms for whom the finding is incidental, patients with specific respiratory symptoms, or patients with associated anomalies. Respiratory symptoms are nonspecific and include, dyspnea, tachypnea, cough, wheezing, and failure to thrive. Recurrent pneumonia and bronchitis are the most common clinical problems. Infection in the single lung must always be considered a life-threatening problem and aggressive non-operative management is indicated.

On physical examination, the chest may initially appear symmetric, but as the patient ages, there can be a lack of growth on the affected side. Breadth sounds are typically bilateral because the solitary lung expands and crosses into the contralateral chest, but typically only anteriorly, none are heard in the axilla or the base. Heart sounds may be shifted.

The plain radiograph in unilateral pulmonary agenesis is abnormal but nonspecific. Typically one can see a homogeneous density on the affected side with total absence of normal, aerated lung. Herniation of the contralateral lung is best visualized on the lateral film, where it appears in the anterior mediastinum, directly beneath the sternum. On AP film, the ipsilateral diaphragm is elevated and the mediastinum is shifted towards the affected side. On careful inspection, one can see a closer approximation of the ribs on the side of the agenesis versus the normal side. Chest CT scan can be useful in showing the absence of pulmonary parenchyma and tracheobronchial tree. The definitive diagnosis is made by bronchoscopy and the findings are a normal trachea and contralateral mainstem bronchus with complete absence of the ipsilateral bronchus. In children with congenital heart disease, angiography or echocardiography demonstrating absence of the ipsilateral pulmonary artery is pathognomonic. Contrast bronchography is not recommended because it has significant risk to the single normal lung.

The standard treatment for unilateral pulmonary agenesis is nonoperative supportive measures, particularly aggressive antibiotic treatment for recurrent infections. Historically, the prognosis for these patients was poor, and only about one-half of patients with unilateral pulmonary agenesis survived to age 5 years.13 Most of this mortality is related to perinatal death, problems of associated anomalies, or recurrent pulmonary infections. In more recent years, the prognosis for these patients appears to be improving.

Pulmonary hypoplasia refers to the reduction in size of an entire lung and its individual components. In contrast to pulmonary agenesis and pulmonary aplasia, lung tissue is present, but it is hypoplastic. This condition is characterized by small lung size and low ratio of lung weight to body weight. The mainstem and proximal bronchi are normal, but there are decreased distal bronchial generations and alveoli. Critical factors for normal lung growth include; secretion of lung fluid, distension of air spaces by glottic closing, and space to expand. The embryologic origin is thought to relate to “crowding” in the thorax during organogenesis; therefore any fetal intrathoracic mass lesion can result in pulmonary hypoplasia. Primary pulmonary hypoplasia is rare, with the majority of cases being secondary to some associated abnormality.

The most common cause of secondary pulmonary hypoplasia is a decrease in the volume of the affected hemithorax. There are several causative etiologies including; congenital diaphragmatic hernia (the most common lesion), giant abdominal wall defects (giant omphalocele), pleural effusion (as in hydrops fetalis), or to a small thoracic cage, as in asphyxiating thoracic dystrophy (Jeune syndrome). The next most common cause is oligohydramnios, possibly related to compression of the fetal thorax by the uterus, preventing the lung from growing. Another theory is that the internal stint of fluid that keeps the lung expanded in utero is diminished in oligohydramnios, causing the lung to underdevelop. A third cause of pulmonary hypoplasia results from a decrease in pulmonary vascular perfusion, associated with cardiovascular malformations, such as Tetralogy of Fallot, hypoplastic right heart, or pulmonary artery agenesis. A less common cause is a decrease in fetal respirations which are required to expand the fetal thoracic cage. This decrease in fetal breathing might possibly cause a loss of fetal lung fluid, with resultant pulmonary hypoplasia. Finally, miscellaneous causes include the trisomies 13, 18 and 21. Pulmonary hypoplasia is also seen in Werdig-Hoffman disease or phrenic nerve agenesis.
The newborn clinical presentation varies and depends on the amount of functioning lung tissue and associated congenital malformations. In severe cases, infants demonstrate pulmonary hypertension, persistent fetal circulation, and respiratory failure. For affected infants with respiratory insufficiency, supportive strategies include; standard mechanical ventilation, high frequency oscillatory ventilation, and in carefully selected cases extracorporeal membrane oxygenation (ECMO).

**ACQUIRED LUNG ABNORMALITIES**

**Lung Abscess**

A lung abscess is a necrotic, infected cavity within the lung parenchyma caused by pyogenic, toxin-producing bacterial organisms. Lung abscesses are uncommon and most often occur in patients with physiologic vulnerability due to an immunocompromised state. Predictable settings include; (1) post-pneumonic, (2) aspiration of oropharyngeal or gastrointestinal contents, (3) hematogenous seeding, (4) direct spread from the abdomen or from trauma or surgery. Abnormal areas of lung parenchyma with inadequate clearing mechanisms are particularly susceptible. Lung abscesses are considered primary if they occur in an otherwise healthy child, and secondary when seen in association with pre-existing conditions. Typically a lung abscess communicates with the normal tracheobronchial tree.

There are many risk factors that increase the risk of lung abscess including; altered mental states associated with swallowing dysfunction, hematologic or oncologic disorders, primary or acquired immunodeficiency states, suppressed cough reflex secondary to anesthesia, head injury, or medications, and conditions associated with bronchial obstruction. Aspirated foreign bodies can also lead to pulmonary abscess, as can esophageal functional disorders (achalasia) because they frequently lead to recurrent aspiration. Institutionalized children with periodontal and dental disease and patients treated with chronic antibiotics may also be at increased risk because of development of a large proximal reservoir of potentially pathogenic bacteria. The lung tissue surrounding the abscess typically demonstrates atelectasis and pneumonia. A chronic lung abscess occurs when a surrounding rim of circumferential fibrosis develops.

The inflammatory response associated with a lung abscess recruits phagocytic cells that generate cytotoxic oxidants and proteases that can rapidly destroy adjacent lung parenchyma. The destructive process involves both cellular lung elements and extracellular lung matrix and the result is cavitation.

Lung abscesses are typically polymicrobial and reflect oral flora, with both aerobic and anaerobic bacteria. Predominant organisms include; Bacteroides sp, Group B hemolytic Streptococci, Escherichia coli, Pseudomonas sp, and Aerobacter aerogenes. Staphylococcus aureus and Klebsiella pneumoniae are also common and associated with aggressive parenchymal destruction. Fungal infection may also lead to primary or secondary lung abscesses, particularly in immunocompromised patients. Aspergillus, Actinomycoses, and Nocardia sp are most common.

The clinical presentation of a patient with a lung abscess is characterized by fever, cough, chills, night sweats, anorexia, and weight loss. With progression of the destructive process, cavitation and bronchial erosion are heralded by productive cough, purulent sputum, and possibly hemoptysis. Chest radiographs typically show an air-fluid level within a thick-walled cavity in a dependent location, most frequently the right lung; the superior segment of the lower lobe and the posterior segment of the upper lobe. In patients with a lung abscess, consideration should be given to the possibility of an underlying congenital cystic lesion. Definitive evaluation for this possibility is often impossible in the acute setting. Generally, sequential films demonstrate resolution of pneumonia or an abscess, while congenital cystic lesions persist and become more evident.

The medical therapy for a lung abscess requires aggressive antibiotic administration and, as with any abscess, drainage. Drainage commonly occurs spontaneously into the tracheobronchial; thus producing large amounts of purulent sputum. Bronchoscopy may at time be necessary to obtain cultures. Chest physiotherapy, postural drainage, and suctioning are all fundamental elements of care for patients with a lung abscess. This approach should lead to resolution of the abscess in the majority of cases; although a six to twelve week course of antibiotics is generally necessary. Infants, small children, and others who do not expectorate sputum effectively may require more aggressive endoscopic and surgical measures.
Drainage of a lung abscess can be accomplished by a variety of interventional procedures. Endoscopic drainage into the tracheobronchial is possible using needles or catheters passed through a rigid or flexible bronchoscope. The significant risk of these procedures is contamination of an adjacent bronchus or the contralateral lung. Techniques used to lower this risk include; selective intubation of the affected lung, balloon exclusion of the opposite mainstem bronchus, and positioning the involved lung dependently. These risks make general anesthesia required in most cases. Transpleural diagnostic aspiration and both open and closed external drainage are appropriate for selected patients. The risks of generalized pleural contamination and empyema, however, make these approaches desirable only in circumstances in which the abscess is peripheral in location and chronic enough that there is symphysis between the visceral and parietal pleura. These approaches are best reserved for specific indications in complex abscesses after failure of initial drainage and antibiotics and often performed using CT or ultrasound guidance. Regardless of the drainage technique selected, microbiologic evaluation of the abscess contents is important to guide antibiotic therapy.

Initial empiric antibiotic therapy for patients without risk factors should cover anaerobic organisms as well as gram negative bacteria and Staphylococcus. Clindamycin rather than penicillin G is recommended due to increasing numbers of resistant oral anaerobes and resistant Staphylococcus organisms. Ampicillin-sulbactam and Ticarcillin-clavulonate are combinations that also provide excellent broad spectrum empiric coverage. Patients with risk factors such as chronic aspiration or immunodeficiency states should also have coverage for gram-negative bacterial organisms. Long-term antibiotic therapy is the standard for management of lung abscesses, typically 6 to 12 weeks, although the duration of therapy is adjusted based on clinical response (fevers, leukocytosis) and clearing of the chest radiograph.

In addition, immunodeficiency states that can be corrected or modified should have this done. Modulation of immunosuppressive drugs in transplant patients, delay in chemotherapy for oncology patients, treatment with granulocyte colony-stimulating factor for neutropenic patients, and other similar approaches are appropriate when possible.

Operative management of a lung abscess is reserved for patients who fail nonoperative management and demonstrate signs and symptoms of persistent or recurrent infection, and those who develop specific related complications including; massive or recurrent hemoptysis, bronchopleural fistula, and a persistent cavitory lesion. In these settings, operative resection of the involved lung may be necessary. The most common procedure is lobectomy because of the destruction of segmental architecture from infection and inflammation and concern for persistent air leak with wedge or segmental resection. A formidable technical challenge for pulmonary resection in the setting of infection is secure closure of the bronchial stump to prevent bronchopleural fistula and persistent air leak. The use of standard GIA or endoscopic stapling devices has contributed to lowering the morbidity for these resections, and in particular, for wedge and segmental resection.

Bullous Lung Disease

Bullae or blebs are saccular collections of subpleural air within the lung that are thought to result from an air leak from an adjacent alveolus. Generally, the term bleb refers to a smaller air collection within the layers of the visceral pleura and bulla to an emphysematous space greater than 1 cm in diameter. An important functional difference is that bullae are generally associated with the loss of adjacent lung parenchyma, while this is not true for blebs. Blebs and bullae are not associated with normal alveoli or capillaries; hence, no gas exchange occurs within them, although they do communicate with the tracheobronchial tree.

Bullae and blebs may be congenital or acquired. Congenital lesions presumably represent a developmental abnormality of the alveoli and terminal airways during organogenesis. Acquired lesions are believed to result from lung changes related to chronic infection. The process begins with destruction of lung parenchyma leading to loss of elasticity in association with inflammatory changes in the terminal bronchioles producing expiratory obstruction. Consequently, progressive trapping of air, derived from bronchial airflow and/or collateral interalveolar ventilation, occurs in the airway distal to the obstructed bronchus during expiration. The increased pressure that develops with this protracted air trapping causes
secondary distension and finally disruption of alveolar walls, producing a bulla. Acquired bullous disease is typically seen in association with conditions associated with chronic or recurrent pulmonary infections such as cystic fibrosis or α-1 antitrypsin deficiency.38

Congenital blebs classically present in the teen-age years as spontaneous pneumothorax from rupture into the pleural space. Acquired bullous disease is most often seen in patients with chronic lung disease and therefore the presentation is related to progressive respiratory insufficiency. A common scenario leading to discovery is exercise intolerance from diminished lung volumes and inadequate respiratory reserve. The standard evaluation of these patients includes plain chest radiographs and contrast-enhanced thin-cut CT scan. Congenital bleb disease is typically located in the lung apices and is frequently bilateral. Acquired bullous disease generally correlates with the underlying parenchymal disease. α-1 antitrypsin deficiency is unique in its propensity to form basal blebs.

The management of blebs and bullae is dependent on several factors including; clinical presentation, degree of symptomatology, and associated underlying lung disease. The classic patient with congenital bleb disease is a tall, thin, athletic teen-aged child who presents with a spontaneous pneumothorax and otherwise normal lungs. Initial management in symptomatic patients is placement of a tube thoracostomy to re-expand the lung and appose the visceral and parietal pleura. After stabilization, CT scan with “thin cuts”, particularly in the apical areas, provides excellent evaluation for blebs. Video-assisted thoracoscopic surgery (VATS) has become the standard approach for definitive operative treatment and the procedure involves resection of the apical blebs using an endoscopic stapling device and pleurodesis, generally using mechanical abrasion, talc, or a combination of both. The thoracoscopic approach has lowered morbidity and complications compared to traditional thoracotomy and suture closure of the lung resection margin. Without bleb resection, most series report recurrent pneumothorax in 20-50% of patients after an initial pneumothorax and the recurrence rate approaches 80% after a second pneumothorax.39 Patients may elect for nonoperative management with the initial presentation based on their ability to tolerate a recurrent pneumothorax. This less aggressive approach is reasonable provided they have complete re-expansion of the affected lung and resolution of any air-leak. Nonoperative management is ill advised if the initial presentation was associated with tension pneumothorax, hemothorax, or hemodynamic instability. The outcome after bleb resection is predictably excellent because parenchymal resection is minimal and the underlying lung is normal.

Surgical management of bullous disease associated with chronic lung disease and infection is more complex and outcomes less good. Bullous disease may affect adjacent normal lung parenchyma by causing compression atelectasis. In these patients with associated lung disease, preoperative planning is essential to correlate areas of disease with physiologic dysfunction and to assess expected tolerance for the procedure and lung resection. This evaluation would typically include ventilation-perfusion scan and pulmonary function tests and is not different than the planning of resectional surgery in any patient with chronic lung disease. In this setting, if preoperative evaluation shows that the bullae occupy more than one-third of the ipsilateral thorax, if ventilation-perfusion scan shows little or no function in the area of the bullae, and if pulmonary function studies indicate tolerance for thoracotomy and lung resection, the outcome is potentially favorable.

**Bronchiectasis**

Bronchiectasis refers to the structural and functional destruction of the bronchi by chronic and recurrent infection. The most common etiologies in childhood are cystic fibrosis and the chronic lung disease seen in patients with gastroesophageal reflux and recurrent aspiration. The destructive process involves pyogenic bacterial infection that injures and then destroys the structural elements of the airways including; elastin, cartilage, and smooth muscle, and leads to marked collagen deposition and epithelial metaplasia, with replacement of the normal ciliated respiratory epithelium by squamous epithelium. Loss of the normal ciliary transport mechanism further impairs bronchial clearing and perpetuates the infectious process.

Several genetic abnormalities are associated with recurrent pulmonary infections and bronchiectasis in children including; cystic fibrosis, α-1 antitrypsin deficiency, immotile cilia syndrome, and certain...
immunodeficiency states. Congenital deficiencies of the pulmonary supporting tissues such as bronchomalacia, Williams-Campbell syndrome and Kartagener’s syndrome are uncommon associated causes of bronchiectasis. In addition, occasionally endobronchial tumors can result in chronic infection and eventually bronchiectasis distal to the obstruction.

Bronchiectasis can also develop following acute pulmonary infection in an otherwise normal individual, and measles and adenovirus are the most common pathogens. Tuberculosis and pertussis are also important causes in certain susceptible populations. Aspiration of foreign objects that is unrecognized and leads to chronic inflammation and infection is another well recognized cause of bronchiectasis in childhood, particularly in neurologically impaired children.

Bronchiectasis tends to occur in specific lobar distributions, with the lower lobes most frequently involved. Generally the problem occurs in older children and adolescents because the bronchial destruction evolves from chronic infection in a time-dependent manner that typically involves a number of years.

The symptoms of bronchiectasis are a persistent, productive cough and purulent sputum. Because young children often swallow sputum rather than expectorate, the large volumes may be unrecognized. Failure to thrive and poor growth and weight gain are found frequently in association with bronchiectasis with as many as one-half of patients being less than 10th percentile for height and weight. Hemoptysis is rare.

The hallmark of bronchiectasis on plain chest radiographs is persistent findings of focal pneumonia and dilated bronchi associated with hyperinflation in the surrounding lung. Plain radiographs are nonspecific and generally insufficient to adequately evaluate the disease process. Chest CT scan with intravenous contrast and MR imaging have become the standard to assess the extent of involvement and have replaced contrast bronchography and bronchoscopy for evaluation (Fig. 39.7).

Medical therapy consists of antibiotic therapy, including aerosolized antibiotics, when acute pulmonary exacerbations occur and vigorous pulmonary physiotherapy to facilitate bronchial drainage. Bronchoscopy is occasionally needed to assist in clearance of secretions and acquisition of adequate cultures.

Fig. 39.8: Excised pneumonectomy specimen of a lung with bronchiectatic changes

Surgical Excision (Fig. 39.8)
The surgical aspects have been discussed in chapter 38.

Echinococcal Lung Disease

Echinococcus granulosus and Echinococcus multilocularis are parasites responsible for hydatid (watery) cystic lung disease in children. Echinococcus or hydatid cystic disease is endemic in sheep- and cattle-raising areas of the world such as the Middle East, Australia, India, and the Mediterranean countries. The incidence in Turkey has been reported as high as between 1 and
Echinococcal infection is endemic but rare among native populations of the Southwest United States, Northwestern Canada, and Alaska. The predominant vector in North America is the dog. Humans become infected as intermediate hosts when their hands or food becomes contaminated by the scoleces of these parasites, which are ingested. The eggs hatch in the stomach and proximal small intestine, releasing the embryos (larval stage), which penetrate the intestinal mucosa to enter the portal venous circulation. Most of the embryos are filtered out in the liver, but some escape the liver to be disseminated, the common sites being lungs, brain, and bone; however, any organ may be involved. The embedded embryos that survive phagocytosis develop into hydatid cysts. In adults, liver involvement is most common, followed by lung, brain, spleen, and other organs. In children, pulmonary echinococcal cysts are more common than liver cysts.

The clinical manifestations of a pulmonary hydatid cyst depend on several factors; whether it is complicated or uncomplicated, the location of the cyst in the lung (central versus peripheral), and the size of the cyst. Some patients demonstrate nonspecific respiratory symptoms such as cough, dyspnea, fever, and chest pain, and others are asymptomatic. Solitary lung cysts are often large, and air-fluid levels may be seen on chest radiograph. Calcifications are rare. Rarely, a large peripheral cyst may produce acute respiratory distress by intrapleural rupture with hydropneumothorax. A central pulmonary hydatid cyst may produce symptoms of bronchial compression with cough, minor hemoptysis, and dull, aching chest pain. Rupture of the hydatid cyst into the bronchus manifests by vigorous coughing up of salty-tasting sputum; hypersensitivity reaction with urticaria, pruritis, severe bronchospasm, and anaphylactic shock; asphyxiation; and secondary infection of the cyst.

Diagnosis of pulmonary hydatid cyst should be suspected in any patient, above the age of 3 years in an endemic area, presenting with single or multiple opacities on the chest radiograph. Uncomplicated hydatid cyst has a sharp outline but is seldom completely circular because it is so soft that it is dented and configured by adjacent structures. Peripheral blood eosinophilia occurs in about one-third of patients with echinococcus. The diagnosis can be confirmed with an accuracy of > 80% with one or more of the following serologic tests; indirect hemagglutination, complement fixation, dot immunobinding, or enzyme-linked immunosorbent assay. Transpleural aspiration is also diagnostic, demonstrating *Echinococcus* sp hooklets and protoscoleces.

The diagnosis of a pulmonary hydatid cyst is an indication for surgery. Antibiotic treatment alone is unlikely to resolve the cyst and surgical resection eliminates the potential for secondary bacterial infection of the cyst. Patients should be treated with perioperative mebendazole and prompt surgical resection of the thick-walled cyst, with care taken to avoid pleural contamination. The risks of anaphylaxis and local implantation of scoleces appear low with lung disease, but most surgeons experienced with this disease take precautions to avoid spillage whether at the time of diagnosis or treatment.

Removal of the cyst by enucleation without needle aspiration is preferred. At times, wedge or segmental resection is necessary, and even lobectomy if the surrounding lung tissue has been destroyed by prolonged compression or infestation. Agents such as hypertonic saline or ethyl alcohol have been used in conjunction with resection, but the risk is substantial if drainage of these agents into the tracheobronchial tree occurs.

**Opportunistic Lung Infections**

The number of infants and children who develop opportunistic pulmonary infections (mycobacterial, protozoan, viral, fungal, and bacterial pathogens) is increasing as aggressive treatment regimens for childhood cancer create more immunocompromised hosts. Children at greatest risk include; transplant recipients, oncology patients, patients with human immunodeficiency virus infection, and others. Typically, at risk patients develop diffuse interstitial pneumonitis with a broad range of clinical symptoms from cough and fever to life-threatening respiratory distress. Depending on the underlying disease, many receive empiric antibiotic therapy with trimethoprim-sulfamethoxazole to treat suspected *Pneumocystis carinii* or other possible pathogens. A definitive tissue diagnosis becomes necessary for progressive or refractory disease. The most common surgical requirement for these immunosuppressed patients
with interstitial pulmonary disease is to provide tissue samples for histopathology and microbiologic analysis to direct specific therapy. A fundamental principle in the care of these patients is to employ minimally invasive techniques as possible, particularly in neutropenic patients, because of their compromised wound healing ability. Bronchoalveolar lavage may be helpful in identifying some pathogens in immunosuppressed children with pneumonia. Both transbronchial biopsy and percutaneous lung biopsy yield small tissue samples that may be helpful in differentiating among infectious, rejection-related, and inflammatory lung processes. Formal lung biopsy, however, whether by limited open thoracotomy or thoracoscopic techniques, is often preferred because the larger specimens obtainable are more likely to be definitive. Although the surgical procedure is generally well-tolerated, its combination with the underlying disease process yields substantial perioperative morbidity and mortality. In one review of open lung biopsies among childhood bone marrow transplant recipients with interstitial lung disease, the 30-day mortality rate was 45% and the overall mortality rate was 74%.42 A definitive diagnosis results from open lung biopsy in between 50% and 90% of immunosuppressed patients with interstitial lung disease, although the incidence of treatable disease is substantially lower.43 The thoracoscopic approach with use of a stapled wedge resection has rapidly gained acceptance in children who are sufficient size to use the commercially available stapling devices the thorax (about 15 kg). Smaller children may also have thoracoscopic lung biopsy, although suture closure of the lung is likely necessary. Conventional open lung using a limited incision biopsy remains an appropriate alternative in selected patients such as those with focal, central disease or prior thoracotomies.

**LUNG TUMORS**

**Primary Lung Tumors**

Primary lung tumors are exceedingly rare in children. In a comprehensive review of the world literature in 1983, Hartman and Shocat reported 230 primary tumors, of which approximately two-thirds were malignant.15 Distinctions between malignant and benign forms of pediatric primary lung tumors are often subtle.

**Malignant Tumors**

**Bronchial adenoma:** The most common primary lung tumors in children are a heterogeneous group of low-grade adenocarcinomas termed bronchial adenomas. They constitute about 35% of all primary pulmonary neoplasms in children. Patterns of histology in these tumors have given rise to descriptive names: carcinoid, mucopidermoid carcinoma, and adenoid cystic carcinoma (cylindroma). The term adenoma is misleading because all are neoplasms with the potential for malignant spread, although the incidence of metastases is low, ranging from 5-10%.15

Bronchial carcinoid tumors are the most common, representing approximately 85% in most reported series. These lesions, like other carcinoid tumors, are derived from neural crest stem cells and retain their potential for serotonin and peptide hormone synthesis. Plasma serotonin and urine 5-hydroxyindoleacetic acid levels may be elevated in these patients, and they are therefore potentially useful tumor markers.44 Bronchial carcinoids most often arise in a primary or secondary bronchus and the most frequent presenting signs are hemoptysis, cough, and partial bronchial obstruction with recurrent or persistent pneumonia. The duration of symptoms ranges from 1 month to 12 years, with a mean of just over 1 year. These tumors generally involve major bronchi; which explains the fact that the symptoms and physical signs are those of bronchial obstruction. Because of the critical anatomic location, these tumors generally become symptomatic while relatively small, although it appears that the rate of growth is slow. The right lung is affected approximately twice as often as the left.

Bronchial carcinoid tumors generally occur in one of two patterns: (1) as endobronchial polypoid masses that produce segmental bronchial obstruction followed by atelectasis and infection and (2) as “iceberg” lesions with predominantly extrabronchial growth—the small intrabronchial extent of which gives rise to mucosal ulceration and hemoptysis. The carcinoid syndrome has been reported in a single child with an endobronchial carcinoid tumor.

Radiographic imaging is most often nonspecific and nondiagnostic. Bronchoscopic findings are, however, unique and compelling. The lesion is best described as a pink, friable mulberry. Biopsy is not
recommended for several reasons: (1) hemorrhage can be substantial or even life-threatening, (2) the histopathology is difficult to evaluate with a small specimen and frozen section techniques, (3) the gross appearance is predictable from a diagnostic point of view and (4) obstructing bronchial adenomas require resection, the nature of which is determined by anatomic rather than pathologic features.

Careful endoscopic mapping under direct vision is essential to planning operative management. Endoscopy and video systems have evolved rapidly and offer substantial improvement in this aspect of evaluation. Although endoscopic resection has been reported, it is not recommended because of the risks of hemorrhage, bronchial stenosis, local recurrence, and the inability to examine regional lymph nodes.

In older children and those with small tumors without lymphatic spread, successful segmental bronchial resection has been done. Most patients with endobronchial carcinoid tumors, however, require lobectomy or pneumonectomy, depending on the precise location of the tumor. Regional lymph node sampling, particularly of clinically suspicious nodes, is also appropriate.

Endobronchial carcinoid tumors are radiosensitive, and this may be an appropriate therapy for non-resectable disease, although there are no guidelines due to lack of sufficient data. The 10-year survival rate in children after surgical resection for endobronchial carcinoid tumors is about 90%.15

Endobronchial mucoepidermoid carcinomas represent 10-20% of bronchial adenomas. These are typically pedunculated endobronchial tumors that arise most often from the trachea or mainstem bronchi. The presentation and approach for diagnosis and surgical management is essentially identical to that described for endobronchial carcinoid tumors. The principal difference relates to the histopathology; these lesions have both mucus-secreting glandular and epidermoid cells. The incidence of malignancy reported for children with this tumor appears to be extremely low. Only one child is reported to have had malignant spread of this lesion, and in this case the tumor was described to have a predominance of epidermoid cellular elements. The postoperative survival rate approaches 100%.

Adenoid cystic carcinomas (cylindromas) are the least common form of bronchial adenoma in childhood. These are most commonly found in the trachea and are made up of cuboidal or flattened epithelial cells arranged in two layers. The important distinction for this tumor is the observation that it is an indolent malignancy with a propensity for submucosal spread and late recurrence. Clinical presentation, physical signs, and diagnostic approach are similar to those in patients with carcinoids. Intraoperative frozen-section analysis is, therefore, recommended when resecting a bronchial adenoma.

Bronchogenic carcinoma: Primary bronchogenic carcinoma is extremely rare in children, with only about 50 reported cases. Among these rare tumors, most pediatric cases of bronchogenic carcinoma are adenocarcinomas and undifferentiated carcinomas and only 10% are squamous cell carcinomas. These tumors may occur in children of any age, but they are most commonly found during adolescence. The significant risk factor in adults is cigarette smoking; in children papillomatosis is a common antecedent. Most patients are symptomatic with cough, recurrent pneumonia, pleural effusion, or hemoptysis. The disease is typically widespread at diagnosis with mediastinal and distant metastases. Findings suggestive of metastatic disease, such as anemia, weight loss, and bone pain are also common. Although rare, persistent case reports suggest an important etiologic association with pre-existing cystic bronchopulmonary foregut malformations. The experience with bronchogenic carcinoma in children is dismal. The average survival from the time of diagnosis is 7 months.

Childhood bronchogenic carcinoma should be managed according to reasonable adult guidelines, with resection of operable tumors. The limited experience with these tumors precludes meaningful statistical analysis of adjuvant therapy; and treatment is generally individualized. For children with localized disease who undergo complete resection, a small Japanese experience suggests that about one-half have long-term survival.45

Pleuropulmonary blastoma: Pleuropulmonary blastoma (PPB) is an embryonal tumor of the lung that appears to arise during organ development, much like Wilm’s tumor in the kidney, hepatoblastoma in the liver, and rhabdomyosarcoma and neuroblastoma in soft tissue and sympathetic nervous system sites, respectively.
PPB primarily affects young children; 95% are less than 6 years of age at diagnosis.

Histologically, pleuropulmonary blastoma of childhood differs from adult pulmonary blastoma because of its primitive and embryonic stroma, absence of carcinomatous component, and potential for sarcomatous differentiation. Dehner and colleagues have defined three subtypes of pleuropulmonary blastoma of childhood: type I is exclusively cystic, type II exhibits both cystic and solid components, and type III is a solid tumor without cystic spaces lined by epithelium. Patients with type I tumors appear to have a better probability of survival; however, the evidence for clinical and pathological progression from type I to type III is strong. The embryonic origin of this tumor is uncertain but the tumor resembles fetal lung and is thought to be an expression of the somatopleural mesoderm or the thoracic splanchnopleura. Chromosomal abnormalities, including trisomy of chromosome 8 and abnormalities of chromosome 2q, have been reported and confirmed by comparative genomic hybridization studies. The profile of this tumor bears similarities to that of embryonal rhabdomyosarcoma. Mutations of \textit{p53} and \textit{MYCN} amplification have also been reported in a few cases. Patients with alterations of \textit{p53} appear to have a poor prognosis, raising the possibility that inactivation of \textit{p53} could be a valuable predictor of outcome in these patients.

Approximately 25% of patients registered in the pleuropulmonary blastoma registry have a constitutional or familial association with other neoplasias or dysplasias. Lung cysts are identified radiographically in one-third of affected patients. Cystic nephroma has also been reported in association with this tumor. Neoplastic conditions reported in family members of patients with pleuropulmonary blastoma include; germ cell and brain tumors, lymphoma, leukemia, sarcomas, histiocytosis, Wilms’ tumor, thyroid tumors, neuroblastoma, and Sertoli-Leydig tumor. These observations suggest that pleuropulmonary blastoma is a strong marker for familial disease.

The median age at presentation of pleuropulmonary blastoma is 34 months, but those with type I tumors present at a younger age (10 months). Presenting symptoms are nonspecific and commonly include respiratory distress, fever, chest or abdominal pain, pulmonary infections, pneumothorax, cough, anorexia, and malaise.

The lesion generally can be recognized on plain chest radiograph. These are generally peripheral lesions and lobar resection is the most common surgical procedure. Chemotherapy with sarcoma-targeted agents (vincristine, dactinomycin, and cyclophosphamide) has also been used. The overall prognosis is poor with less than 50% survival at two years. Patients with mediastinal or pleural involvement have a significantly poorer clinical outcome.

Other malignant neoplasms: The inventory of other rare primary lung malignancies in children is categorized. Neurofibrosarcoma, fibrosarcoma, mesothelioma, endothelial sarcoma and others have case reports. The general approach is the same as for the lesions previously discussed; resection of all gross disease and maximal preservation of normal lung tissue. Radiographic imaging is best obtained for all primary lung neoplasms with either CT or MR imaging. Lobectomy or pneumonectomy are appropriate for these lesions if the disease is localized at the time of diagnosis. The limited experience for these rare lesions precludes meaningful statistical analysis of adjuvant therapy, and treatment is generally individualized.

Benign Lung Tumors

Inflammatory pseudotumor: Inflammatory pseudotumor is a rare lesion that presents as a solitary lung nodule in children. As the term suggests, it is not malignant, nor is it truly neoplastic. The lesion is comprised of proliferating spindle cells (fibroblasts and myoblasts) with mitotic figures and inflammatory cells, particularly plasma cells. The histopathology also shows lymphocytes, fat-laden macrophages, as well as other lung parenchymal cell types. The spectrum of histopathology for this lesion has given rise to an abundance of descriptive names; plasma cell granuloma, histiocytoma, xanthofibroma, and lung adenoma. The pathogenesis of this unique local inflammatory process is unknown.

Inflammatory pseudotumor is the most common benign lung mass in infants and children. Seventy-five percent of the children are older than 5 years of age, as this process takes time to develop. Only a small percentage, (20%) have a history of previous pulmonary infection and the lesion may be an incidental finding on chest radiograph. Other presentations include cough, fever, chest pain, hemoptysis, and airway obstruction. Pneumonia is
diagnosed in about 10% of these children. Large inflammatory pseudotumors have resulted in esophageal obstruction and death from extrinsic compression of mediastinal structures.

The imaging approach is not different than for other mass lesions in the thorax. Plain chest radiographs are followed by either CT or MR imaging. The lesions appear as solid parenchymal nodules or larger masses and may be indistinguishable from neoplasms. Calcification is common and may be dramatic.

The natural history of these lesions is generally one of either slow growth or spontaneous resolution. Metastatic spread has not been observed. Although a benign lesion, definitive diagnosis is often not possible on intraoperative biopsy. Formal lobectomy or local resection is appropriate, depending on the degree of diagnostic uncertainty and the anatomic relations involved. In large lesions where resection would require a morbid procedure such as pneumonectomy, it would be appropriate to await permanent pathology before proceeding with resection.

Hamartomas: Hamartomatous lung nodules are rare in children. They may occur in either endobronchial or parenchymal sites and are characterized by the presence of cartilage, respiratory epithelium, and collagen. Because peripheral lesions are more common, hamartomas are frequently asymptomatic. Predictably, endobronchial lesions are likely to cause clinical symptoms at a relatively small size. Parenchymal lesions may be large and can produce symptoms of respiratory distress or mediastinal compression. Death in the neonatal period has been reported. Surgical indication is the need to establish a diagnosis and the majority can be managed with wedge resection. The results after local resection are expectedly excellent for these benign lesions.

Metastatic Lung Tumors

The approach to children with metastatic lung tumors is considerably different than for adults with similar lesions because patient survival is much better in children. The most common causes of metastatic lung tumors in children are Wilms’ tumor and osteogenic sarcoma. Approximately 50% of children with Wilms’ tumor will demonstrate pulmonary metastases. The initial approach in the child who presents with Wilms’ tumor with pulmonary metastases involves standard surgical management by radical nephrectomy with regional lymphadenectomy and abdominal lymph node sampling and systemic chemotherapy. Pulmonary metastatic lesions which persist after initial chemotherapy or which develop on therapy are resected. These patients are also treated with bilateral whole lung irradiation. About one-half of patients with pulmonary metastases from Wilms’ tumor can be saved with this approach.

Adjuvant chemotherapy in the management of patients with osteogenic sarcoma has reduced the incidence of metastatic lung lesions from about 80-30% during the past two decades. Protocols in the United States include an aggressive surgical approach to pulmonary metastases after adequate chemotherapy and appropriate resection of the primary tumor. With a combination of chemotherapy and sometimes multiple (sequential) or bilateral pulmonary resections, approximately 40% of patients with metastatic lung disease from osteogenic sarcoma can be saved. Lung metastases in osteogenic sarcoma are typically small, subpleural nodules that may be numerous. The operative surgical principal is to carefully evaluate the lung at the time of resection and resect all nodules with limited wedge resections and maximize preservation of lung parenchyma. It is common that operative exploration and bimanual palpation reveal lesions not detected on preoperative imaging studies. This is a compelling argument for open thoracotomy rather than thoracoscopy in these patients because the open approach allows bimanual palpation of the lung for detection of small metastatic nodules.

A host of other metastatic lung tumors have been treated surgically in children. The general principles are that the lesions must be stable, the primary disease controlled, the metastatic disease isolated to the lungs, and an aggressive approach supported by oncologists, surgeons, and the patient and family. Generally, these patients first require adjuvant chemotherapy and receive irradiation for radiosensitive tumors.

CHAPTER 40

Bronchiectasis and Lung Abscess

Shilpa Sharma, DK Gupta

BRONCHIECTASIS

The incidence of childhood bronchiectasis has declined in the recent past with the widespread use of antibiotics, improved general awareness, better hygiene, better nutrition and childhood immunization against the diseases like pertusis, influenza, pneumococci and measles. Yet, it does remain as an indication for lobectomy in children, especially in the developing world.¹

DEFINITION

Bronchiectasis is defined as an irreversible focal bronchial dilation, usually accompanied by chronic infection. The bronchial tubes become enlarged and distended forming pockets harboring infection. The damaged bronchial walls impair the complex mechanism of the cilia lining the bronchial tubes, resulting in accumulation of dust, mucus and bacteria.

ETIOLOGY AND PATHOGENESIS

Bronchiectasis may occur in both, the congenital and the acquired forms.

In congenital bronchiectasis, the periphery of the lung fails to develop, resulting in cystic dilation of developed bronchi.

Acquired bronchiectasis develops later in life and may be due to:
1. Direct bronchial wall destruction as a result of infection, noxious chemicals, immunologic reactions, or vascular abnormalities
2. Mechanical alterations due to atelectasis with increased traction on airways, leading to bronchial dilatation and secondary infection.

Predisposing Factors

1. Congenital anomalies — Cystic fibrosis, immune deficiencies, α₁-antitrypsin deficiency, congenital abnormalities of cartilage and connective tissue, e.g. Mounier-Kuhn syndrome, Williams-Campbell syndrome, yellow nail syndrome.
2. Inherited primary ciliary abnormality.
3. Severe pneumonia — following measles, pertussis, adenovirus by weakening bronchial walls and causing pockets of infection to form.
5. Bronchial obstruction — Intrinsic or extrinsic - foreign body, enlarged lymph nodes, mucus plug or lung tumor. In childhood this most commonly results from choking on food. When this happens the wall of the tube is injured and air is prevented from passing out beyond the obstruction. The bronchial tube, distal to the obstruction balloons out, to form a pocket for harboring infection and pus.
6. Chronic fibrosing lung diseases—aspiration pneumonia.
7. Immunologic deficiencies—AIDS.
8. Kartagener’s syndrome. In 1933, Manes Kartagener, a Zurich pulmonary physician, reported four patients with the triad of sinusitis, bronchiectasis, and situs inversus.²

Bronchiectasis may be focal, limited to a single segment/lobe, or widespread affecting multiple lobes in one or both lungs. It most often affects the lower lobes, although the right middle lobe and lingular portion of the left upper lobe are often affected.

mebooksfree.com
Bronchial wall damage may be mediated by bacterial endotoxins and proteases, superoxide radicals and antigen-antibody complexes. On histological examination, the bronchial walls show extensive destruction, chronic inflammation, increased mucus, and loss of cilia with tissue reorganization and fibrosis.

Extensive anastomoses develop between the bronchial and pulmonary vessels with vascular engorgement in cases presenting late. The resultant increased blood flow, right-to-left shunts, and hypoxemia lead to pulmonary hypertension and cor pulmonale in the late phase of the disease.

CLINICAL FEATURES

Bronchiectasis can develop at any age but most often begins in early childhood, though the symptoms may appear much later. The cases presenting late usually have a long history of chronic cough with large quantities of green or yellow sputum that may be foul smelling. Typically, the bout of cough occurs in the early morning when the patient wakes up. The symptoms may occur after an attack of respiratory infection but tend to worsen gradually over the months and the years. Occasionally, although chronic infection exists, the patient may be asymptomatic.

Hemoptysis may result from erosion of the capillaries near the surface of the thinned walls of the bronchial tubes that are prone to rupture easily or from the anastomoses between the bronchial and pulmonary arterial systems. The bleeding is generally minor and self-limiting and may be the first and the only complaint. Occasionally the patient may present with massive hemoptysis as a major emergency. Coughing up blood indicates an added infection.

Recurrent fever or pleuritic pain, wheezing, shortness of breath and cor pulmonale may occur in advanced cases with associated chronic bronchitis and emphysema.

In Williams-Campbell syndrome, there is total or partial absence of cartilage beyond the main segmental bronchi. This produces wheezing and dyspnea early in infancy and imaging modalities may show inspiratory ballooning and expiratory collapse of the affected bronchi.

In yellow nail syndrome, there is congenital hypoplasia of the lymphatic system associated with primary lymphedema, exudative pleural effusion and bronchiectasis. The children presenting late generally have chronic malaise, poor weight gain with decreased appetite.

About 60% cases of foreign body aspiration may present with pneumonia, bronchiectasis and bronchoesophageal fistula. Sterile foreign bodies may remain embedded for months without much respiratory distress symptoms. Skiagram chest may be helpful in the diagnosis of a radiopaque foreign body. CT scan may pick up the radiolucent foreign bodies. However, the undiagnosed organic foreign bodies are troublesome resulting in not only ipsilateral but the risk of contralateral chronic infection also.

The physical findings are usually nonspecific, but persistent crackles over any part of the lungs suggest bronchiectasis. Signs of airflow obstruction like decreased breath sounds, prolonged expiration, or wheezing may be picked up. Finger clubbing may be identified with extensive disease and persistent chronic infection (Fig. 40.1). In very late cases, chest wall defects may be visible due to underlying unhealthy lung and acquired postural changes to counteract the force of chronic coughing.

INVESTIGATIONS

Routine Blood Tests

The hemoglobin level may be reduced in patients presenting with hemoptysis. The total and differential leucocyte count may help to identify the presence of
infection. ESR may be raised in patients chronic underlying disease especially the tuberculosis.

**Skiagram Chest**

It may show increased bronchovascular markings due to peribronchial fibrosis and intrabronchial secretions, crowding from an atelectatic lung, tram lines (parallel lines outlining dilated bronchi due to peribronchial inflammation and fibrosis), areas of honeycombing, or cystic areas with or without fluid levels (Fig. 40.2). Cystic fibrosis may be suspected in areas where it is common, if the X-ray abnormalities are mostly in the apices or upper lobes. Congenital abnormalities of tracheal or bronchial cartilage and connective tissue are usually detected on X-ray.

**CT Scan**

High-resolution CT scans of chest has largely replaced bronchography (Figs 40.3A and B). Characteristic findings are dilated airways, indicated by tram lines, by a signet ring appearance with a luminal diameter more than 1.5 times that of the adjacent vessel in cross-section, bronchial wall thickening, airway obstruction, consolidation or the grapelike clusters (Figs. 40.4A and B). Dilated medium-sized bronchi may extend to the pleura due to destruction of lung parenchyma. Helical CT may be superior for knowing the extent of bronchiectasis and its distribution within a given segment, but it has an additional radiation exposure.

**Bronchoscopy**

Fiberoptic bronchoscopy may be useful to localize endobronchial tumor or foreign body. Abnormal cilia may be found in children with chronic respiratory disease. Ultrastructure and motility examination of cilia obtained on bronchial biopsy or brushing may be done. The nasal ciliary clearance time may be measured. Sputum cultures, bronchial washings, fungal serologic studies and tissue biopsy may be indicated.
Rationale and timely use of appropriate antibiotics in respiratory infections has a great role in prevention of the damage that leads to bronchiectasis.

Identification of congenital and hereditary conditions that predispose to aspiration and bronchiectasis, immunoglobulin replacement in deficiency states, the early detection and removal of foreign bodies and the treatment of recurrent sinusitis, aid in prevention of bronchiectasis.

The treatment revolves around prevention of complications of pneumonia.

Medical treatment of infection includes antibiotics, bronchodilators, and postural drainage.

Hemoptysis may subside after appropriate antibiotic treatment. Blood transfusion may be required if there is massive loss of blood. Oxygen may be required for chronic hypoxemia, pulmonary hypertension, secondary polycythemia, respiratory failure or cor pulmonale.

Postural drainage, clapping, and vibration performed regularly may facilitate sputum clearance in some patients. Postural drainage is important to drain the affected areas of the lungs by gravity. Early treatment of superimposed infection causing fever, chest pain and a change in sputum quality and quantity can prevent complications. Bronchiectasis limited to a very small isolated part of the lung causing recurrent pneumonia can be removed surgically (Fig. 40.5). Surgical resection is rarely necessary but should be considered when conservative management yields to recurrent pneumonia, disabling bronchial infections and frequent hemoptysis. Surgical treatment of bronchiectasis is more effective in patients with localized disease and is usually not advisable if it is a widespread disease. The principles of surgical resection have been discussed in a separate chapter. Anatomic localization of the disease should be mapped by radiologic and scintigraphic investigations. The operative mortality rate varies from 2-6% and the morbidity rate varies from 10-20%. Complete resection results in significantly better clinical outcome.

Figs 40.4A and B: CECT with evidence of bronchial wall thickening, consolidation and grapelike clusters suggestive of bronchiectasis. Collapse of the ipsilateral lung with compensatory emphysema of the contralateral lung is also noted.

Fig. 40.5: Operative photograph showing the bronchiectatic lobe.
than incomplete resection. Pneumonectomy is well tolerated in children without an increase in morbidity and mortality and thus preferred instead of leaving residual disease when bronchiectasis is unilateral.6

Mediastinal shift and lung overinflation may occur after pneumonectomy. Pulmonary resection does not alter respiratory function since the resected segments do not contribute much to ventilation.1

In case of massive pulmonary hemorrhage, an emergency resection or embolization of the bleeding vessel may be lifesaving. Kartagener’s syndrome is an autosomal recessive disorder characterized by the clinical triad of bronchiectasis, sinusitis and dextrocardia (situs inversus). Lobectomy may be required for symptomatic cases (Fig. 40.6).7 Lung transplantation can be performed in patients with advanced cystic fibrosis and bronchiectasis.

**Case Report—Congenital Bronchiectasis**

A ten-year-old female presented with cough since 3-4 yrs of age. There was no fever, hemoptysis, respiratory distress or pneumonia. On examination, the air entry was decreased in the left lower region with presence of crepitations. The CT scan chest depicted an atelectatic left lower lobe with multiple fibrocystic lesions replacing lung parenchyma, traction bronchiectasis of the left upper and lower lobe segmental bronchi. There was mediastinal shift to the left with the compensatory hyperinflation of the right lung (see Figs 40.3A and B).

On left sided thoracotomy, the lower lobe and lingula and more than half of the upper lobe, were found solid in consistency. The lower lobe bronchus was filled with purulent material. Left lower lobectomy was done. The cut section showed features of congenital bronchiectasis with absence of bronchial cartilage and abnormal parenchyma within the area of involvement that was confirmed histologically (Figs 40.7A and B).

**CHRONIC LUNG ABSCESS**

Pediatric lung abscess usually follows an episode of aspiration or bacterial pneumonia. Associated

---

**Figs 40.7A and B:** A. The cut section of lobectomy specimen showing dilated bronchial tree, B. Close up view showing the thickened bronchial wall, with non-aerated lung at periphery

**Fig. 40.6:** Excised specimen following lobectomy of a bronchiectatic lobe
conditions include leukemia, congenital immune deficiency, endocarditis, cerebral palsy, and prematurity. Most children have polymicrobial infections, usually containing both aerobic and anaerobic bacteria. The success of medical treatment has been found to be age related; with children below 7 years, requiring chest tube drainage or resection of the involved lobe for cure and adolescents recovering on antibiotics and chest physiotherapy. The chest tube drainage may be performed for solitary peripheral bacterial abscesses. Wedge resection is required for multiple, central, or fungal abscesses. Lung abscesses are now uncommon but are seen in immunocompromised children who are vulnerable to fatal infections. Medical failures can be identified within the first week of treatment. Early and aggressive surgical treatment is indicated in such children, and may be lifesaving.

When medical therapy for lung abscess fails, tube drainage may be considered. Chronic lung abscesses are usually associated with severe sepsis or complicated by a bronchopleural fistula that may not respond to medical treatment and the chest tube thoracostomy. Lobectomy should be considered in patients who have major life-threatening bleeding or massive pulmonary necrosis. The required surgical procedures include decortication, lung debridement, bronchial closure, lobectomy or segmentectomy. Few cases may have persistent air leakage due to poor healing amidst infection requiring treatment by repeated bronchial closure. Adequate treatment with follow up is essential as secondary lung abscesses due to inadequate response to medical therapy may require lobectomy.

Hydatidosis of lung may rarely be diagnosed in children only after complications like empyema, lung abscess and bronchiectasis ensue. A lung abscess may cause bronchiectasis of the adjoining lung tissue due to compression effect (Fig. 40.8). The diagnosis may be missed on initial appearance due to overshadowing by the complications. However, a high degree of suspicion may help in timely diagnosis and needful precautions as the disease needs special handling due to the antigenicity of the fluid. Chest radiographs and thoraco-abdominal ultrasound are very useful for the diagnosis of pulmonary hydatidosis. Immunological tests for hydatidosis may supplement the diagnosis. In a series of 232 cases of pulmonary hydatid cyst in children, bronchiectasis was observed in seven cases. CT is useful for diagnosis of atypical or complicated lesions and to detect associated bronchiectasis.

REFERENCES

Thoracic surgery owes its inception to the high incidence of pulmonary tuberculosis and its complications seen in the pre-antibiotic era. However, with the introduction of Rifampicin in the 1960’s, the role of surgery has decreased considerably. In recent years, the emergence of multidrug resistant strains of *M. tuberculosis* coupled with an increase in atypical mycobacterial infections has led to the increase in surgical interventions for pulmonary tuberculosis.

The World Health Organization (WHO) declared tuberculosis (TB) to be a global public health emergency in 1993. Today, 19-43.5% of the world’s population is infected with *Mycobacterium tuberculosis* with more than 8 million new cases of TB occurring each year. Tuberculosis is one of the major causes of morbidity in developing countries. According to WHO, developing countries including India, China, Pakistan, Philippines, Thailand, Indonesia, Bangladesh, and the Democratic Republic of Congo account for nearly 75% of all cases of TB, accounting for about 0.5 million deaths every year by this disease, worldwide. The incidence and severity of pulmonary infections due to tuberculosis are expected to increase with the increasing incidence of HIV infection. The highest TB incidence and HIV infection prevalence are recorded in sub-Saharan Africa, and, as a consequence, children in this region bear the greatest burden of TB/HIV infections.

WHO’s new Global Plan to Stop TB 2006-2015 advises countries with a high burden of tuberculosis (TB) to expand case-finding in the private sector as well as services to the patients with HIV and multidrug-resistant TB (MDR-TB). Tuberculosis control program is a balance between accurate diagnosis of the disease and effective treatment of cases to eliminate the disease in the community. Thus, undiagnosed cases resulting from inadequate diagnostic facilities contribute an impediment to TB control efforts in the community. Hence, there is an urgent need to have more accurate, affordable tools that would be available for use at all levels of health care to achieve total eradication of TB in the community.

The need of applying science to the diseases of poverty has been felt and considered essential also. Collaboration between national TB and HIV programs and some degree of integration of services at the local level have been advocated by World Health Organization and other International bodies. There has been a decrease in mortality in cases with pulmonary tuberculosis without HIV infection, attributed to improved health care and prompt initiation of therapy.

Diagnosis of tuberculosis in children is difficult as children are less likely to have obvious symptoms of tuberculosis. Tuberculosis in infants and children younger than four years of age is much more likely to spread throughout the body through the bloodstream. Thus, children are at much greater risk of developing miliary tuberculosis. Hence, the need for the prompt diagnosis and treatment of tuberculosis.

**CHILDREN AT RISK**

1. Children living in a household with an adult who has active tuberculosis
2. Children infected with HIV or with an immuno-compromised state following chemotherapy or prolonged steroid use.
3. Children living in high endemic regions
4. Poor socioeconomic status. It is common in children residing in rural areas.
5. Undernourished children.
6. Children living in small enclosed areas and in areas with poor ventilation.
7. Infections like measles, varicella, and pertussis, may activate quiescent TB.
8. Hereditary factors. Children with certain human leukocyte antigen (HLA) types have a predisposition to TB. Presence of a Bcg gene has been implicated in sensitivity to acquisition of TB.

**Tubercular Bacilli**

*Mycobacterium tuberculosis* is the most common cause of TB. Other rare causes are *Mycobacterium bovis* (bovine source) and *Mycobacterium avium* (from birds). *M. bovis* infection has been traced to the use of cheese made from unpasteurized milk.

*M. tuberculosis* is an aerobic, non-spore-forming, non-motile slow-growing bacillus with a curved and beaded rod-shaped morphology. It can survive under adverse environmental conditions. The acid-fast characteristic of the mycobacteria is its unique feature. Humans are the only known reservoirs for *M. tuberculosis*.

**Pathophysiology**

The route of infection is inhalation of the aerosolized bacteria. The small size of the droplets allows them to remain suspended in the air for a prolonged period of time. The organism is slow growing and tolerates the intracellular environment, where it may remain metabolically inert for years before reactivation and causing disease. The main determinant of the pathogenicity of TB is its ability to escape host defence mechanisms, including macrophages and delayed hypersensitivity responses.

Although a single organism may cause disease, 5-200 inhaled bacilli are usually necessary for infection. Primary infection of the respiratory tract, thus occurs as a result of inhalation of these aerosols.

After inhalation, the bacilli are deposited, usually in the midlung zone, into the subpleural distal respiratory bronchioles or the alveoli. The alveolar macrophages then phagocytose the inhaled bacilli but are unable to kill them, thus the bacilli continue to multiply unimpeded. The infected macrophages are then transported to the regional lymph nodes. The initial pulmonary site of infection and its adjacent lymph nodes is known as the primary complex or Ghon focus.

Progression of the primary complex may lead to enlargement of hilar and mediastinal nodes with resultant bronchial collapse. The primary focus may progress when it cavitates and the organisms spread through contiguous bronchi.

Lymphohematogenous dissemination of the mycobacteria may occur to other lymph nodes and distant regions in the body like kidney, epiphyses of long bones, vertebral bodies, meninges and occasionally, to the apical posterior areas of the lungs. A widespread miliary TB may occur when caseous material reaches the bloodstream from a primary focus or a caseating metastatic focus breaks in the wall of a pulmonary vein (Weigert focus). Bacilli may remain dormant in the apical posterior areas of the lung for several months or years, with progression of disease later on.

A cell-mediated immune response terminates the unimpeded growth of the *M. tuberculosis* 2-3 weeks after initial infection. The CD4 helper T cells activate the macrophages to kill the intracellular bacteria with resultant epithelioid granuloma formation. The CD8 suppressor T cells lyse the macrophages infected with the mycobacteria, resulting in the formation of caseating granulomas. Mycobacteria cannot continue to grow in the acidic extracellular environment, thus most infections are controlled. The only evidence of infection is a positive tuberculin skin (Mantoux) test result.

**Clinical Features**

Children with asymptomatic infection may be identified on a routine examination, or they may be identified subsequent to tuberculosis diagnosis in a close contact.

**Primary Pulmonary Tuberculosis**

Tuberculosis may present with generalized symptoms like fever of unknown origin, failure to thrive, night sweats, anorexia, significant weight loss, nonproductive cough, or unexplained lymphadenopathy.

Pulmonary TB may manifest as endobronchial TB with focal lymphadenopathy, progressive pulmonary disease, pleural involvement, and reactivated pulmonary disease.

Endobronchial TB with enlargement of lymph nodes is the most common form of pulmonary TB.
Symptoms result from pressure on various structures by the enlarged lymph nodes. Persistent cough may be indicative of bronchial obstruction, while difficulty in swallowing may result from esophageal compression. Vocal cord paralysis may be suggested by hoarseness or difficulty in breathing.

Progression of the pulmonary parenchymal infection leads to enlargement of the caseous area and may lead to pneumonia, atelectasis and air trapping in young children. The child usually appears ill with symptoms of fever, cough, malaise, and weight loss.

Tubercular pleural effusion may present with acute onset of fever, chest pain that increases in intensity on deep inspiration, and shortness of breath. Fever usually persists for 14-21 days.

Reactivation TB usually has a subacute presentation with weight loss, fever, cough, and rarely, the hemoptysis. Reactivation TB typically occurs in older children and adolescents.

Tuberculosis can present in any form and has been reported even in infants presenting as a superior mediastinal mass extending into the right chest. Extrapulmonary TB includes peripheral lymphadenopathy, tubercular meningitis, miliary TB, skeletal TB, and other organ involvement.

Any child with pneumonia, pleural effusion, a cavitary or mass lesion in the lung that does not improve with standard antibacterial therapy should be evaluated for tuberculosis.

**PHYSICAL EXAMINATION**

Primary TB is characterized by the absence of any signs on clinical evaluation. Tuberculin hypersensitivity may be associated with erythema nodosum and phlyctenular conjunctivitis. The classic signs of pneumonia include tachypnea, nasal flaring, grunting, dullness to percussion, egophony, decreased breath sounds, and crackles. Mediastinal shift may be present with massive pleural effusion. There may be post-tussive crackles.

**INVESTIGATIONS**

Definitive diagnosis of TB depends upon isolation of *M. tuberculosis* from secretions or biopsy specimens. Newer diagnostic modalities have been developed including nucleic acid detection (NAD) and gamma-interferon assays.

**Erythrocyte Sedimentation Rate (ESR)**

This is a non-specific marker for chronic infection. It is however, useful to monitor the progression of the disease while the child is being investigated. It is also useful to follow the course of the disease after the initiation of anti tubercular treatment. In cases where no positive finding is available for documentary evidence, a trial of anti tubercular treatment may be started on the basis of clinical findings amidst a raised ESR. The fall in ESR will then be supportive in favour of a diagnosis of tuberculosis.

It has been reported that there is a rise in serum zinc levels in various age groups of children after antitubercular therapy (mean 61.89 +/- 3.21-65.24 +/- 3.60 microg/dl) and significant fall in serum copper levels in different age groups of children (mean 129.96 +/- 3.18 to 124.91 +/- 3.48 microg/dl). The Cu/Zn ratio also changed significantly from 2.11 +/- 0.12 to 1.92 +/- 0.12.

Specimens for bacteriologic examination—Sputum, gastric lavage, bronchoalveolar lavage, lung tissue and lymph node.

Gastric aspirate may be used in place of sputum in children less than 6 years as they may not be able to cough out sputum. An early morning sample should be obtained for undiluted bronchial secretions accumulated during the night. Initially, the stomach contents should be aspirated, and then a small amount of sterile water injected through the orogastric tube, should also be aspirated. As gastric acidity is poorly tolerated by the tubercle bacilli, neutralization of the specimen should be done immediately with 10% sodium carbonate or 40% anhydrous sodium phosphate. Even with utmost care, the tubercle bacilli can be detected in only 70% of infants and in 30-40% of children with disease. Sputum specimens and bronchoalveolar lavage may be used in older children. Nasopharyngeal secretions and saliva are not acceptable.

**Acid Fast Bacilli (AFB) Staining**

This provides preliminary confirmation of the diagnosis. It also can give a quantitative assessment of the number of bacilli being excreted (e.g. 1+, 2+, 3+).

For a reliable positive result, smears require approximately 10,000 organisms per millilitre.
Therefore, the results may be negative in early stages of the disease or with sparse bacilli. A single organism on a slide is highly suggestive and warrants further investigation. Ziehl-Neelsen staining method is used. However, AFB smear cannot be used to differentiate *M. tuberculosis* from other acid-fast organisms such as other mycobacterial organisms or *Nocardia* species.

**Mycobacterium Culture**

This is the definitive method to detect bacilli and more sensitive than examination of the smear. Approximately 10 AFB per millimetre of a digested concentrated specimen are sufficient to detect the organisms by culture. A culture also allows identification of specific species and testing for drug sensitivity. Due to the emergence of MDR organisms, determination of the drug sensitivity panel of an isolate is important so that appropriate treatment can be ensured.

However, since *M. tuberculosis* is a slow-growing organism, a period of 6-8 weeks is required for colonies to appear on conventional culture media. Conventional solid media include the Löwenstein-Jensen medium (an egg-based medium) and the Middlebrook 7H10 and the 7H11 media (which are agar-based media). Liquid media (e.g. Dubos oleic-albumin media) also are available, and they require incubation in 5-10% carbon dioxide for 3-8 weeks.

Modern automated radiometric culture methods (e.g. BACTEC) have enabled rapid growth of mycobacteria. The methodology employs a liquid Middlebrook 7H12 medium containing radiometric palmitic acid labelled with radioactive carbon-14 ($^{14}\text{C}$). Several antimicrobial agents are added to this medium to prevent the growth of nonmycobacterial contaminants. Production of $^{14}\text{CO}_2$ by the metabolizing organisms provides a growth index for the mycobacteria. Growth is generally detected within 9-16 days.

Mycobacterial growth indicator tubes (MGITs), with round-bottom tubes with oxygen-sensitive sensors at the bottom indicate microbial growth and provide a quantitative index of *M. tuberculosis* growth.

**Nucleic Acid Techniques**

These include nucleic acid probes and polymerase chain reaction (PCR). Although their sensitivity and specificity in smear-positive cases exceed 95%, the sensitivity of smear-negative cases varies from 40-70%.

Nucleic acid probes help advance identification of the *M* tuberculosis complex. Sensitivity and specificity approach 100% when at least 100,000 organisms are present.

Polymerase chain reaction (PCR). Nucleic acid amplification tests allow direct identification of *M. tuberculosis* in clinical specimens, unlike the nucleic acid probes, which require substantial time for bacterial accumulation in broth culture.

The US Food and Drug Administration has approved 2 tests, the amplified *M. tuberculosis* direct test that targets RNA and the AMPLICOR *M. tuberculosis* test that targets the DNA. The most commonly used target sequence for the detection of *M. tuberculosis* has been the insertion sequence IS6110. The amplified M. tuberculosis direct test is an isothermal transcription-mediated amplification.

**Enzyme-linked Immunoassay (ELISA) Test**

A new test, Quantiferon (QFT-g), has recently been approved (May, 2005) by the US Food and Drug Administration (FDA). The test basically detects the presence of interferon gamma release protein (IFN-g) from the blood of sensitized patients, when the blood is incubated with the early secretory antigenic target-6 (ESAT6) and culture filtrate protein 10 (CFP10) peptides. The test is as sensitive as, and more specific than, the tuberculin skin test and has been recommended as a screening tool for diagnosing the disease as well as infection.

No available serodiagnostic test for TB has adequate sensitivity and specificity for routine use in diagnosing TB in children.

**Mantoux Test**

Although the sensitivity and the specificity are less than 100%, it is still widely used.

The dosage of 0.1 mL or 5 TU purified protein derivative (PPD) is injected intradermally into the volar aspect of the forearm using a 27-gauge needle. A detergent called Tween 80 to prevent loss of efficacy on contact and adsorption by glass stabilizes the PPD. A wheal should be raised and should measure approximately 6-10 mm in diameter. The test is read 48-72 hours after administration. The amount of
induration and not erythema is measured transverse to the long axis of the forearm.

The test is interpreted on the basis of rule of 5, 10, and 15 mm.

Induration of 5 mm or more is considered positive in i. children having close contact with known or suspected contagious cases of the disease, ii. children with immunosuppressive conditions (e.g. HIV).

Children who have an abnormal CXR finding consistent with active TB, previously active TB, or clinical evidence of the disease.

Induration of 10 mm or more is considered positive in; children who are at a higher risk of dissemination of tuberculous disease, including those younger than 5 years or those who are immunosuppressed because of conditions such as lymphoma, Hodgkin disease, diabetes mellitus, and malnutrition; children with increased exposure to the disease.

Induration of 15 mm or more is considered positive in children aged 5 years or older without any risk factors for the disease.

False-positive reactions often are attributed to asymptomatic infection by environmental nontuberculous mycobacteria (due to cross-reactivity). The Mantoux test may be positive in children who have immigrated or been adopted from areas where tuberculosis is rampant. This does not mean that they are infected. It only indicates that they have been exposed to the bacilli. About 90-95% of the population in endemic areas is supposed to be MT positive.

False-negative results may be due to vaccination with live-attenuated virus, anergy, immunosuppression, immune deficiency, malnutrition, improper administration, improper storage, and contamination.

Not all children exposed to the bacilli become infected, and it may take 3 months for the Mantoux test to become positive. Unfortunately, children younger than 5 years may develop disseminated TB in the form of miliary disease or tubercular meningitis before the Mantoux test result becomes positive. Thus, a very high index of suspicion is required when a young patient has a history of contact.

Children may have asymptomatic infection with a positive Mantoux test without any clinical or radiographic manifestations.

**Imaging Studies**

Chest radiograph is the most important diagnostic tool for evaluating pulmonary TB (Fig. 41.1 and 41.2).

Computed tomographic scan and magnetic resonance imaging. These are not routinely indicated when CXR findings are unremarkable. However, in the presence of pulmonary TB, these imaging studies can help demonstrate the hilar lymphadenopathy,

![Fig. 41.1: Skiagram chest PA view with multiple heterogenous opacities suggestive of Kochs](image1)

![Fig. 41.2: Skiagram chest PA view with mass left upper lobe, that was excised. The histopathology was suggestive of tuberculosis](image2)
endobronchial TB, pericardial invasion, and early cavitations or bronchiectasis (Figs 41.3A-D to 41.5).4,5

MEDICAL TREATMENT

Current recommendations for the treatment of pulmonary TB include a 6-month course of INH and rifampin, supplemented during the first 2 months with pyrazinamide. Ethambutol is not routinely recommended for children less than five years of age as one of its side effects is impaired vision and that is difficult to monitor in younger children. Streptomycin may be added if the infection is massive or drug resistance is suspected.

Drug sensitivity studies may not be required if the risk of drug resistance is not significant. Significant risk factors include residence in areas with greater than 4% primary resistance to INH, history of previous treatment with anti-tubercular drugs and history of exposure to a drug-resistant case. The purpose is to decrease the development of MDR-TB in areas where primary INH resistance is high.

Another treatment option is a 2-month regimen of INH, rifampin, and pyrazinamide daily, followed by 4 months of INH and rifampin twice a week. Effective treatment for the hilar adenopathy (when susceptible organisms) includes a 9-month regimen of INH and

Fig. 41.3A to D: CECT chest with evidence of airspace opacities of the left upper lobe, collapse consolidation of left upper lobe, medial segment right middle lobe and lingual lobe
rifampin daily or a 1-month regimen of INH and rifampin once a day followed by 8 months of INH and rifampin twice a week.

**Directly Observed Therapy (DOT)**

Since non-compliance to these regimens is a common cause of treatment failure, (DOT) is recommended. This involves administration of the medication under supervision by a health care provider or nurse. DOT should be used for all children with tuberculosis. The lack of pediatric dosage forms of most anti-tuberculosis medications necessitates using crushed pills and suspensions. Even when drugs are given under DOT, tolerance of the medications must be monitored closely. Intermittent regimens should be monitored by DOT for the duration of therapy because poor compliance may result in inadequate drug delivery.

**Extrapulmonary TB**

Most cases of extrapulmonary TB, including cervical lymphadenopathy, can be treated with the same regimens used to treat pulmonary TB. Exceptions include bone and joint disease, miliary disease and meningitis. For these, the recommendation is a regimen of 2 months of INH, rifampin, pyrazinamide and streptomycin once a day, followed by 7-10 months of INH and rifampin once a day.

The other recommended regimen is 2 months of 4 drugs; INH, rifampin, pyrazinamide, and streptomycin, followed by 7-10 months of INH and rifampin twice a week.

Capreomycin or kanamycin may be given instead of streptomycin in areas where resistance to streptomycin is common.

**Tuberculosis and HIV**

The use of a regimen that uses rifabutin instead of rifampin has been advised when treating HIV disease and TB simultaneously.

The treatment regimen for TB initially should include at least 3 drugs and should be continued for at least 9 months. INH, rifampin, and pyrazinamide with or without ethambutol or streptomycin should be administered for the first 2 months. Treatment of disseminated disease or drug-resistant TB may require the addition of a fourth drug.

The tuberculin skin test (TST) or the Mantoux test, which is the standard marker of *Mycobacterium tuberculosis* infection in immunocompetent children, has poor sensitivity when used in HIV-infected children. Novel T cell assays may offer higher sensitivity and specificity, but these tests still fail to make the crucial distinction between the latent *M. tuberculosis* infection and the active disease and are limited by cost considerations.

Symptom-based diagnostic approaches are less helpful in HIV-infected children, as TB-related symptoms cannot be differentiated from those caused by other HIV-associated conditions.

HIV-infected children are at increased risk of developing active disease after TB exposure or infection, which justifies the use of isoniazid preventive therapy once active TB has been excluded. HIV-infected children should also receive appropriate supportive care, including co-trimoxazole prophylaxis, and antiretroviral therapy, if indicated. The management of children with TB/HIV infection could thus be vastly improved by better implementation of readily available interventions.

**Multidrug Resistant TB**

Primary resistance is defined as the resistance developing to anti-TB treatment in an individual who has no history of prior treatment. Secondary resistance involves the emergence of resistance during the course of ineffective anti-TB therapy.

Risk factors for the development of primary drug resistance include patient contact with drug-resistant contagious TB, residence in areas with a high prevalence of drug-resistant *M. tuberculosis*, HIV infection, and the use of intravenous drugs. Secondary drug resistance reflects non-compliance to the regimen, inappropriate drug regimens, and/or interference with absorption of the drug.

According to the current guidelines, the child who is at risk or the one who has the disease resistant to INH, at least 2 drugs (to which the isolate is sensitive on culture) should be administered. Another principle is not to add only a single drug to an already failing regimen. The pattern of drug resistance, toxicities of the drugs, and patients’ responses to treatment, all determine the duration and the regimen selected.

The initial treatment regimen for patients with MDR-TB should include 4 drugs, e.g. at least 2
bactericidal drugs (e.g. INH, rifampin), a pyrazinamide, and either the streptomycin or another aminoglycoside (also bactericidal) or high-dose ethambutol (25 mg/kg/d) should be incorporated into the regimen.

Six-month treatment regimens and intermittent therapy are not advocated for patients with strains resistant to INH or rifampin. In isolated INH resistance, the 4-drug, 6-month regimen should be started initially for the treatment of pulmonary TB. INH should be discontinued when resistance is documented. Pyrazinamide should be continued for the entire 6-month course of treatment.

In the 9-month regimen, INH should be discontinued upon the documentation of isolated INH resistance. If ethambutol was included in the initial regimen, continue treatment with rifampin and ethambutol for a minimum of 12 months. If ethambutol was not included, then sensitivity tests are repeated, INH is discontinued and 2 new drugs are added (e.g. ethambutol and pyrazinamide).

Resistance to both INH and rifampin is a complicated issue. The initial drug regimen is continued (with 2 drugs to which the organism is susceptible) until bacteriologic sputum conversion is documented; followed by at least 12 months of 2-drug therapy. The role of new agents such as quinolone derivatives and amikacin in MDR cases remains unclear.

**Fig. 41.4:** CECT chest with evidence of patchy ground glass densities in bilateral lung fields

**Fig. 41.5:** CECT chest with evidence of small (R) paratracheal precarinal, subcarinal and left hilar lymph nodes suggestive of infective etiology

**Antitubercular Drugs**

Antimycobacterial agents against *Mycobacterium* species are used to treat TB, leprosy, and other mycobacterial infections. These are classified as first-line and second-line drugs. First-line agents include rifampin, isoniazid (INH), pyrazinamide, ethambutol, and streptomycin. First-line drugs have less toxicity with greater efficacy than second-line drugs. All first-line agents are bactericidal with the exception of ethambutol.

Second-line agents are capreomycin, ciprofloxacin, cycloserine, ethionamide, kanamycin, ofloxacin, levofloxacin, and para-aminosalicylic acid.

INH and rifampin are effective against bacilli in necrotic foci and intracellular populations of mycobacteria. Streptomycin, aminoglycosides, and capreomycin have poor intracellular penetration. MDR-TB is defined as resistance to at least INH and rifampin. The emergence of drug-resistant strains has necessitated use of second-line agents.

There is a promising pipeline of more than 20 new anti-tuberculosis agents at various stages of development, and several are already entering early clinical trials. Donald PR.

Childhood tuberculosis (TB) comprises a significant part of the TB caseload, particularly in developing communities. It is essential that the pharmacokinetics and toxicity of any new agent should be assessed in a population of children over a range of ages.14
Rifampin: Bactericidal for M. tuberculosis. Penetrates well into all body fluids including CSF. For use in combination with at least one other antituberculous drug. Inhibits RNA synthesis in bacteria by binding to beta subunit of DNA-dependent RNA polymerase, which, in turn, blocks RNA transcription. Dose - 10 mg/kg.

Isoniazid: Commonly referred to as INH. Best combination of effectiveness, low cost, and minor adverse effects. Prophylactic dose of pyridoxine is recommended with it. Dose- 5-10 mg/kg.

Streptomycin: For treatment of susceptible mycobacterial infections. Use in combination with other antituberculous drugs (e.g. INH, ethambutol, rifampin). Dose 0.75 gm - 1 gm/day IM.

Pyrazinamide: Pyrazine analog of nicotinamide that may be bacteriostatic or bactericidal against M tuberculosis, depending on concentration of drug attained at site of infection. Dose -15-30 mg/kg.

Ethambutol: Diffuses into actively growing mycobacterial cells, such as tubercle bacilli. Impairs cell metabolism by inhibiting synthesis of one or more metabolites, which in turn causes cell death. Not given in younger children. In children more than 12 years if no previous antituberculous therapy has been taken, then 15 mg/kg PO, otherwise -25 mg/kg.

Ethionamide: Bacteriostatic against M tuberculosis. Recommended when treatment with first-line drugs (INH, rifampin) has failed. Treats any form of active TB. However, only should be used with other effective antituberculous agents. 15-20 mg/kg/d divided tid/qid; not to exceed 1 gm/d; concomitant administration of pyridoxine recommended.

Para-aminosalicylic acid: Bacteriostatic agent useful against M tuberculosis. Inhibits onset of bacterial resistance to streptomycin and INH. 150 mg/kg/d PO divided tid/qid; not to exceed 12 gm/d.

Kanamycin: Aminoglycoside antibiotic produced by Streptomyces kanamyceticus. May be used as second-line agent in treatment of TB. 15-30 mg/kg/d IM.

Rifabutin: Ansamycin antibiotic derived from rifamycin S. Inhibits DNA-dependent RNA polymerase, preventing chain initiation, in susceptible strains of Escherichia coli and Bacillus subtilis but not in mammalian cells. If GI upset occurs, administer dose bid with food. 10-20 mg/kg/d orally.

Fluoroquinolones have not been approved for use in patients less than 18 years.

Monitoring for Side Effects

Adverse effects of INH (e.g. hepatitis) are rare in children; therefore, routine determination of serum aminotransferase levels is not necessary. Monthly monitoring of hepatic function tests may be done for patients with severe or disseminated TB, miliary TB, concurrent or recent hepatic disease, clinical evidence of hepatotoxic effects and those receiving high daily doses of INH (10 mg/kg/d) in combination with rifampin, pyrazinamide, or both. In the rare event the patient has symptoms of hepatitis, discontinue the regimen and evaluate liver function. If the tests are normal or return to normal, then a decision to restart the medications may be made. Re-introduce the drugs one by one.

FOLLOW UP

A regular follow-up in every 4-8 weeks should be done to ensure compliance and to monitor the adverse effects of and response to the medications administered. The weight of the child should be measured at each visit. The sclera should be examined for any evidence of jaundice.

Follow-up ESR and CXR may be obtained after 2-3 months of therapy to observe the response to treatment in patients with pulmonary TB. However, hilar lymphadenopathy may take several years to resolve. Thus, a normal CXR is not required for termination of therapy.

COMPLICATIONS

1. Miliary tuberculosis
2. Tubercular meningitis
3. Pleural effusion
4. Pneumothorax
5. Complete obstruction of a bronchus - if caseous material extrudes into the lumen
6. Atelectasis
7. Bronchiectasis
8. Stenosis of the airways
9. Bronchoesophageal fistula
10. Endobronchial disease.
ROLE OF SURGERY

It must be emphasized that medical therapy remains the mainstay of treatment in pulmonary tuberculosis and surgical treatment is primarily used to handle complications and hasten recovery.

In children, the primary complex is usually directly or indirectly the primary etiologic factor for surgical intervention. The indications for surgical intervention are limited in children and the challenge lies in determining the timing and nature of intervention. Table 41.1 lists the indication for surgery in pediatric pulmonary tuberculosis.15-18

Pre-operative Management

Tuberculosis is cured by effective antitubercular therapy and all surgical candidates must have preferably completed at least 3 months of appropriate antitubercular treatment before any surgical intervention. The probable exception to this principle are children with acute airway obstruction, drug resistant organisms, children with evidence of progressive disease while on treatment and other complications like massive hemoptysis and bronchopleural fistula. The preoperative assessment includes a pulmonary function test, room air ABCJ analysis and nutritional assessment. Total parenteral nutrition or Ryle’s tube feeding may be initiated to counter the chronic debilitating effects of tuberculosis. The serum albumin level is maintained above 3 gm/dl and anaemia is treated prior to surgery. Rigorous chest physiotherapy, incentive spirometry and deep breathing exercises are instituted prior to surgery. Patient counseling is important and the child is motivated to adopt the above measures with a view to continue in the postoperative period. These measures are absolutely vital to decrease morbidity and ensure success after surgery.

Endobronchial Tuberculosis

Primary tuberculosis lymphadenopathy of the subcarinal and paratracheal nodes can result in airway obstruction and secondary damage due to atelectasis, obstructive emphysema and pulmonary infection. A "node compression syndrome" has been described in infants and children.19 The narrow, compliant pediatric airway may be compressed between the subcarinal and paratracheal lymph node groups. The lymph nodes may erode into the bronchus causing bronchial ulcerations and intraluminal obstruction.

In the review by Hewitson et al, 64 of the 168 (38%) children who required surgical intervention for pulmonary tuberculosis presented with acute or chronic major airway obstruction.15 Almost half of the children who require hospitalization for complications of pulmonary tuberculosis have radiological evidence of mediastinal lymphadenopathy.20

The diagnosis of major airway obstruction can be suspected on an over penetrated chest radiograph or a high Kilovolt radiograph. A chest computed tomography (CT) scan is the definitive modality to diagnose airway compression and identify the enlarged mediastinal nodes. The lung parenchyma can be evaluated to see the extent of obstructive emphysematous or atelectatic changes.

Steroid therapy is widely used to relieve the airway obstruction and acts by reducing mucosal edema and perilymphatic inflammation. However, the response to corticosteroids is only transient and surgical decompression is the definitive treatment for this complication.

</table>
Surgery should always be preceded by rigid bronchoscopy to evaluate the site of airway compression and also assess any intraluminal erosion or involvement. The surgical procedure advocated in lymph node compression syndrome is incision and curettage of the node with partial preservation of the capsule which is usually adherent to the hilar structures. Evacuation of nodes is easily achieved in cases of caseous degeneration. Lymph node excision should never be attempted as it can lead to damage of the airway wall or other vital structures. A reduced hospital stay and faster recovery following surgical decompression of mediastinal adenopathy causing airway obstruction has been reported. The subcarinal nodes are more easily accessible and decompression of these nodes can relieve obstruction to both the main bronchi.

The treatment of chronic airway compromise is medical therapy, but some authors recommend early surgery. Long-term compression can lead to bronchial stenosis and the obstructed lung segment may be permanently damaged due to secondary bacterial infection. Surgery is however, more hazardous in these patients with chronic obstruction due to dense adhesions and fibrosis seen in these patients. In some patients, despite node decompression, airway narrowing may persist due to the fibrous scarring associated with the lesion.

Intraluminal obstruction can occur secondary to the endobronchial tuberculosis or due to granulomatous tissue obstructing the airway. Bronchoscopic removal of the caseous material or granulation tissue can lead to re-inflation of the distal atelectatic segment. Hemorrhage and damage to the bronchial wall are potential complications.

**Post-tuberculosis Pulmonary Destruction**

In cases with poor response to medical therapy or multi-drug resistance, the lung may be extensively damaged. The decision about pulmonary resection is based primarily on symptomatology and the risk of contralateral lung damage. In contrast to adult patients, children with post-tuberculous pulmonary destruction usually have chronic bronchiectatic disease of the lower lobes. The probable etiology for this lesion is usually untreated nodal compression. Hence, most authors recommend aggressive and early surgical management of nodal compression to prevent subsequent damage. The bronchiectatic lesions in pulmonary tuberculosis are usually peripheral and are of the cylindrical type. The middle lobe syndrome is an atelectasis persisting for more than 1 month. The large lymph nodes, the relatively narrow lumen and peculiar angle of take off, all lead to middle lobe atelectasis and secondary infection. The indications for pulmonary resection in tuberculosis are listed in Table 41.2. Lobectomy is the first surgical option, but in extensive lesions, with completely damaged lung tissue, pneumonectomy may be indicated.

Preoperative physiotherapy and broad spectrum (including anaerobic) antibiotics are used routinely to decrease sputum production. Overholt et al described the use of the posterior thoracotomy in a prone position to avoid contralateral lung contamination. Single lung ventilation is used routinely to prevent contamination. Rib resection is usually required for a contracted hemithorax. The latissimus dorsi muscle may be preserved as a flap, based on the thoracodorsal artery and can be used to cover the bronchial stump. An extrapleural approach for pneumonectomy is advocated to minimize iatrogenic trauma and blood loss. Postoperatively, bronchopleural fistulae are the most common complication. Covering the bronchial stump with latissimus dorsi, intercostal muscle, biological glue or omentum has been described to decrease the incidence of bronchopleural fistulae. Extensive skeletonization of the bronchial stump should be avoided to ensure good vascularity and healing.

Role of Pulmonary Resection for Multi-drug Resistant TB

The goal of surgical treatment in multidrug resistant tuberculosis is to eliminate the predominant bacterial foci in the lungs. Atypical mycobacterial infections often require surgical resection to decrease the incidence of complications and progressive damage. In adult patients, Pomerantz et al have reported selective left lung destruction twice more commonly in cases with multidrug resistant tuberculosis. This has been termed as the left bronchial syndrome. The typical left lung affliction has not been noted in atypical infections. Lobectomy or segmental resections are preferred in such cases.

Miscellaneous Indications

Tuberculous pleural disease may need surgical intervention in the acute phase or in the chronic phase of pleural fibrosis. Pleural fibrosis regresses with time and therefore, the indication for decortication is primarily based on sympotomatology or postural problems (like scoliosis). During primary tubercular infection, pleural effusions are seen in 8-10% cases and may require tube thoracostomy for drainage.

Peribronchial lymph nodes may cause circumferential bronchial constriction which will heal with scarring and lead to bronchial stenosis. Endobronchial tuberculosis can also result due to direct inoculation prior to effective antitubercular therapy. A 10-15% patients with active pulmonary disease have evidence of endobronchial tuberculosis. The left main bronchus is more commonly involved as it is more prone for extrinsic lymph node compression and is also anatomically compromised by the aortic arch. Surgery is indicated to prevent the complications of obstructive emphysema, bronchiectasis and infection. In the presence of damage to the distal lung parenchyma, a lobectomy is indicated. Bronchoplastic procedures or stenting are options in bronchial stenosis with preserved lung parenchyma.

Phrenic nerve palsy and eventration can occur due to nerve entrapment. Debunking of the nodes with or without diaphragmatic plication may be indicated in these patients.

Massive hemothysis is rarely seen in children and can result due to erosion of a bronchial artery or secondary to Aspergillus superinfection. The site of bleeding is localized by angiography or bronchoscopy. Bronchial blockage (to prevent flooding of the contralateral lung) and embolization are the immediate measures. Failure to respond to conservative measures necessitates surgical excision of the involved lobe.

Bronchopleural fistulae are rare but pose difficult problems, seen in pulmonary tuberculosis. The immediate management includes an intercostal drainage of the pneumothorax. Surgical management is indicated for unresponsive bronchopleural fistulae. Pulmonary resection is usually required to eliminate the involved lobe and its bronchus.

In conclusion, surgical management of pulmonary tuberculosis has a definite role. The indications for surgical intervention are not well defined and the decision should be based on symptomatology and the risk of ongoing damage. Preoperative physiotherapy and optimization of lung function is vital for good postoperative results. In children, aggressive surgical treatment of the tuberculous adenopathy is indicated to prevent pulmonary damage. Pulmonary resections during childhood are required for the sequelae of airway obstruction and chronic tuberculous secondary infection. Morbidity after surgical intervention is common but mortality in most series is less than 2%.

PREVENTION

BCG vaccine is usually given at birth to all newborns in developing countries where the disease is endemic.

The best method to prevent cases of pediatric tuberculosis is to find, diagnose, and treat cases of active tuberculosis among adults. Children do not usually contract tuberculosis from other children or transmit it themselves. Adults pass tuberculosis on to the children. Improved contact investigations and use of directly observed therapy should increase the success rate of finding and treating the adult cases of tuberculosis, therefore reducing the number of cases of pediatric tuberculosis.

Mothers infected with tuberculosis should remain away from their babies till their sputum is negative. This is usually after 2 months of a 4 drug regimen given to adults.
PROGNOSIS

Prognosis varies according to the clinical manifestation. Poor prognosis is associated with disseminated TB, miliary disease, and tubercular meningitis. Higher mortality rates occur in children younger than 5 years (20%).

The new WHO Stop TB Strategy, released in 2006 has identified six principal components to reduce the global burden of TB by 2015. They are

1. Pursuing high quality DOTS expansion and enhancement.
2. Addressing Tb/HIV, MDR-TB and other challenges.
3. Contributing to health system strengthening.
4. Engaging all care providers.
5. Empowering patients and communities;
6. Enabling the promoting research.

REFERENCES

Chylothorax refers to an accumulation of lymphatic fluid in the pleural cavity, and has a variety of causes (Table 42.1) of which the most common is idiopathic chylothorax of infancy. Chylothorax may occur in up to 1% of children following thoracic surgery and is a less frequent complication of central line placement. In iatrogenic cases, it is usually caused by direct injury to the thoracic duct.

**ANTENATAL CHYLOTHORAX**

Congenital chylothorax may be diagnosed on antenatal ultrasonography, but fetal thoracentesis to measure the lymphocyte count in the pleural effusion does not establish its cause with certainty.

<table>
<thead>
<tr>

</tbody>
</table>

Antenatal pleuroamniotic shunting may improve the prognosis of congenital chylothorax with hydrops and allow the chylothorax to resolve before birth, with delivery at term and no ongoing respiratory disease. In other fetuses, the chylothorax persists, may require premature delivery and intensive respiratory support including mechanical ventilation and prompt thoracocentesis, although the optimal timing of delivery of chylothorax diagnosed in the third trimester is yet to be determined. Intrapartum thoracocentesis in four fetuses with severe bilateral chylothoraces under ultrasonographic guidance prior to cesarean delivery at 31-34 weeks has been described. All four infants were born in relatively good condition, but all eventually required intubation, ventilation and chest tubes. Two of these survived.

About 50% of fetuses with pulmonary lymphangiectasia abort between 19 and 24 weeks gestation with multiple malformations or anencephaly.

**POSTNATAL CHYLOTHORAX**

Spontaneous chylothorax in the neonatal period has a 2:1 male predominance. Several cases of congenital chylothorax in siblings have been described, with a pattern consistent with autosomal recessive inheritance. Reports of recurrent congenital chylothorax in male offspring have led to the suggestion of a possible X-linked recessive inheritance pattern in some families.

Chylothorax may develop after repair of congenital diaphragmatic hernia, perhaps more frequently than generally appreciated. It has been described also in older children with unexplained rib and other
fractures, and failure to thrive, in which situation it is suggestive of child abuse.\textsuperscript{16,17}

Traumatic causes include operative trauma and also during the hyperextension of the spine, with the rupture of the duct from stretching as occurs during diving and wrestling.

Lymphoma may cause chylothorax. Less commonly, it is seen in association with neuroblastoma.\textsuperscript{18} In one infant with a mediastinal neuroblastoma it resolved following ligation of the thoracic duct after multiple thoracentesis and chest tube drainage had failed. Congenital chylothorax has been reported in fetal (neonatal) thyrotoxicosis secondary to maternal Graves’ disease, and with congenital hypothyroidism.\textsuperscript{19,20}

When chylothorax occurs with multiple cutaneous lymphangiomas it tends to have favorable course, with complete regression of the cutaneous lymphangiomas.\textsuperscript{21} Primary congenital pulmonary lymphangiectasis (CPL) is a relatively rare and poorly understood condition that produces chylous pleural effusions and pulmonary hypoplasia and is assumed to be due to a developmental error of the lymphatic system that results in pulmonary lymphatic obstruction.\textsuperscript{8} Most cases are sporadic, but CPL can occur in siblings, or as part of a multiple congenital anomalies syndrome such Noonan, Ullrich-Turner and Down’s syndromes.\textsuperscript{8,22-24}

### INVESTIGATIONS

A plain X-ray of the chest is usually the first radiological investigation performed. Computerised tomography of the chest and nuclear lymphangiography may assist in identification of the origin of the pleural effusion, but are usually unable to demonstrate a congenital fistula or other pathology of the thoracic duct. Localisation of the site of lymphatic leakage has been demonstrated by scintigraphy after oral administration of a\textsuperscript{127} I labelled long-chain fatty acid derivative iodophenyl pentadecanoic acid (IPPA).\textsuperscript{25} The full extent of disseminated lymphangiomatosis that presents with chylothorax (including bone lesions and other visceral involvement) is best demonstrated on T2-weighted MR images.\textsuperscript{26}

Evaluation of the content of the pleural fluid confirms the diagnosis of chylothorax (Table 42.2). Chyle is usually opaque (“milky”), but if the infant is not being fed orally the low fat content may make it appear serosanguinous or straw-colored.

### MEDICAL TREATMENT

Non-operative treatment of chylothorax is effective in up to 80\%.\textsuperscript{1,27} Total parenteral nutrition (TPN) may be more effective than oral medium chain triglyceride (MCT) in the treatment of spontaneous congenital chylothorax.\textsuperscript{28} A medium chain triglyceride (MCT) diet reduces lymphatic flow through the thoracic duct, and is primarily indicated in the treatment of post-operative chylothorax of the newborn. Intermittent thoracentesis under echo-guidance to drain the chyle from the chest may be effective, although the thoracentesis may need to be performed several times. The development of superior vena cava thrombosis or obstruction indicates that conservative management is less likely to be successful.\textsuperscript{1}

The combination of ventilatory support, repeated thoracentesis, thoracotomy tube drainage, total parenteral nutrition (TPN) and MCT feeds would be expected to result in resolution of the chylothorax in the majority of patients (Fig. 42.1). One report suggests that high-frequency ventilation (HFV) may have a role where conventional mechanical ventilation has failed.\textsuperscript{29} Continuous somatostatin infusion for 14 days for chylothorax after cardiac surgery has been employed.\textsuperscript{30} Most effusions resolve within six weeks.\textsuperscript{9}

The thoracic duct carries a large number of T-lymphocytes and the continuous loss of lymph may lead to the setting of immuno-deficiency.

### SURGICAL TREATMENT

Surgical intervention for congenital chylothorax is recommended if medical treatment (including MCT diet, TPN and chyle drainage) is unsuccessful.
Surgery is more likely to be required in congenital chylothorax than in chylothorax that occurs following cardiothoracic surgery.\(^1\)

Early surgical intervention should be considered where the child has an elevated right heart pressure or central venous thrombosis, as non-operative treatment is less likely to be successful.\(^{27,31}\) Surgical intervention tends to be earlier if the less invasive procedures of thoracoscopy or insertion of a pleuroperitoneal shunt are used.\(^{31,32}\) Overall, surgical intervention reduces hospital stay.\(^9\) Thorascopic techniques have now been adapted to allow identification of the leak site, application of surgical clips or fibrin glue to control it, and to assist in the accurate placement of pleuro-peritoneal shunt tubing.\(^{33}\)

The usual purpose of surgical intervention is to occlude the thoracic duct, by identifying the point of chyle leakage and under-running it. Where the exact source of chyle cannot be identified, surgery is directed at limiting the accumulation of chyle by obliterating the pleural cavity: For example, partial pleurodesis may be used where there is difficulty identifying the exact leakage point at thoracotomy or thorascopy. Alternatively, fibrin glue can be applied to the general area of leakage.\(^{11}\)

Pleuro-peritoneal shunt may be helpful where repeated thoracentesis has failed and may be effective in 75-95%.\(^{11,31}\) The shunt is best placed subcutaneously. In a series where the pump chamber was externalised, shunt malfunction and infection were recognised as complications.\(^{34}\) The most common indication for the procedure has been refractory chylothorax following surgical correction of congenital heart disease. In a series of seven patients in whom Denver double-valved shunts were implanted under general anesthesia, the shunts were required for an average of 44 days.\(^6\)

**Table 42.3: Therapeutic modalities available**

| 1. Decrease lymphatic flow through thoracic duct | • Medium chain triglyceride diet  
• Nil orally, total parenteral nutrition |
| 2. Drain chyle from pleural space | • Needle thoracentesis  
• Tube thoracentesis |
| 3. Obliteration of thoracic duct or area of leakage | • Surgical occlusion (via thoracotomy or thorascopy)  
• Pleurodesis |
| 4. Supportive treatment | • Ventilatory assistance  
• TPN |
| 5. Monitor protein levels and lymphocyte numbers | • Drainage of chyle also includes protein and lymphocytes |

Empyema Thoracis

Shilpa Sharma, DK Gupta

Thoracic empyema is a life-threatening condition in pediatric surgical practice.

Empyema thoracis in children has been dealt since ages by pediatricians initially who then refer the case to the pediatric surgeon when they feel the need. It is thus vital for every pediatric surgeon to be well versed with the etiology, stages of empyema and its natural course. Empyema thoracis forms about 5-15% of the cases seen by a pediatrician. Empyema is usually a post-pneumonia sequelae. *Staphylococcus aureus* is the commonest etiological agent (77%); with clustering seen during hot and humid months. Community acquired methicillin resistant *S aureus* (MRSA) is showing an increasing trend. Most children are treated with parenteral cloxacillin and an aminoglycoside. Culture positivity has decreased significantly over the years due to the availability of broad spectrum antibiotics which the patients receive before presentation. Tube drainage is used in 80-90% of fibropurulent cases and is successful in 70-80% cases. At a referral center, upto 3-5% of the cases may require decortication. Early diagnosis and appropriate treatment may prevent the need for any surgical intervention. Surgery is mainly required by children with persistent pleural sepsis after 10 days of Tube drainage. Delaying surgery has a significantly higher potential of requiring decortication.

**HISTORICAL BACKGROUND**

Empyema has been recognized since ancient times. Around 500 BC, 2500 years ago, Hippocrates made the first recorded description of empyema and advocated the concept of open drainage and irrigation. Aristotle identified the increased morbidity and mortality associated with empyema and described drainage of empyema fluid with incision. In 1876, Hewitt described a method of closed drainage of the chest in which a rubber tube was placed into the empyema cavity and drained via a water seal drainage. Decortication for treating empyema was popularized by George Farber in the late 19th Century. The US Army empyema commission recommended closed drainage in the 1920's to decrease the mortality associated with open drainage. In the early 20th century, surgical therapies for empyema (thoracoplasty, decortication) were introduced. However, the greatest impact on the history of treatment of empyema has been the introduction of broad spectrum antibiotics that decreased the morbidity and mortality.

The practice of surgical drainage as part of therapy for empyema has continued into the era of modern medicine with an ongoing debate regarding timing and indications.

**DEFINITION**

Empyema is defined as a collection of purulent material in the pleural space as a result of combination of pleural dead space, culture medium of pleural fluid and inoculation of bacteria. Empyema is an advanced parapneumonic effusion.

Though parapneumonic effusions may be noted in 50-90% of childhood pneumonias, the progression to empyema is rare. In a study with 3248 children with pneumonia, 1 in 155 cases progressed to empyema.
ETIOLOGY

The etiology of empyema may arise from any source of infection in close vicinity to the pleura.
1. Pneumonia- Viral, Bacterial, Tubercular, Myotic
2. Postoperative infection
3. Lung abscess
4. Trauma
5. Subphrenic abscess
6. Generalized sepsis
7. Adjacent infections—retropharyngeal or medi-astinal abscess
8. Esophageal perforation
9. Retained tracheobronchial foreign bodies
10. Cystic fibrosis
11. Endotracheal tumor
12. Instrumentation
13. Congenital anomalies
14. Malignancy
15. Immunocompromised, disseminated infections.

Empyema is a well-recognized complication of pneumonia and its prevalence is increasing in the childhood population. Bacterial pneumonia is the most common of pleural empyema. Pulmonary infections of these patients extend into the pleural space.

Empyemas may result due to—
1. Direct extension of infection to the pleural space from the lung. Subpleural pneumatoceles seen in *Staphylococcus pneumonia* may rupture spontaneously and transmit the infection to the pleural space. Empyemas can result from rupture of a lung abscess into the pleural into the pleural space.
2. Contiguous infections of the esophagus, mediastinum, or sub-diaphragmatic region may extend to involve the pleura. Similarly, retropharyngeal, retroperitoneal, or paravertebral processes may extend to adjacent structures and involve the pleura as well.
3. Obstruction of pulmonary lymphatics may lead to seeding of the pleural fluid and lead to empyema
4. Increased pleural permeability may be associated with lung abscesses.
5. Hematogenous spread may be responsible for secondary infection of a sterile parapneumonic effusion.
6. Host factors that contribute to alterations in pleural permeability, such as inflammatory diseases, infection, trauma, or malignancy, may allow accumulation of fluid in the pleural space, which becomes secondarily infected.

BACTERIOLOGY

The bacteriology of parapneumonic empyemas has changed over the years. The most common bacteria implicated for empyema are *Staphylococcus aureus, Pneumococci, E. coli, pseudomonas, Klebsiella* and anaerobes (Table 43.1).

The cultures are sterile in 30-50% of the cases due to antibiotics.

Ravitch et al had reported that *staphylococcus aureus* was the most common pathogen (92% cases) associated with empyema in children below 2 years of age. The presence of associated superficial skin lesions, osteomyelitis and cystic fibrosis is associated with *Staph.Aureus* empyema. In a study by Hardie et al in 1996 of community acquired pneumonias complicated by empyema, *Streptococcus pneumonia* was the most common pathogen seen in 40% cases.

Hoff et al noted 44% of patients had negative cultures and none of the empyemas were associated with *Staph.Aureus or Haemophilus influenzae*. In adolescents, the most commonly implicated organisms are *Staphylococcus aureus, Streptococcus pneumoniae*, and group A *streptococci*. Group A *streptococci* may be observed as a complication of an infected skin disorder, such as

varicella, impetigo, or infected eczema. Historically, *Streptococcus pneumoniae* was the most common organism but with the routine use of pneumococcal vaccine, *Staphylococcus aureus* is now the most commonly retrieved organism.\textsuperscript{16,17}

There has been an increasing incidence of methicillin resistant staphylococci infections.\textsuperscript{18-20} *Haemophilus influenzae* is rarely encountered since the advent of the *H. influenzae* B vaccine.

*Pseudomonas* is a common organism, which is frequently isolated in sick, ventilator dependent children. Anaerobic organisms have emerged as important pathogens in sick, hospitalized children and in empyemas resulting from underlying aspiration pneumonia or lung abscess. Anaerobes have also been recognised as important cause of childhood and adolescent empyema.\textsuperscript{21}

Tuberculosis being rampant in developing countries may present as acute empyema. In cases of late diagnosis, noncompliance with antitubercular treatment and resistant strains of mycobacterium, it is usually a chronic disease with underlying parenchymal involvement.\textsuperscript{2} Rare organisms like *Serratia marcescens* have also been implicated.\textsuperscript{22}

Mycoplasma pneumoniae and viruses can rarely result in exudative pleural effusions.

## Pathophysiology

The development of parapneumonic effusions is a slow process.\textsuperscript{23}

The pleural space is a potential space lined by mesothelial membrane, containing only small volumes of transudative fluid, with a protein content less than 1.5 gm/dL. The pleural fluid normally is composed of lymphocytes, macrophages, and mesothelial cells, with an absence of neutrophils. Interaction of the mesothelium with the invading bacteria, polymorphonuclear leukocyte and inflammatory mediators can increase the pleural permeability. Further recruitment results in the increased neutrophil chemotactic mediators and thus pleocytosis.

The American Thoracic Society (1962) described three stages of empyema that continue to be applied in the classification of the disease. The progression of pleural fluid collection evolves from stage 1-3 (Table 43.2).

1. **Exudative (Acute) stage:** The pleural inflammatory reaction results in increased permeability and a small fluid collection. The fluid contains mostly neutrophils, and often is sterile. At this stage, the effusion is thin with few cellular elements and amenable to thoracentesis. The exudative pleural fluid is a nutritionally rich culture media for bacterial pathogens. Host defenses are inhibited because phagocytosis is prevented by a lack of surface for adhesions. The pleura and lung are mobile and the pleural fluid pH, glucose and LDH levels are normal. This stage lasts only 24-72 hours and then progresses to the fibrinopurulent stage if the infection is not controlled at this stage with appropriate antibiotics.

2. **Fibrinopurulent (Transitional) stage:** This stage is characterized by invasion of the organism into the pleural space, progressive inflammation and polymorphonuclear (PMN) leukocyte invasion. Protein and fibrinous material accumulate with formation of fibrin membranes, which forms partitions or loculations within the pleural space. Inflammation is characterized by progressive decreases in the pleural fluid glucose and pH and increased protein and lactate dehydrogenase. White blood cells are present within the fluid, and the Gram’s stain is usually positive. The pH and glucose values show a fall with increase in LDH levels. This consolidation of the infected pleural fluid also leads to loss of lung mobility. Loculation in the fibrinopurulent stage walls of the infection and prevents resolution. This stage lasts for 7-10 days and often requires more aggressive treatment like tube thoracostomy.

3. **Organizing (Chronic) stage:** A thick pleural peel is formed by resorption of fluid and as a result of fibroblast proliferation and fibrin resorption. The organized collagen on the pleural surface is called

<table>
<thead>
<tr>

<tr>
<td>Lung expansion</td>
</tr>
</tbody>
</table>
the peel. The lung parenchyma becomes entrapped, forming a fibrothorax, capillary proliferation extends from the fibrinous peel into the visceral pleura. This stage usually occurs within 2-4 weeks after the initial presentation.

The pleural inflammatory response thus leads to an increased procoagulant activity and depressed fibrinolytic activity, causing fibrin deposition. Loculations are formed with fibrin strands covered by fibroblasts that proliferate and deposit basement membrane proteins over the pleura. These proteins prevent the separation of the visceral and parietal pleura and lead to the formation of a pleural peel.

Following timely initiation of proper antibiotic therapy, the inflammatory process resolves. Re-epithelialization of the pleura occurs with migration of pleural mesothelial cells into areas of denudation. However, inappropriate or delayed treatment leads to exuberant pleural inflammation resulting in pleural fibrosis and restrictive lung disease.

The bacteriology of the pleural fluid has an impact on the progression of the empyema. It is established that anaerobic organisms lead to early loculation, which impairs closed drainage. The pleural peel is thicker in *Streptococcus* and *Hemophilus empyemas* as compared to staphylococcus empyemas. Empyema may be localized (encapsulated) or may involve the entire pleural cavity.

**CLINICAL PRESENTATION**

The clinical features of acute empyema in children are usually a manifestation of the primary underlying infection. Most acute cases present with symptoms of bacterial pneumonia like fever, dull chest pain, cough, dyspnea, and possibly cyanosis. Children are also likely to have respiratory distress, headache, febrile seizures and abdominal distension secondary to paralytic ileus. The clinical picture of empyema can be blunted due to the use of antibiotics. Pleuritis may cause abdominal pain and vomiting.

Tubercular empyema is usually chronic and presents with malaise, low-grade fever, weight loss and anorexia. Immunocompromized patients may be afebrile.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis include lung abscess, hemothorax, pleural effusion, pulmonary infarction, pulmonary sequestration and rarely cases of congenital diaphragmatic hernia with delayed presentation and post-traumatic diaphragmatic rupture. Inadvertent placement of chest tube in the latter two cases has been shown to increase morbidity due to intestinal injury.

**INVESTIGATIONS**

**Blood Investigations**

*Hemoglobin:* It may be decreased.
WBC Count: An elevated WBC count and a predominance of polymorphonuclear leukocytes is seen in acute cases.

Erythrocyte sedimentation rate: It may be raised.

Serum C-reactive protein levels: These have been reported to be higher among children with empyema than among those with uncomplicated pneumonia (234 mg/L vs. 178 mg/L; p = 0.037).

Blood culture: It may be obtained to assist in the identification of the offending organism.

HIV screening: It may be advised in emaciated children with chronic illness and pyrexia.

Sputum: if present may be sent for AFB culture if there is suspicion of tuberculosis.

Mantoux test: A strongly positive mantoux test may aid in the diagnosis of tubercular etiology though it may be negative in immunocompromised individuals.

Radiologic Evaluation

Standard Chest Skiagram

Postero-anterior and lateral view in upright position is essential to assess the diaphragmatic margins for pleural fluid, which are obliterated with pleural fluid collections (Fig. 43.1). Upto 400 ml may be required before these costophrenic angles are obscured in older children and adolescents, therefore further diagnostic imaging may be needed. In the presence of posterior costophrenic angle obliteration, a decubitus CXR is mandatory to assess the degree of fluid collection. Parapneumonic effusions more than 10 mm thick on decubitus view are considered significant and thoracentesis must be carried out. Air fluid levels and early loculation suggests anaerobic infection. The other potential causes of air-fluid levels include bronchopleural fistula, ruptured lung abscess, or esophageal perforation. The presence of pneumatoceles suggests staphylococcal infection. In cases of tuberculosis, associated underlying lung pathology may be identified. With moderate effusion, the radiograph may demonstrate displacement of the mediastinum to the contralateral hemithorax as well as scoliosis.

Lateral decubitus views are required for indistinct diaphragmatic contours. Free-flowing pleural effusions suggest less complicated parapneumonic processes, which may not require extensive diagnostic and therapeutic interventions.

Ultrasonography

Ultrasonography may be helpful in few cases to distinguish between fibrinous septations or presence of consolidated lung.

CT Scan

CT imaging has emerged as the study of choice in patients with complex fluid collections (Figs 43.2 to 43.5).

Chest CT imaging can be used to detect and define pleural fluid and image the airways, precisely define the loculations guide interventional procedures, and discriminate between pleural fluid and chest consolidation. The amount of pleural thickening is well appreciated on a CT scan image (Fig. 43.2). The mediastinal window is very helpful to study the extent of the pleural fluid and also to identify loculated lesions (Figs 43.3A to C). Split pleura sign and lenticular collection in a case of empyema may be identified on CT scan. A CT scan is mandatory in an opacified chest (white-out). Computed tomogram (CT) scan with intravenous (IV) contrast in preoperative evaluation of childhood empyema is also helpful to identify pediatric intrathoracic tumors that can mimic childhood post-pneumonic empyema.

Fig. 43.1: Skiagram chest depicting obscured right costophrenic angle and air fluid level suggestive of fluid collection
The associated underlying lung pathology may also be studied in detail especially in cases of tuberculosis. The degree of lung trapping can be assessed that is particularly important in the child because hampered lung growth can effect subsequent function. A lung abscess is depicted as an intrapulmonary fluid pocket while an extrapulmonary fluid pocket is suggestive of an empyema on cut sections of CT scan.

CT or US guided thoracentesis helps in diagnosis as well as treatment. It is also important to remember that the radiological picture may lag behind the clinical stage. Radiographic evidence of pleural thickening may persist for several months following empyema treatment. A CT image is also helpful to follow the progress of the disease and see if the chest tube is at the appropriate place in cases of loculated collections (Figs 43.4A to C).

**Examination of the Pleural Fluid**

Detailed examination of the aspirated fluid is essential for identifying the causative organism and the stage of the empyema to institute proper therapy accordingly. Cell count and differential is done. The fluid is turbid and contains > 15,000/dL white blood cells. Gram’s stain may reveal gram-positive or negative organisms. The aspirated pleural fluid may
be investigated for glucose, Lactic dehydrogenase, pH, specific gravity, protein, amylase, Lipid stain or triglycerides and Serologic studies. A pH of less than 7, glucose estimation of < 40 mg/dL and LDH levels of > 100 i\(\mu\)L/L is suggestive of empyema (Table 43.3). 28,29 Others however, do not rely completely on these criteria in isolation as they have low sensitivity (18-53%). 30 Pleural fluid assessment is helpful in planning drainage and instituting antibiotic therapy.

It is important to note that pleural fluid pH measurements are not valid if the patient is acidotic with a low serum pH.

Bacterial, mycobacterial, and fungal cultures of the fluid may be sent but the treatment should be initiated based on the clinical course. Community-acquired methicillin-resistant *S. aureus* is a substantial and increasing proportion of *S. aureus* infections in previously healthy neonates most commonly in male infants 7 - 12 days of age.31 In a series of 304 patients, a total of 292 microorganisms were cultured from the pleural fluid samples of 207 patients (to yield a positive microbiological culture rate of 68%).32 Isolated bacteria included aerobic gram-negative bacteria (n = 129), aerobic gram-positive bacteria (n = 105), anaerobic bacteria (n = 51) and *M. tuberculosis* (n = 7).32 Of these aerobic bacterial infections, gram-negative bacteria were isolated more frequently from the older population and involved a significantly higher mortality rate and longer stay, compared to those with other bacteria (p = 0.001 and p < 0.001 respectively).32

Pleural fluid latex agglutination (or counter immuno electrophoresis [CIE] for specific bacteria) may be helpful if the cause of the infection cannot be ascertained from culture results.

### TREATMENT

The therapy in pediatric empyema is directed to save life, eliminate the empyema, ensure lung re-expansion, restore mobility of the chest wall and diaphragm, restore respiratory function to normal and reduce hospital stay. The treatment is based on the stage of disease at presentation, the type of bacteria involved, the response to initial therapy and the degree of lung trapping.

The objectives of treatment are:
1. Control of the infection.
2. Drainage of the purulent pleural fluid and eradication of the sac to prevent chronicity.
3. Re-expansion of the affected lung to restore function.

Complicated cases require tube thoracostomy or surgery for their resolution.

The therapy instituted depends on the causative factor, stage of empyema, state of the lung, presence of bronchopleural fistula, ability to obliterate the space and the patients condition.

The therapeutic decision depends on available clinical, radiologic, and laboratory evidence and host factors with individualization for each case. General
measures include increase in the protein and fluid intake. Physiotherapy and breathing exercises will help in early re-expansion of the lung following evacuation of the fluid.

THORACENTESIS

Aspiration of pus from the pleural space establishes the diagnosis of empyema. Small or loculated collections may require radiologically guided aspiration. The aspirated fluid should be collected anaerobically and placed on ice.

It can provide both significant diagnostic information and therapeutic relief for parapneumonic effusions. The presence of pus establishes the presence of an empyema, and the determination of the Gram’s stain, cell differential, and biochemical analysis helps to guide therapy. In cases of streptococcal infection, the pus is very thin with pH above 7.2, glucose above 40 mg/dL and LDH below 1000 IU per litre. In such cases, only a diagnostic needle aspiration suffices.

Performing thoracentesis before the initiation of antibiotics increases the diagnostic yield of the fluid cultures and allows more specific antimicrobial therapy.

In cases of tubercular etiology, antitubercular chemotherapy should be started immediately, and the pus in the pleural space aspirated through a wide-bore needle till it ceases to reaccumulate. In many cases no other treatment is necessary.

ANTIBIOTIC THERAPY

Appropriate antibiotic should be based on the Gram’s stain and culture of the pleural fluid. However, because many patients may have already received antibiotics at the time of thoracentesis, an empiric selection of the most appropriate antibiotics is done based on the most common pathogens causing pneumonia for the patient’s age and geographic location.16

When the organism is identified, change of antibiotics to the most specific cover for the pathogen is done.

The response to therapy determines the duration of treatment. The patient receives 10-14 days of intravenous antibiotics followed by oral antibiotics for 1-3 weeks.

Antitubercular treatment is mandatory for tubercular empyema. A 6 month course with 4+2 drugs or a 9 month course with 3 drugs is recommended. The treatment may be required for a longer time in cases with associated Pott’s spine. Compliance with the treatment is essential.

It is believed that effective antibiotics usually ensure sterility of even loculated collections. But the lysis of bacteria leads to interleukin production and other inflammatory mediators which cause persistent fever and other symptoms. Therefore, adequate drainage is vital to ensure the cessation of this inflammatory cascade.

The most controversial area in the management of parapneumonic effusions is the identification of patients who would benefit from pleural drainage and the selection of the appropriate drainage intervention. However, long-term follow-up studies show no differences in pulmonary function or exercise capacity between groups managed by antibiotics drainage and those who underwent drainage procedures in the early stages of empyema.

TUBE THORACOSTOMY

Chest tube drainage with an underwater seal is done for cases in stage 2. Diagnostic thoracentesis and chest tube drainage are effective therapy in more than 50% of patients. Prompt drainage of a free-flowing effusion prevents the development of loculations and a fibrous peel. Most children with nontubercular empyema heal well in the long run, even without immediate surgical intervention.

A large bore intercostal drainage tube is placed in the most dependent area of the cavity. The most dependent site can be determined by previous thoracentesis or radiography. The chest tube is connected to a underwater seal with mild to moderate negative suction (–10 to –15 cm H2O). It is important to ensure patency of the chest tube by regular milking and keep the water column low.

Studies which have shown good results with just drainage and antibiotics have usually predominant Staph. aureus infection. Anaerobic infections are known to loculate early and a more aggressive surgical drainage is warranted. Response to initial therapy is the most important factor which determines subsequent treatment. Cessation of fever, decrease in
leucocytosis and lung re-expansion should be noted in 24-48 hours after chest drainage. When inserted in early stages of empyema, ICD may be sufficient if kept for 5-7 days or till drainage decreases to less than 30 ml/day and the patient is afebrile. Antibiotic therapy is continued till 3-4 weeks. The degree of lung trapping as defined by CT scan/CXR is an important factor that decides mode of treatment in pediatric empyemas. Significant lung trapping in children required a more aggressive approach. Sometimes two intercostals tubes are needed for adequate decompression, one for the air and one for the fluid that is in the dependent position (Fig. 43.6).

The tube is removed when the lung re-expands and drainage ceases. If the fluid is not free flowing, further radiologic imaging are undertaken to better define the pleural space disorder.

INTERVENTIONAL RADIOLOGY

The placement of small-bore catheters, specifically localized to loculated pleural fluid collections, has helped to facilitate drainage. Smaller diameter tubes are better tolerated with less morbidity. Radiologists can lyse adhesions directly using imaging during the tube placement.

Interventional radiologists have used fibrinolytics in complicated empyema with loculations and ameliorated fibrous peel formation and fibrin deposition.

Intrapleural fibrinolytics like urokinase, streptokinase and tissue plasminogen activator (TPA) have been used to treat obstructed thoracostomy tubes, increase drainage in multiloculated effusions, and to lyse adhesions. Intrapleural urokinase treatment in children with complicated parapneumonic effusion has been reported as an effective and safe therapy. The mean fluid drained during the first 24 hours and the first 72 hours after urokinase instillation were significantly greater than those during 24 hours before instillation, p = 0.002 and p < 0.001, respectively. The total volume of fluid drained was also greater in the urokinase group than that in the control group (p < 0.001). The mean duration of chest tube drainage was significantly shorter in the urokinase group (8.7 +/- 2.8 days vs. 14.7 +/- 6.1 days, p < 0.02). The mean length of hospitalization was also significantly shorter in the urokinase group.

Streptokinase 1-2 lacs u/Kg/dose) is diluted to 50 ml with saline and instilled through the chest tube; the chest tube is clamped for 2 hours and the patient is rotated at 15 minute intervals. The irrigation if carried out for 5 days has shown good results.

Bronchopleural fistula BPF, bleeding diathesis and hypersensitivity to fibrinolytic agents formation of anti streptokinase antibody are contraindications to this form of therapy.

SURGICAL TREATMENT

There is a difference in surgical approaches for empyema in adults and children.

Early decortication and fibrinolytic treatment are sufficient for pediatric patients, while a variety of techniques including open drainage, rib resection and thoracomyoplasty are required in adult patients with empyema.

Since the 1990s two new treatment modalities have been described; fibrinolysis and early VATS (video-assisted thoracoscopic surgery). Both these treatments have now been used as a first-line therapy resulting in a shorter hospital stay and fewer complications than the conservative approach.

Surgical treatment is required for chronic empyema which may be caused by delayed medical attention, inadequate antibiotic therapy, inadequate drainage, presence of foreign body, infliction of postresectional space and chronic pulmonary infection like mismanaged tuberculosis. Other causes of ICD failure include improper positioning of tube, improper selection of tube size, inadequate physiotherapy, presence of BPF and underlying pleural thickening. The pleural thickening is akin to scar formation after any inflammation. Thickened parietal pleura restrict chest wall movement while thickened visceral pleura immobilizes lung and prevent it from expanding. Multiloculated empyema or persistently symptomatic effusion is likely to require surgical intervention.

Rib Resection

Resection of a short segment of rib is necessary if the pus is thick and loculated or if the patient remains toxic after intercostals tube drainage. This provides adequate exposure, allows one to evacuate the pus, break up loculations and adhesions, and assess the need for decortication. After cleaning the cavity...
thoroughly, a tube may be placed in its most dependent portion and attached to underwater seal drainage.

**Open Drainage**

In chronic cases with thick pus, a wide bore tube may be left in place, open to atmospheric pressure. This is helpful in adolescents with chronic tubercular empyema after a 3-5 weeks period closed intercostal tube drainage when the amount of 24 hour draining pus has decreased to less than 25 ml. Open drainage prevents the intercostal tube from getting blocked by flakes of pus at the bottom of the underwater seal bag and allows the empyema cavity to heal from inside outwards. The antitubercular chemotherapy prevents formation of further purulent fluid. With a small polythene bag attached to the tube, the adolescent can carry on with his daily chores and not having to carry a heavy underwater seal bag.

Eloesser had described the open ‘U’ shaped flap procedure in 1935 for open drainage. It was originally described for tuberculous empyema, combines some of the virtues of open and closed drainage and eliminates the need for wide-bore tubes open to the air. It is rarely required now due to improved diagnostic modalities and effective antibiotics.

**Decortication**

Thoracotomy is done to remove the pleural peel and lyse the adhesions if the patient does not respond promptly to treatment. The term decortication refers to the removal of the thick fibrotic visceral pleural peel. Infact, the actual procedure, which is usually performed, is pleural debridement and breaking up of the loculations which ensures drainage. A mini thoracotomy procedure for treating pediatric empyemas has also been described. A 5 cm incision is centered over the empyema and the underlying rib is resected. The purulent debris is evacuated and the loculations are broken. An early decision to perform thoracotomy and pleural debridement is also advantageous because the peel is thinner and loculations can be lysed with less blood loss. A mini thoracotomy and pleural toilet/decortication definitely ensures complete adhesiolysis and effective drainage.

Decortication is indicated in encased lung, lung adherent in twisted positions, crowding of ribs, scoliosis and pneumothorax in radiographs without column movement in ICD indicating rigid immobile collapsed lung. Decortication comprises removal of the organized inflammatory membrane. It comprises of two types of procedures:

1. Removal of the visceral peel alone and
2. Empyectomy comprising of extrapleural dissection outside the parietal pleura and removal of the complete cavity (Fig. 43.6).

Striping the parietal pleura may be done by extrapleural dissection before opening the pleural cavity. Length of hospital stay, duration of antibiotics and long-term morbidity are reduced by this more aggressive approach with rapid resolution of symptoms, but it is a major operative procedure with increased cost and short-term morbidity. Early decortication has been reported as a safe and curative treatment in childhood empyema thoracis with low morbidity.

Thoracotomy and decortication is very effective, with a reported 95% success rate for patients with fibrinopurulent effusions and is likely to remain a treatment of choice for advanced empyema.

**Video-assisted Thoracoscopic Surgery (VATS)**

Preoperative CT scan will help to assess the location and thickness of pleural peels and enable to site thoracoscopic ports more effectively. VAT has proved to be an effective and less-invasive replacement for the limited decortication procedure.
Video-assisted thoracoscopic surgery has been safely and effectively performed for neonatal empyema in a 1-month-old infant with staphylococcal pneumonia complicated with multiloculated empyema.\textsuperscript{49}

Thoracoscopic debridement closely imitates open thoracotomy and drainage. Mechanical removal of purulent material and the breakdown of adhesions loculi can be accomplished easily with no attempt to peel away the thickened pleura. Thoracoscopic debridement alone is inadequate in very late stages where the encasing thick pleura need to be removed.

Thoracoscopic decortication has also been done by few enthusiastic surgeons. The drawbacks include suboptimal decortication of parietal pleura in the presence of bleeding and inadvertent lung injuries causing incidental air leaks which in turn obscures endoscopic vision. It may, thus, not be beneficial for very thick pleura of stage 3 was noted in 8 of 9 patients and no patients required a second surgical intervention.

Thoracoscopy has to be performed early in the course of the disease while the peel is pliable and can be removed.

The main prognostic factor for thoracoscopic treatment of pleural empyema is the interval between diagnosis and surgery.\textsuperscript{50} A 4-day limit, corresponding to the natural process of empyema organization, is significant. The assessment of loculations by ultrasonography alone is not sufficient to predict the postoperative course.\textsuperscript{50}

VATS results in more rapid relief of symptoms, earlier hospital discharge, and significantly less discomfort and morbidity.

About 90\% of TS patients can be discharged within 5-7 days and all by 3 weeks. Normal skiagrams of the chest have been reported by 1 month follow up.\textsuperscript{51}

Recent studies support the early application of video-assisted thoracic debridement in children with empyema compared with traditional therapy, as it decreases the number of procedures and studies performed and the duration of chest tube drainage and is associated with less pain and shorter recovery period than open thoracotomy.\textsuperscript{52}

Despite the benefits, a small percentage of patients still progress to require thoracotomy VATS is most effective in the slightly less affected patients in whom early and potentially more aggressive treatment has been initiated. However, some authors feel that there is no evidence to support a better clinical outcome from VATS compared to a chest drain with intrapleural fibrinolytic in children with empyema.\textsuperscript{53}

A balloon-assisted single-port thoracoscopic debridement in children with thoracic empyema has been described.\textsuperscript{54}

A balloon connected to a 12 F feeding tube is inserted into the thoracic cavity and inflated with air before the entrance of the thoracoscope. By this maneuver, a cavity is formed just under the entrance point following which a routine debridement and chest irrigation are performed by thoracoscopy.

A balloon inflated in the thoracic cavity may achieve a wider field of vision for thorascopic surgery, and single-port thoracoscopy has been reported as sufficient and safe for the dissection.

**Lobectomy and Pneumonectomy**

Surgical excision of a lobe or the whole lung though not described frequently by many in the west, remains an important component of the management in our country where tuberculosis is rampant. In a minority of patients even after adequate decortication the lung does not expand due to necrosis of the underlying lung. In such cases, resection of the affected lung segment will be prudent. The author’s large Institutional experience shows that the lung excision (complete or in part) of Empyema Thoracis patients, is required not only to excise the diseased lung but also to prevent the other lung from being flooded with the secretions from the diseased lung. Also, rib excision may have to be done to have a good access to thorax in the advanced cases with deformed chest. Rarely, the cases may be so difficult that even a second look thoracotomy may be required before a lobectomy could be performed. In the West, patients are seen much early in the course of disease so that the pleural thickening seldom exceeds 1-2 mm. In contrast, Indian patients are seen in advanced stage of disease so that the pleural thickening may reach even 2-3 cm.

Indication for pulmonary resection in cases of tubercular empyema include

1. Persistently positive sputum cultures with cavitation after 6 months of continuous optimal chemotherapy with 2 or more drugs. Resistant tuberculosis should be ruled out. Relative
indications for surgical intervention like severe cavitation, bronchiectasis, or bronchial stenosis may contribute to failure of chemotherapy in some patients.

2. Localized pulmonary disease caused by atypical mycobacterium or *M. tuberculosis* with broad resistance to chemotherapy. Localized disease is defined as that encompassing 1-2 segments of the lung.

3. A mass lesion of the lung in an area of tubercular involvement. This helps for simultaneous diagnosis of the mass lesion and treatment of tuberculosis.

4. Massive life-threatening hemoptysis or recurrent severe hemoptysis. Massive hemoptysis is defined as more than 600 ml in 24 hours and severe hemoptysis is more than 200 ml in 24 hours. Asphyxiation is the usual cause of mortality from hemoptysis. Bleeding arises from abundant bronchial arterial circulation to the cavitated portion of the lung. Bronchoscopy is performed to determine the lobe from which bleeding arises, as frequently bilateral cavitary changes may be present. In stabilized patients with localized site of bleeding, lobectomy is the most definitive form of therapy for severe hemoptysis.

5. A broncho pleural fistula secondary to mycobacterial infection that does not respond to tube thoracostomy.

### COMPLICATIONS

The complications have been listed in Table 43.4.

**Empyema Necessitans**

A swelling appears over the chest wall which is in communication with the underlying empyema. It has a positive cough impulse. It usually does not require any additional treatment and heals spontaneously with adequate treatment of the underlying empyema.

Fibrothorax, is a rare complication seen in adolescents who have presented very late.

**Bronchopleural Fistula (BPF)**

BPF is a troublesome complication of ET and it delays discharge from hospital. BPF prevents expansion of lung by creating positive intrapleural pressure and in turn rigid encased and splinted lung around the fistulous opening prevents spontaneous closure of BPF. To break this vicious cycle decortication is essential. Most of the BPF will spontaneously close within 48 hours of satisfactory lung expansion. Formal suturing of BPF will often fail due to the friability of underlying diseased lung. The usual options are either to apply a stapler more medial to BPF or to resect the affected lung segment. Vascularized latissimus dorsi flap is a viable option for closing BPF. Hence surgeons should avoid damage to this muscle during open thoracotomy. Some surgeons claim that BPF will most often close by conservative ICD. According to one surgeon only one out of five BPF require thoracoscopic intervention. Although PTFE is used to suture BPF in adults, it is not known whether it has ever been used in pediatric cases. BPF should not be confused with post decortication air leaks as the later will settle promptly within 10 days.

*Streptococcus pneumoniae* is an uncommon etiological organism in children with hemolytic uremic syndrome (HUS). Patients with *S. pneumoniae*-associated HUS commonly have a pneumonia or meningitis. Historically, *S. pneumoniae*-associated HUS usually has a poor clinical outcome. Patients with empyema complicating pneumococcal pneumonia have been reported to develop renal failure with oliguria requiring peritoneal dialysis for a period of 9 to 26 days. S. pneumoniae-associated HUS remains a rare but severe complication of invasive pneumococcal infection in children. It is important for pediatricians to note that children with pneumococcal pneumonia with severe hematologic and renal dysfunction should be investigated for evidence of *S. pneumoniae*-associated HUS.

The mortality in pediatric empyemas is less than 10% in most series.

### Table 43.4: Complications of empyema

- Empyema necessitans
- Bronchopleural fistula
- Anemia
- Osteomyelitis of ribs/vertebrae
- Pericarditis
- Pulmonary esophageal fistula
- Metastatic abscess—Mediastinal, vertebral, other sites
- Wound infection
- Empyema relapse
- Persistent atelectasia
LONG-TERM EFFECTS

Despite the variability in presentation, most patients recover without sequelae.

A number of studies have demonstrated resolution of the radiographic abnormalities by 3-6 months following therapy, with little to no symptoms reported at follow-up examination of 122 children (median age 4.3 years), 103 (84%) required chest drains of whom 83/103 (81%) received urokinase; 5 (4%) required surgical decortication. On admission, 56 (46%) had a scoliosis, 68 (62%) on the 2nd radiograph, and 68 (59%) at discharge; overall 87 (71%) had a scoliosis at some stage. In all cases, there was a single thoracic curve with the direction towards the side of the effusion.

There was no association between scoliosis and size or type of effusion, nor inflammatory markers. There was a statistically significant but small effect from duration of illness prior to admission. At follow-up, 6 (5%) had a mild residual scoliosis but all subsequently resolved. Intraobserver variability for measurement of Cobb angles was +/– 4.6° and interobserver variability was +/– 5.8°. Scoliosis was common but always resolved so therapy is unnecessary; follow up is recommended to exclude coincidental idiopathic scoliosis.

Pulmonary function testing performed following hospitalization has not shown marked abnormalities, regardless of clinical course. The only abnormality observed may be slight expiratory flow limitation. Mild obstructive abnormalities were the only findings observed in patients evaluated 12 years (+ 5) following recovery from empyema. In advanced stages of Empyema, few patients silently suffer restrictive lung disease and abnormal spirometry. Some increased bronchial reactivity has been reported at later follow-up examinations; however, lung function and exercise response return to normal for most patients.

Early recognition of pneumonia with parapneumonic effusion, effective intervention to identify the causative organism, and initiation of definitive therapy reduce morbidity and complications associated with this process.

Mild airway obstruction was noted with reduced EFV values in nearly 50% of the children. None of the children had any restrictive features on spirometry and these was no difference noted between children treated with or without chest drainage.

Chest Wall Deformities

Congenital thoracic wall deformities represent a spectrum of musculoskeletal disorders of the anterior chest wall. Most of these deformities fortunately are not life-threatening and do not manifest in severe functional pathophysiology of the thoracic organs. The management of these deformities, however, have gained more importance in the past decade because of the increased participation in competitive school sports as well as athletics, and the changing trends in the world of fashion which expose more of the chest to the public view. It is important to note that, although thoracic wall deformities do not arouse the sympathy generated by limb or cranial anomalies, children with such deformities are viewed with curiosity by their classmates and are often confronted by teasing remarks.

Except for severe chest wall deformities, it is generally extremely difficult to predict the course of progression after the deformities have been discovered in early infancy. Therefore, mild forms of abnormalities warrant the wait-and-watch approach during the first 4-5 years before operative management could be considered. In mild cases, the dormant deformity sometimes becomes accentuated during adolescent growth. Since, the deformities can also manifest frequently primarily during the pubertal spurt often with rapid progression, operative correction in young adults is more favorable in mild cases. The wait-and-watch approach much consider the vertebral anomalies such as scoliosis that may significantly result or affect the secondary deformities of the thoracic cage.

CARDIOPULMONARY EFFECTS

Chest wall depression is better tolerated in infancy, however many older children report subjective complaints such as dyspnea, cardiac dysthesia and limited work performance. Chest wall depression results in a variable displacement of the heart to the left and could be associated with significant rotation. This is well documented by CT scans of the thorax that demonstrate the degree of cardiac compression resulting from the sternum and costal cartilages. Although, surgical correction has been performed in many centers mainly for esthetic and psychological reasons, however, compression and secondary changes of the intrathoracic organs have been indications for surgery (Fig. 44.1). Many individual patients reported with specific cardiac problems, such as supraventricular tachycardias and recurrent heart failure, were relieved by correction of the depressed sternum.

Fig. 44.1: Magnetic resonance image showing the degree of cardiac compression in a mild form of funnel chest deformity
Mechanical factors such as cardiac displacement due to the deformity are furthermore responsible for the functional disturbances of the right and left sides of the heart in systole and diastole. This has been attributed to be more a disorder of compliance of the right side of the heart than the output of the ventricle. Decreased right ventricle filling due to impaired function of the right atrium is also responsible for the reduced stroke volume during exercise. Preoperative echocardiographic and Doppler’s findings have also correlated well with the extent of cardiac displacement. A significant increase in the cardiac index after operation is evident when patients performed exercises in sitting position, presumably on the basis of an increased stroke volume. A decrease in the heart rate at any given work performance after operation, evident as the improvement in exercise capacity, is due to the result of an increase in cardiac stroke volume and could explain the subjective circulatory stabilization experienced by the patients.

Restrictive impairment of pulmonary function, expressed by reduced total lung capacity and inspiratory vital capacity is found in patients with funnel chest although normal functions have also been observed. Even after surgical correction of the deformity there is a significant reduction in the total capacity and inspiratory vital capacity of the lungs, probably a result of the decreased compliance of the chest wall. However, the efficiency of breathing (ratio of tidal volume/inspiratory vital capacity) at maximal exercise improves significantly after operation.

CLASSIFICATION

Patients with chest wall deformities are best graded according to the Willital’s classification, which is based on morphologic findings of the thorax (Fig. 44.2). This classification divides congenital chest wall deformities into 11 types - funnel chest (4 types), pigeon chest (4 types), combination of funnel and pigeon chest, chest wall aplasia and cleft sternum (Table 44.1). Since most of the centers today employ metal struts for the correction of this deformity, this classification allows assessment of the operation technique with regards to the location of implantation of the metal struts, as well as the determination of the number of struts to be used for internal stabilization of the chest wall. Records of patients with thoracic wall deformities at our medical center have shown 86% with depression deformities, 8% with protrusion deformities, 4% with combined depression-protrusion deformities, and 2% with other forms.

PECTUS EXCAVATUM

Historical Background of Surgical Repair

Pectus excavatum (funnel chest), a depression deformity of the chest wall was first reported by Bauhinus 1594 case published by Schenck. The
deformity was however first described by Eggel in 1870.13,14 The earliest surgical repair of this deformity was reported by Meyers in 1911 and subsequently by Sauerbruch in 1913.15,16 Ochsner and DeBakey then reviewed the early experiences with repair and reported them in 1938.17 The clinical problem was carefully analyzed and a simplified operative technique was described by Brown in 1939 which initiated the trend of modern surgical management.18 Later on, in 1949 Ravitch’s report on a technique involving the excision of all deformed cartilages with anterior fixation of the sternum using Kirschner’s wires and silk sutures in, and Hegemann’s report on surgical management with metal struts to stabilize the sternum in 1965, laid the foundation for the present techniques practiced worldwide.19,20 Since the 1960’s a variety of techniques are presently being used for the correction of funnel chest, however no procedure is universally accepted as a the optimal procedure. It is very important that the primary correction of the deformity is successful since secondary repair of recurrent funnel chest is technically more challenging and difficult to perform.

**Clinical Relevance**

The incidence of funnel chest is 1 in 1000 live births with a 3:1 male-female predominance (Fig. 44.3).21 Although it appears that the vast majority of instances are sporadic, familial incidences have been frequently documented.22 An autosomal dominant inheritance accounts for the genetic predisposition of this deformity.23 However, acquired chest depression deformities secondary to cardiac surgery has been observed at our center. Pectus excavatum is more severe in patients with an associated Marfan’s syndrome. It is also important to consider Marfan’s syndrome in all patients with this deformity that have scoliosis (Fig. 44.4). Ophthalmologic evaluation to identify subluxation of the lens, and echocardiographic examinations to identify the dilatation of the aortic root or mitral valve regurgitation, must be carried out preoperatively to support the diagnosis of Marfan’s syndrome, if present. Musculoskeletal abnormalities, most frequently scoliosis, are associated with pectus excavatum, and may not require surgical evaluation. Our method of repair is shown and explained under the surgical technique section.

**PECTUS CARINATUM**

**Historical Background of Surgical Repair**

Pectus carinatum (pigeon chest), a protrusion deformity is the second most common malformation of the anterior chest wall. Ravitch in 1952 was the first to suggest that surgical correction was the only effective method for the treatment of this deformity. He surgically corrected the chondromanubrial prominence by resecting the multiple deformed costal cartilages and performing a double osteotomy.24 Later on, Lester in 1953 performed a repair involving
resection of the anterior part of the sternum, but abandoned this approach due to unsatisfactory results. He then reported a second less radical technique which involved subperiosteal resection of the lower body of the sternum and sternal ends of the costal cartilages. Chin in 1957 and Brodkin in 1958 employed an operative procedure which used the traction effect of the rectus muscles to relocate and maintain the sternum in a corrected position. This method was further modified by Howard who preferred the radical resection of cartilages and a sternal osteotomy. Later, in 1960, Ravitch reported another surgical procedure that left the sternum alone, and involved the resection of the affected costal cartilages along with the shortening of perichondrial strips with reefing sutures. In 1963, Ramsay utilized a rectal muscle flap to fill the lateral defects resulting from the protrusion without altering the position of the sternum or resecting the deformed costal cartilages. Also in 1963, Robicsek reported a technique that involved subperichondrial resection of the deformed lateral asymmetric costal cartilages, transverse sternal displacement, and resection of the protruding lower portion of the sternum along with the reattachment of the xiphoid and rectus muscles to the new lower margin of the sternum. Welch in 1973 and Pickard in 1979 reported techniques which were similar and involved costal cartilage resection and sternal osteotomy.

Clinical Relevance

Pectus carinatum represents an array of abnormal development of the anterior chest wall. In our single center surgical experience it constitutes 12% patients operated upon with anterior chest wall deformities with a 2:1 male-female predominance. Although the pathogenesis of pigeon chest is not exactly defined, excessive overgrowth of costal cartilages has been implicated in the etiology of both, pectus excavatum as well as pectus carinatum. The delayed clinical presentation of pectus carinatum when compared to pectus excavatum, may be due to the fact that the protruding infantile abdomen accentuates pectus excavatum in early childhood and recession of the abdominal contour which occurs in the later years emphasizes the protrusion defect in early adolescence. Musculoskeletal abnormalities, most frequently scoliosis, are associated with pectus carinatum, and may not require surgical correction. The severity of the deformity is extremely variable. Surgical correction has been performed mainly for esthetic and psychological reasons, however, displacement and secondary changes of the intrathroracic organs have been indications for surgery (Fig. 44.5).

SURGICAL TECHNIQUE FOR PECTUS EXCAVATUM AND PECTUS CARINATUM

The Willital technique has been the standard technique for the correction of pectus excavatum, pectus carinatum and other combined forms of protrusion-depression combined deformities at our center with excellent long-term results. Using this technique, repair is performed using a standard method of double bilateral chondrotomy parasternally and at points of transition to normal ribs. This is followed by detorsion of the sternum, retrosternal mobilization, correction of the inverted ribs and stabilization of the displaced sternum with one trans-sternal and two bilateral parasternal metal struts. The technical steps have been elaborated below to explain this surgical procedure.

A vertical midline incision is made in boys; otherwise in girls, a submammary incision that is curved upward at the midpoint (over the deepest point of the sternal defect) is preferred, thus avoiding the complication of breast deformity and impaired breast development (Fig. 44.6). In the incision, skin, fat and pectoral muscles are reflected in a single flap and the entire dissection is performed with a needle-tipped
The pectoral muscles are severed from its insertion at the edge of the sternum and costal cartilages to expose the entire impression of the deformity, generally formed by 5-8 pairs of ribs (third to tenth rib). When the deformed costal cartilages have been completely exposed, the perichondrium is incised with the needle-tip cautery in form of an H (Fig. 44.8). The subperichondrial dissection is carried out with small, sharp periosteal elevators and the perichondrium is scraped away from the underlying cartilage (Fig. 44.9). The deformed costal cartilages are resected parasternally from their junction with the rib to within 1 cm of the sternum as well as at the level of transition to the normal ribs, leaving the uppermost normal cartilages intact (Fig. 44.10). The attachment of the rectus muscle to the sternum is severed, and the sternum is elevated with a Kocher clamp and dissected free from the anterior mediastinal tissue after retrosternal mobilization. A partial transverse sternal wedge osteotomy is
Chest Wall Deformities

performed at the Angle of Ludovici. Once the sternum is dissected free as described, a perforated steel strut is then passed trans-sternally, with its edges resting anteriorly on the ribs. The strut must be bent in such a way so that it fits the thorax wall perfectly at the edge of the impression. Two parasternal metal struts are also employed, with the points of fixation being the second rib and the lowest end of the rib cage (Figs 44.11A and B). The trans-sternal strut is fixed to the two parasternal struts with stainless steel wires for additional support. The two parasternal struts also provide anchorage to the completely mobile chest segments, which were formed as a result of double bilateral chondrotomy (Fig. 44.12). Heavy resorbable suture material is then used to close the sternal osteotomy as well as to secure the struts to the chest wall. Two single limb chest tubes are placed in parasternal positions at the level of the highest costal cartilage resection. The pectoral muscle flaps and the severed rectus muscles are then sutured and fixed to the sternum. The overlying subcutaneous and cutaneous structures are finally united in the conventional manner to restore the normal chest wall anatomy.

Perioperative antibiotic therapy is administered; with ceftriaxone being the drug of choice. All patients are also administered strong analgetics for first 24-72 hours. The chest tubes are generally removed on the third day or when the drainage is < 25 ml for a twelve-hour shift. Wound infections are rare and the patients are mobilized after chest tube removal. On the fourth day pulmonary exercises are commenced and are continued for a period of three weeks. At the time of discharge patients are advised to avoid body contact sports until the struts have been removed. The struts are removed after a period of 12 months in patients >12 years, but are retained for 15-24 months in younger

children, so as to stabilize the thorax that is still under the growth spurt.

Stainless steel alloy implants have been accepted as the standard prosthetic implant material for the operative treatment of thoracic wall deformities. Allergy to stainless steel alloy implants is seldom experienced in patients, but may have fatal outcomes if not detected prior to surgery. Patients with allergy to nickel, an element that is present in stainless steel alloy implants, have been managed using titanium implants using polyethylene terephthalate sutures which exhibit fixation capabilities of similar magnitude to 20-gauge stainless steel wires to secure the sternum and ribs.37

RESULTS AND COMPLICATIONS

Repairs are generally completed with an extremely limited number of mild complications like pneumothorax, pleura effusions or wound infections. Cardiopulmonary injuries are rare and blood transfusions are seldom required. Good long-term results have been reported worldwide after the surgical correction of funnel chest deformities with a relatively low recurrence rate of 2-5%. Lower rates of recurrence have been observed also in many long-term studies after the correction of funnel chest (Figs 44.13A and B) Irrespective of the technique, we consider the main reasons for recurrence are

(a) inadequate mobilization of the depressed chest wall
(b) unstable fixation of the mobilized chest wall and
(c) no or inadequate remodeling of the lowest parts of the deformed ribs.42 Complete exposure of sternum and ribs is necessary for satisfactory results as it allows complete intraoperative assessment of the deformity and is of significant importance in patients >15 years of age who may require an additional trans-sternal strut because of the extensive area of sternal depression (Fig. 44.14). This also allows placement of struts and stainless steel wires under complete vision and avoids serious complications such as cardiac perforation.43

POLAND’S SYNDROME

Poland’s syndrome is a spectrum of anomalies that include the absence of the pectoralis major and minor muscles along with a complex of hand anomalies including syndactyly, brachydactyly or ectrodactyly, deformed or absent ribs, absence of axillary hair and decreased amount of subcutaneous fat (Fig. 44.15) Lallemand in 1826 and Froriep in 1839 initially described this syndrome, however it was Poland, an English medical student, in 1841 who published a partial description observed during his anatomic dissection.44-46 It was however Thomson in 1895 who elaborately described the full spectrum of the deformity.47
The extent and the severity of involvement of the anomalies is variable and its presentation can differ in the affected patients. Poland’s syndrome is seldom familial and is associated with a sporadic occurrence in approximately 1:30000 live births. 48,49 The exact etiology of Poland’s syndrome is however not yet established. It is however though that abnormal migration of the embryonic tissue forming the pectus muscle, hypoplasia of the subclavian artery or intrauterine injuries may be responsible. Surgical correction for patients with Poland’s syndrome is reserved for patients with severe aplasia of the ribs with a major depression deformity. Several techniques such as split rib grafts with Teflon felt and latissimus dorsi muscle flaps with placement of rib grafts have been employed for the correction of the deformed ribs.50-52 We prefer to use the surgical technique described previously, for the correction of the partially hypoplastic thoracic cage with excellent results. Breast reconstruction is required in most girls but it is best delayed until late puberty to achieve optimal reconstructive results compared to the growth of the contralateral breast. Most of the surgeons prefer the reconstruction with latissimus dorsi flaps, however atrophy of flaps with time has been observed. Prosthetic implants have also been employed with mixed results as to their complete success reported. It is of paramount importance to discuss the expectations of the patients and the parents prior to the onset of surgical management to achieve acceptable results.

**STERNAL DEFECTS**

These defects constitute a broad spectrum of rather rare deformities of the sternum and heart. While the specific cause is yet unexplained, a partial or complete failure of fusion is responsible the defects that occur. Cardiac pulsations are quite prominent with each type of cleft sternum, suggesting that the heart is partially outside the chest wall (ectopia cordis) in true cases. Associated cardiac defects and multiple anomalies in other body regions usually preclude survival. In 1818 Weese provide the first anatomic classification of the defects. Later on Roth in 1939, Shaotsu in 1957 and Cantrell in 1958 provided further classifications of sternal defects. Review of the medical literature on this topic provides four types of sternal defects which are largely based on the tissue coverage of the heart.

1. **Thoracic Ectopia Cordis**

This type of sternal defect constitutes a completely open heart with no overlying somatic structures. There open heart is found to be associated with intrinsic cardiac anomalies. The sternum is generally fused cranially however entire split sternum is rare. The pathology is further associated with a lack of midline somatic tissues and a smaller than normal thoracic cavity in the affected infants. Upper abdominal defects such as rectus diastases or omphalocele are frequent but are rarely associated with the eventration of the abdominal viscera.

The first attempted repair of ectopia cordis was performed in 1925 by Cutler and Wilens, however, in 1975 it was Knoop who performed the first successful repair.53,54 Skin flap coverage had been since used in a two stage reconstruction for the management of thoracic ectopia cordis. However, successful one staged correction has been reported by Amato who performed a construction of the partial anterior thoracic cavity surrounding the heart, but however avoided the return of the heart to its orthotopic location.55
The successful repair of such anomalies are dictated by the presence and the severity of the intrinsic cardiac anomalies rather than the type of surgical approach itself. There have been no recent advancements or successes reported in the management from the surgical point of view, however advances in fetal ultrasound techniques have aided in the early recognition of the deformity and termination of the fetus in pregnancy.

2. **Cervical Ectopia Cordis**

Cervical ectopia cordis occurs rather infrequently when compared to thoracic ectopia cordis. The patients present with cranial displacement of the heart and the fusion of the apex of the heart and the mouth of the cleft. Several craniofacial anomalies frequently accompany cervical ectopia cordis. Unfortunately this group of patients face the same fate of morbidity and mortality as those with thoracic ectopia cordis. No successful management or survivors with this anomaly have been reported to date.

3. **Thoracoabdominal Ectopia Cordis**

Syndrome of cardiac and parietal anomalies are generally a part of the defect in the distal closure of the sternum. This syndrome is referred commonly to as a pentology with the following associated anomalies: (a) distal cleft sternum, (b) ventral defect of the anterior abdominal wall that may be a true omphalocele, (c) pericardiopleural communication through an inferior pericardial defect, (d) anterior diaphragmatic defect, and (e) congenital cardiac defect generally in the form of tetralogy of Fallot. It is important to note that these clefts may also occur without the full syndrome. In this defect the heart lacks the severe anterior rotation as seen in thoracic ectopia cordis and is covered by a thin membrane or skin overlying the distal cleft sternum. The position of the heart may also vary from lying in the thoracic cavity to an extreme localization entirely within the abdominal cavity. An interesting finding in this anomaly is the diverticula of the left ventricle which quite frequently protrudes through the diaphragmatic and pericardial defect into the abdominal cavity.

The operative correction of the cleft sternum and associated defects require a staged approach, with priority given to the management of the severe defects.

The general approach however would most likely mandate primary correction of the omphalocele with a delayed approach to the treatment of the cardiac defect. Advances and experience gained in pediatric cardiac surgery have decreased the morbidity and mortality of these anomalies. Early repair of the defect provides a better opportunity for the direct closure of the sternal defect with the attachment of the diaphragm. Successful operative outcomes and long-term survival are better when compared to thoracic ectopia cordis.

4. **Cleft or Bifid Sternum**

This is the least severe of the anomaly of the sternum represented by a partial or complete sternal cleft. Most cases however involve the upper part of the sternum and manubrium with an intact xiphoid or intact lower-third of the body of the sternum. The heart in these patients is orthotopically located with an intact pericardium along with an intact skin covering. Intrinsic cardiac defects are generally extremely rare. Also, clinically, the patients are asymptomatic and the surgical repair is directed to render protection to the heart. Surgical repair is recommended in infancy within the first 3 months of life when the chest wall is most flexible and primary closure is accomplished without difficulty. Modifications of techniques, with the basic principle of bilateral oblique incision through the costal cartilages to produce greater length to allow midline approximation of the longitudinal sternal ends, lateral cartilage division and medial relocation to close the defect as well as the utilization of prosthetic materials, have been successfully employed for the closure of this defect.

Disorders of the Umbilicus

The most exhaustive work on the umbilicus is the classic text by Cullen, published in 1916. The umbilicus is of vital importance for intrauterine survival of the fetus, but has no physiological significance after birth, though it retains its cosmetic and emotional appeal. This structure is also of importance to the pediatric surgeon, who is often the first to be consulted regarding any umbilical disorder in the child. Moreover, in this modern age of near scarless surgery, this natural scar is being put to novel uses to improve cosmesis.

EMBRYOLOGY

Embryological events of pediatric surgical importance are as follows:

1. The yolk sac is divided into an intracoelomic portion and an extracoelomic portion by the infolding and flexion of the developing body wall of the embryo. The intracoelomic portion becomes the primitive alimentary canal and maintains a connection with the extracoelomic portion through the vitelline or omphalomesenteric duct. This connection is normally lost by the fifth to seventh week of gestation. Persistence of this alimentary connection or its accompanying vessels can cause abnormalities, viz. persistence of whole or part of the omphalomesenteric duct results in Meckel’s diverticulum, patent omphalomesenteric duct, sinus, cyst and umbilical polyp. Portions of the omphalomesenteric arterial remnants can cause a fibrous band to the umbilicus, and is also the artery to a Meckel’s diverticulum. Portions of the omphalomesenteric vein can result in preduodenal portal vein.

2. The allantois is connected by the urachus to the developing bladder. The urachus normally gives rise to the median umbilical ligament but may persist in several abnormal forms, viz. fully patent urachus, umbilical urachal sinus or urachal cyst.

3. After the return of the midgut into the abdomen, the fibromuscular umbilical ring contracts and continues to do so after birth if not closed already. Persistence of the fascial opening results in umbilical hernia.

CLINICAL DISORDERS OF THE UMBILICUS

Umbilical Granuloma

It is a small mass of granulation tissue, developing at the base of the cord after the cord separates and ranges in size from 1-10 mm (Fig. 45.1). This is treated by one or more application of silver nitrate till the area epithelialises. If this is not successful an umbilical polyp is suspected (Figs 45.2A and B).

Umbilical Infections

Acute

Although modern perinatal care has reduced the incidence of omphalitis, life threatening infection can still occur. Common pathogens are *Staphylococcus aureus*, *Streptococcus pyogenes* and gram-negative bacilli. Infections can be polymicrobial. Clinical’s features include purulent umbilical discharge, periumbilical skin discoloration and cellulitis, sometimes progressing to fascitis and gangrene of abdominal
Omphalomesenteric Remnants

There is a broad range of possibilities. Complete patency of the omphalomesenteric duct from the ileum to the umbilicus presents with fecal discharge and occasionally with prolapse of the proximal and distal ileum via the omphalomesenteric duct (Fig. 45.3). The patent duct can be excised via an umbilical or inferior circum-umbilical incision, the duct traced to the ileum, divided and the ileal opening closed. Care must be taken to ligate a vitelline vessel if present along the duct.

Small duct mucosal remnants and sinuses present with nonfecal discharge and surgical exploration is indicated. It is important that a full exploration of all umbilical structures is performed, including the intraperitoneal undersurface of the umbilicus, to identify and remove any bands to the ileum, including a Meckel’s diverticulum if attached to such a band. Cystic remnant of the omphalomesenteric duct may become infected and require preliminary drainage and subsequent excision.

Omphalomesenteric duct remnants or associated vessels may present with mechanical intestinal obstruction or gangrene caused by angulation, volvulus or internal herniation.1

Urachal Remnants

A fully patent urachus presents with urinary discharge from the umbilicus, which can be suspected from the wall. Signs of systemic sepsis are often present. Breakdown of umbilical stump and spontaneous evisceration has been described. Portal venous thrombosis and subsequent extrahepatic portal hypertension can occur. Treatment in early stages is antibiotic therapy, but in cases of necrotising fascitis debridement will be needed.

Chronic

Chronic umbilical discharge is common and can result from infection in umbilical remnants, e.g. umbilical artery. Excision of umbilical remnants is curative.

Delayed separation of umbilical cord has been associated with heritable neutrophil mobility defects. However, normal variation in cord separation is wide (3-67 days mean 14-15 days).
clear nature of the discharge and associated ammoniaceal rash. Frank drainage of urine from the umbilicus requires an investigation of the urinary tract to look for bladder outflow obstruction. Urachal sinus presents with discharge while urachal cysts often present as an infected painful mass between the umbilicus and the suprapubic area. Characteristic CT findings of pyourachus have been described as midline location deep to the rectus abdominis, conical shape extending from a tip at the umbilicus and base over the bladder dome, inflammatory changes in the surrounding tissues including intraperitoneal fluid or abscess if perforation has occurred.\footnote{2}

Uracial remnants are generally excised via an umbilical or infraumbilical incision. The patent urachus is transected and ligated at the level of the bladder with absorbable suture. An infected urachal cyst requires drainage and subsequent removal at laparotomy.

**Umbilical Hernia**

At birth, the umbilicus is surrounded by a dense fascial ring that represents a defect in the linea alba. When the supporting fascia of the umbilical defect is weak or absent, a hernia will result (Figs 45.4A and B). The umbilical hernia in children is surrounded by the dense fascia of the umbilical ring through which a peritoneally lined sac attached to the overlying skin protrudes. The umbilical ring continues to close over time and the fascia of the umbilical defect strengthens, accounting for the spontaneous resolution of this defect in most children.

An “indirect” umbilical hernia with its defect superior to umbilical ring causing a proboscid hernia has also been described. In this defect the umbilical cicatrix is displaced progressively in an inferior direction as the hernia enlarges.

The umbilical hernia of childhood is different from a ‘hernia of the umbilical cord”. The latter is a small omphalocoele, covered with amnion and not with skin.

Childhood umbilical hernias are equally common in boys and girls. The exact incidence is unknown, but is possibly higher in African infants. It is commonly found in premature infants of which most will resolve. Umbilical hernia with small ring diameter (< 1.0 cm) are more likely to close then those with ring diameter >1.5 cm. The hernia tends to disappear abruptly when the fascial ring closes with the child’s growth. Umbilical herniae generally remain uncomplicated but an occasional child presents with strangulation. Incidence of strangulation in umbilical hernia is estimated to be one in 1500 umbilical herniae in childhood.\footnote{3} Strangulation is not an uncommon mode of presentation in African children, though the actual risk of strangulation in the individual case is still very small.\footnote{4,5} Umbilical hernia is commonly observed in Down’s syndrome, trisomy 18, trisomy 13, mucopolysaccharidosis, congenital hypothyroidism and Beckwith Wiedemann’s syndrome.

Events such as incarceration are definite but rare indication for surgery. Persistence to school age is a relative indication, specially for defect > 1.5 cm, though the repair can well be postponed to later childhood. When operating in infancy for a concomitant inguinal hernia, it is tempting to operate on the umbilical hernia, but it is better left alone.
Repair of umbilical hernia is done under general anesthesia. An infraumbilical skin crease incision is made (Figs 45.5A to D). A subcutaneous dissection is performed to circumscribe the sac. The sac is transected and may be dissected from the under surface of the umbilical skin, but this step is unnecessary. Leaving a remnant of peritoneal sac under the skin causes no complication. Suturing good facial edges in one layer is sufficient. Inversion of umbilical skin is maintained with fine absorbable dermal suture between the underside of the umbilicus and the midportion of the facial closure. The skin is closed with intradermal absorbable suture and pressure dressing applied.

**SURGICAL USES OF THE UMBILICUS**

The umbilicus can be used in postnatal life in several ways – cannulation of the umbilical arteries and vein in neonates for vascular access and monitoring, as a port for placement of laparoscopy, to make a “scarless” entry to the children for pyloromyotomy, for placing a intestinal or urinary stoma, and for placing a stoma for Mitrofanoff port.  

**RECONSTRUCTION OF THE UMBILICUS**

Patients of exstrophy of the bladder lack a normal umbilicus and reconstruction of an umbilicus is a part of the cosmetic rehabilitation of these children. The umbilicus may be preserved and transposed more cephalad at the time of bladder closure. Otherwise an “umbilicus” may be created very simply by bringing out catheters via a skin opening made in the position of a normal umbilicus during the bladder closure operation in childhood. More sophisticated techniques have also been described for umbilical reconstruction. The “kangaroo pouch” technique involves making a small cutaneous pouch by folding a vertical, superiorly based rectangular skin flap and anchoring this pouch deeply to the rectus fascia.

**REFERENCES**

Hernial repair in childhood was originally described in the 1st century AD with transcrotal excision of the testis together with the hernial sac. However, an accurate description of hernial anatomy was made in 1756 by Pott, with ligation of the hernial sac described in 1877 by Czerny. Turner, in 1912, documented that high ligation alone of the hernial sac was the procedure of choice.

Inguinal herniae in children are almost exclusively indirect. Hydroceles commonly coexist with inguinal herniae, and the common surgical management of both conditions, namely division of the sac (herniotomy) or the patent processus vaginalis (PPV), is based on the explanation that they have the same embryological basis.

Treatment of inguinal hernia in childhood aims to avoid the complications of this condition. For reducible herniae it is reasonable to undertake surgery as soon as convenient. A hernia presenting acutely incarcerated but then reduced subsequently at presentation should be dealt with as a ‘planned emergency’. The frankly irreducible hernia should be treated operatively, immediately after fluid resuscitation, especially if there is intestinal obstruction or evidence of peritonitis.

Management of hydrocele alone may be more conservative since hydroceles may resolve spontaneously, although division of the PPV is generally undertaken after the first two years of life to prevent unremitting swelling of the testicle which can be unsightly and may become painful. ‘Adult-type’ hydroceles in children are rare, and trans-scrotal operations to address the tunica vaginalis are undertaken after an underlying PPV has been excluded.

**EPIDEMIOLOGY**

Inguinal herniae are much commoner in boys than girls (up to 9:1), commoner with increasing degrees of prematurity, and commoner on the right side (60%). Hydroceles, as stated above, commonly co-exist with herniae since peritoneal fluid is in communication with the scrotal portion of peritoneum as a consequence of PPV. Spontaneous resolution (probably in up to 90% of cases) is the rule. Rowe reported patency of the processus vaginalis as 60% during the first year of life, 40% in the second year. However, a PPV need not necessarily lead to a symptomatic hydrocele as demonstrated by adult postmortem studies.

Approximately 15% of inguinal herniae are bilateral. The issue of bilaterality has been the source of recent controversy, as it has been standard practice since the mid-1950s in some centers to explore the contralateral groin. The early descriptions of contralateral herniae reported incidence of contralateral hernia of up to 75%. More recent data have been at odds with this, and in two recent reports contralateral operation was required in 5.7% and 7.7% of cases. The likelihood of bilateral hernia increases with lower gestational age. A recent report asserts that in order to prevent one contralateral childhood hernia, 30 contralateral groins would require exploration, although for children born at 29 weeks gestation or less, that figure drops to 13. Based on this, many centers (including the authors’) no longer advocate the ‘routine’ exploration of the contralateral groin. Some authors have described the use of ultrasound, plain radiology with pneumoperitoneum at operation on one side, and laparoscopy (discussed later) to address diagnosis of an asymptomatic contralateral hernia.
Inguinal herniae are also associated with testicular maldescent, intersex conditions, and with more complex anomalies such as the exstrophy-epispadias complex.8

EMBRYOLOGY AND ANATOMY

The development and descent of the testis is inextricably linked to the development of herniae and hydroceles developing consequent on abnormalities of the processus vaginalis.9, 10 The descent of the testis can be considered a multistaged process under complex neurohormonal control; an enlarging gubernaculum first anchors the embryonic testis near the groin as the abdominal cavity grows. A peritoneal diverticulum (which evolves into the processus vaginalis) develops within the gubernaculum, and this complex migrates into the scrotum. Following the completion of testicular descent by the 38th week of gestation, the processus vaginalis obliterates between deep ring and upper pole of testis, leaving the testis clothed by a peritoneal layer then called tunica vaginalis. In girls, the processus vaginalis extends into the groin and thus into the labium majus as the ‘canal of Nuck’ in association with the round ligament of the uterus. The canal of Nuck seems to become obliterated earlier in the female than the processus vaginalis in the male (around the 7th month of gestation).

Incomplete obliteration (i.e. a PPV) allows communication of peritoneal fluid, as in a hydrocele, or visceral herniation. A schema considering this spectrum of problems is well described, and in summary is:10

- Wide open PPV throughout its length, allowing visceral herniation
- ‘Congenital’ hernia (Fig. 46.1A)
- PPV only in its proximal portion (‘funicular process’), lower end obliterated
- ‘Acquired’ hernia, which presents later (Fig. 46.1B)
- Narrow PPV throughout its length
- ‘Communicating’ hydrocele (Fig. 46.1C)
- Closed processus vaginalis above and below an encysted remnant
- Encysted hydrocele of the spermatic cord (Fig. 46.1D).

The hernial sac may be associated with viscera (the so-called ‘sliding’ hernia), and commonly this involves cecum (right), sigmoid colon (left) and bladder (both sides). Rarely, inguinal herniae do not involve the processus vaginalis, as in direct herniae. The etiology of these is less clear cut although at operation a deficient posterior inguinal canal wall may be identified.

Hydroceles likewise may occur as secondary events, usually due to intrascrotal pathology. Torsions of testes or testicular appendages, intrascrotal infection, and tumor all commonly give rise to hydroceles. It is also well recognized that acute systemic illnesses (which may, like Henoch-Schonlein purpura, cause orchitis) may give rise to acute hydrocele.

CLINICAL PRESENTATION

The key clinical difference between hernia and hydrocele is the ability to ‘get above’ a hydrocele. Classically the symptoms of a hernia are retold by the parents of the presence of a bulge arising in the groin, when the child cries or strains, descending into the

Figs 46.1 A to D: A. Wide open PPV throughout its length, allowing visceral herniation 'Congenital' hernia B. PPV only in funicular process, lower end obliterated, 'Acquired' hernia C. Narrow PPV throughout its length 'Communicating' hydrocele D. Encysted hydrocele of the spermatic cord
scrotum, reducing spontaneously or with manual assistance. A hydrocele is described as a testicular swelling that may not be related to the activities of the child but frequently waxing and waning over the course of the day. It may be bluish in color. A hernia may cause pain in various guises (‘ache’, ‘drag’, ‘burn’) whereas a hydrocele is rarely symptomatic.

On examination, the presence (or absence) of a testis is noted. A hernia if present is usually reducible with ease (with a characteristic palpable ‘squelch’), whereas a hydrocele generally is not. In girls, a gonad can descend into a hernial sac akin to a ‘lobster in a pot’. It may then present as a lump that the examiner can get above. A hydrocele generally transilluminates brilliantly, but it is worthwhile remembering, especially in infants, that the entire scrotum can be made to transilluminate, therefore this sign may not in itself be diagnostic.

Frequently, the signs are not obvious. A consistent history of a lump from child or parents may be the only clinical features of an inguinal hernia. The spermatic cord may be palpably thicker, with the peritoneal layers of a hernial sac felt to slide over each other in the ‘silk’ sign. A cough impulse is very difficult to elicit in younger children, and one maneuver is to rest (or ‘dangle’) the child, abdomen over a hand or arm to increase intrabdominal pressure and declare the hernia (Gornall’s sign).

Under the age of 1 year, the incarceration rate of an inguinal hernia is up to 30%, dropping to under 15% by the age of 18 months. An incarcerated hernia typically presents with a history of an unsettled crying child, sometimes with a history of vomiting, whence a lump in groin is then noted. The overlying skin may be reddened, edematous, and may be tender. Rarely, there may be frank evidence of intestinal obstruction with abdominal distension and bile stained vomiting, or there may be evidence of peritonitis.

A large inguinoscrotal hydrocele (or abdominoscrotal hydrocele) may rarely be mistaken for an irreducible hernia, since it may not be possible to identify its upper limit. Symptomatically however, it is rarely painful or tender (unless there have been repeated forceful futile attempts at reduction). Sometimes, the only means of differentiating between this and hernial incarceration is operatively.

In the neonate with meconium peritonitis, the scrotum may take on a black tinge, colored by the free meconium having passed via a PPV into the scrotum. In infants and children with a PPV, which need not have been symptomatic, intrabdominal sepsis (such as acute purulent appendicitis) may cause an acute pyoscutum. As mentioned above, intrascrotal pathology may cause a hydrocele de novo, in which case the history and examination findings are dictated by the underlying condition. In the setting of the acute scrotum, the underlying pathology will be demonstrated at scrotal exploration. Painless hydroceles, especially when associated with a palpably abnormal testis, must be imaged with ultrasound, since there may be an underlying tumor. A hydrocele in the absence of PPV or intrascrotal pathology is very rare indeed in children.

**MANAGEMENT**

Any reducible inguinal hernia, which presents in an outpatient setting, may be listed for elective repair. Infant herniae should be repair expediently because of the increased risk of incarceration. Herniae presenting in children on the neonatal intensive care unit should ideally be repaired prior to the child’s discharge, so that lung and other system maturation will have been optimized.

The inguinal hernia that presents incarcerated should be reduced with analgesia and (if required) sedation. Generally, gentle pressure (‘taxis’) in the direction of the neck of the hernia will bring about a successful reduction in the majority of cases. These herniae will generally have associated edema and it is probably best to allow this to settle for 24-48 hours prior to inguinal herniotomy. When a child presents with an acute abdomen, scrupulous attention to fluid resuscitation is necessary, even if the hernia is reduced successfully. The general state of the child is all the more crucial if operative reduction is required.

**Surgical Management**

**Consent**

The authors routinely explain the risk of vas and vessel damage with subsequent testicular atrophy, especially when a hernia has presented incarcerated. Other issues include risks of general anesthesia, wound infection, recurrent hernia, contralateral hernia, and ascending testis.
Anesthesia and Analgesia

It is usual to perform groin exploration for inguinal herniotomy under general anesthesia, although in ex-premature neonates with significant chronic lung disease, spinal anesthetic may be the modality of choice. At the authors’ institution, the use of caudal spinal anesthetic is routine, although some larger children undergo ilioinguinal nerve blockade as an adjunct to general anesthesia.

Operative Procedure

Approach through the Inguinal Canal

The prepared and draped groin in incised preferably along an appropriate crease. Care is taken to site the incision lateral to the pubic tubercle away from the fatty tissue of the mons pubis as this interferes with exposure. A convenient way of siting the incision appropriately is to palpate the course of the spermatic cord containing the hernial sac as it traverses the inguinal canal. The fatty layer of Camper’s fascia and fibrous Scarpas are divided along the line of the incision so that the underlying fibers of the external oblique aponeurosis are visible. Inguinal ligament and external inguinal ring are then identified.

The inguinal canal is entered either via a window created by a stab incision over the canal, widened to allow delivery of the cord, or by extending that incision to lay open the canal to the level of the external ring. The ilio-inguinal nerve can be identified and preserved. The cremasteric fibres running along the line of the canal must be split to reveal the shiny surface of the hernial sac associated with its spermatic cord. The cord is delivered, and holding the glistening sac cephalad along the line of the inguinal canal with a pair of forceps, the remainder of the cord contents are swept away gently from the sac (Fig. 46.2). It is usual to walk along the sac (perpendicular to its direction) whilst sweeping away vas and vessels until it has been defined circumferentially. Care should be taken to avoid picking up vas or vessels so as to lower the risk of crush-type injury to these structures.

When the sac has been isolated with confidence from vas and vessels, it should be dissected along its path to the internal ring, taking care not to loop or kink vas or vessel pedicle, and taking care not to tear what is frequently a very flimsy mesothelial layer: thin sacs in small babies which are edematous as a result of incarceration are especially easy to damage. The usual landmark to announce the peritoneal limit of this dissection is the appearance of extraperitoneal fat. The sac then needs to be sutureligated: it is the authors’ policy to use an absorbable suture such as vicryl, as nonabsorbable sutures have been seen rarely to cause chronic suppuration and suture granulomata.

A sac that is clearly empty may be merely twisted before transfixion. Any suspicion of hernial contents demands the sac be opened to inspect the contents and then reduce. Rarely, one aspect of the sac may comprise a visceral element (the so-called sliding hernia), commonly bladder or mobile bowel. It is safer to fashion a purse-string transfixion taking care not to catch the visceral component of a sliding hernia that can then be reduced. In girls, it is common to open the hernial sac in order to positively identify female internal genitalia, especially if the hernia is bilateral.

The deep ring and posterior wall in infants and children seldom need attention since the etiology is the processus vaginalis. However, with the presence of a very large hernia, the internal ring may become very large and the posterior wall lax. The benefit of plication of internal ring and posterior inguinal canal wall is contentious, but may be undertaken to guard against the risk of a potential direct recurrence. In girls, the internal ring is frequently closed as a matter of course, but in boys it is important not to jeopardise the vas and vessels as they traverse it.
The external oblique aponeurosis, Scarpas and Campers fasciae may be closed in layers, with a subcuticular layer under the skin.

It is imperative after the procedure to document the position of the gonads, since secondary maldescent or ascent of the testis is well described.

**Extracanalicular Approach**

The cord with its coverings may be identified easily, particularly in infants, as it emerges from the external inguinal ring. The sac may be dissected free of vas and vessels without opening the inguinal canal, although it must be remembered that more cord coverings will be encountered on the approach.

**The Preperitoneal Approach**

A hernia may be approached in this manner by incising external oblique above the inguinal canal and dissecting downwards to the internal inguinal ring. It may be a useful approach when dealing with an irreducible or obstructed hernia, allowing access to perform a laparotomy and, if necessary, intestinal resection. Some surgeons use this approach to perform reduction and laparotomy prior to a standard inguinal herniotomy performed through the inguinal canal.

**The Recurrent Inguinal Hernia**

This is a challenging problem, since the inguinal canal may well be encased in scar tissue. A useful approach through the old skin incision is to begin the dissection laterally onto the external oblique aponeurosis where the tissues are virgin. Careful dissection into the inguinal canal and subsequent identification of the sac, vas and vessels should be undertaken prior to completing the herniotomy as described. When taking consent it is important to reiterate the increased risk of vas and vessel damage during the dissection.

**HYDROCELE**

Operatively, a patent processus vaginalis causing hydrocele is approached identically to an inguinal hernia, since its anatomy is identical. Occasionally encysted hydroceles may be excised from the spermatic cord. The distal hydrocele should be drained through the PPV if possible, although direct needle aspiration is easy. Occasionally, a hydrocele may reaccumulate. A pre-emptive approach during herniotomy or division of the PPV is to extend the opening in the distal sac down as far as safely possible. Very rarely, a hydrocele may recur because of recanalisation or incomplete division of the processus vaginalis and requires re-exploration of the groin. Local procedure such as eversion, excision, or plication of the tunica vaginalis may be employed additionally.

**COMPLICATIONS**

Inguinal herniae require operation, since they risk incarceration. As stated above under the age of 1 year, the incarceration rate of an inguinal hernia is up to 30%, dropping to under 15% by the age of 18 months. Incarceration jeopardises the testis and the incarcerated contents of the hernial sac.

Testicular atrophy is described to occur in around 2% of boys who present with an incarcerated hernia. Visceral injury is less common. At operation for an irreducible hernia one must suspect intestinal compromise and carry out a laparotomy if needed. Scrupulous attention must be paid to preoperative resuscitation of a child with an irreducible hernia requiring surgery. Reduction of an incarcerated hernia is achieved preoperatively much more frequently in children than in adults, in whom ‘reduction en masse’ is a concern. This entity is rare in children, but may be considered in a child whose symptoms and signs fail to settle after reduction. In the female ‘lobster in a pot’ hernia whereby an ovary becomes incarcerated in the groin, the trapped gonad is said to be at increased risk of torsion.

Anesthetic-related complications are now rare with more specialisation in pediatric and neonatal anesthesia. There remains a significant risk of postoperative apnea in infants however, especially the ex-premature population. For this reason it is usual to observe the ‘at risk’ group of babies overnight after an inguinal herniotomy. Other postoperative complications of inguinal herniotomy include wound infection, scrotal hematoma, injury to the vas and vessels, recurrent hernia, and iatrogenic ascent of the testis.

Generally wound infection rates are of the order of 1-2%. Prophylactic antibiotics are probably not beneficial and their use is not routine at the authors’ institution. Bleeding at the time of operation is uncommon, and is usually caused from cremasteric
fibers. Rarely it can be from vessel puncture (inferior epigastric or femoral vessels) at the time of plication of the posterior wall or the floor of the inguinal canal. The distal (transected) aspect of the hernial sac, which is usually left in situ, may ooze to contribute to a scrotal hematoma, especially if the hernial sac is inflamed and friable after incarceration. Hemostasis with bipolar diathermy is effective, but vigilance for bleeding and scrupulous technique is also important.

Injury to the vas and vessels is rare (less than 1%). In case of division of the vas, interrupted 7/0 or 8/0 monofilament sutures are placed circumferentially to fashion an end-to-end vasovasostomy. Microvascular anastomosis, when the vessels are divided, is a precise and demanding procedure requiring optical magnification for satisfactory results and is therefore, best undertaken by appropriately trained surgeons.

Recurrent hernia is uncommon, overall rate around 1% or less. The rate of recurrence for neonatal repair is higher. When recurrences occur, they are generally seen within the first postoperative year. Important causes are missed or torn hernial sacs (thus attention to dissection of the sac in its entirety is important), injury to the floor or posterior wall of the inguinal canal (direct hernia), bleeding and infection. Rarer causes such as connective tissue disease should be borne in mind.

Subsequent abnormalities of the testis are well recognised. Atrophy may be seen as a result of incarceration as described above, but decrease in testicular volume has been noted in some patients: the significance of this is unclear. Iatrogenic ascent of the testis has also been recognised in about 1% after inguinal herniotomy. Occasionally a hydrocele develops after herniotomy: it usually settles without intervention but sometimes requires a scrotal procedure or rarely re-exploration of the groin to exclude a ‘recurrent’ PPV.

Rarer complications include suture granulomata, which may present years after operation, and direct visceral (e.g. bladder and bowel when involved in sliding herniae) or vascular injury.

In infant age group, complications of inguinal herniae or herniotomy are commoner than in older children. This probably has implications for more rigorous follow-up of infants undergoing inguinal herniotomy.

### NOVEL APPROACHES

Laparoscopy is becoming increasingly popular in its applications in most aspects of pediatric surgery. In adults, laparoscopy has become established as a reliable means of inguinal herniorrhaphy using a mesh placed at the internal inguinal ring by either trans- or pre-peritoneal approach. Some authors have described laparoscopy in inguinal hernia in children for diagnostic and/or therapeutic means. An angled telescope can be passed with ease through an open hernial sac, although the more traditionally placed paraumbilical port allows both sides to be visualized.

Laparoscopic assessment is crucial if there is associated impalpable testis. Laparoscopic herniotomy with purse-string sutures placed at the inguinal ring has been described.

Finally, there are evolving possibilities of manipulating the mechanisms, which normally cause obliteration of the processus vaginalis. In vitro, calcitonin-gene-related peptide (CGRP) has been demonstrated to cause cellular fusion within the processus. Together with hepatocyte growth factor (HGF), it contributes to transformation of peritoneal mesothelium into mobile mesenchymal cells. The role of CGRP in testicular descent in other species has been characterised, its source probably being the genito-femoral nerve. The work on basic biology of the processus vaginalis raises exciting future possibilities for the nonsurgical treatment of herniae and hydroceles.

### ACKNOWLEDGEMENT

The authors are grateful to Miss Katie Midwinter, FRCS, for the illustrations.

### REFERENCES

All pediatric surgeons are well versed with the repair of congenital inguinal hernias. However, there are times when they are confronted with rare hernias. Rare forms of the inguinal hernia are encountered more frequently when approached by the laparoscopic technique than during the open approach. Routine video recording during laparoscopy provided an objective and absolute picture of the true incidence of these unusual forms of the hernia. On retrospective evaluation of these videos, direct hernias were found in 2.2%, femoral hernias in 1.1%, hernias en pantalon in 0.7% and a combination of indirect, direct, and femoral hernia in 0.4% cases.

**FEMORAL HERNIA**

Femoral hernia is very rare in children and its diagnosis remains a challenging problem in childhood. The incidence is 0.5-1% of all cases of pediatric groin hernias. Femoral hernias are seen more frequently in girls.

In case of the femoral hernia, the defect is through an anatomic triangle surrounded by the inguinal ligament above, the lower border of the pubic bone medially and the femoral vein laterally. The hernia follows the space below the inguinal ligament through the femoral canal. The canal lies medial to the femoral vein and lateral to the lacunar ligament. A femoral hernia is more prone to incarceration or strangulation as it protrudes through a narrow neck.

The swelling during its last part of reduction may be seen to reduce through a defect inferior to the inguinal ligament. The diagnosis is confirmed during operation.

Femoral hernias occur at any age, but are extremely rare in infancy. The hernia is more common on the right side. The duration of symptoms may range from a few days to many years. A correct diagnosis can only be made preoperatively in only 12-70% of the cases, in different series. Childhood femoral hernia is often missed clinically because of difficulty in eliciting their clinical signs.

The most common mode of presentation is a recurrent painless lump in the upper part of the groin on the medial side of the thigh. The swelling reduces with manual compression. If the swelling persists even after the repair of the inguinal hernia, the diagnosis should be revised and the possibility of femoral hernia should be kept in mind. The femoral hernias may be diagnosed during surgery at a negative exploration for a clinically diagnosed inguinal hernia. During an operation for inguinal hernia, it is essential to think of the presence of the femoral hernia when a non-obliterated processus vaginalis is not found. Rarely, the child may present with an incarceration. The rate of irreducible femoral hernia may be quite high (48%).

The differential diagnosis is either an inguinal hernia or a recurrent inguinal hernia. An irreducible femoral hernia needs to be differentiated from the inguinal lymph nodes.

The sensitivity of high resolution ultrasonographic (USG) study in the diagnosis of inguinocural hernias has been reported to be higher (87.5%) than that of the clinical examination (72%). Similarly, the sensitivity in the diagnosis of complications in these hernias was reported to be significantly high on high resolution USG (85%) as compared to clinical examination (36%). A femoral hernia should
positively be excluded if the operative findings at inguinal exploration are inconsistent with the preoperative signs and in any child with a suspected recurrent inguinal hernia.

**Repair**

Femoral hernia has been treated using a variety of techniques such as classic tissue-based and prosthetic mesh repairs. In children, an excision of the sac and repair of the femoral canal is curative. The operation can be done from above or below the inguinal ligament. The author's approach is to repair the femoral hernia with a transverse incision placed below the inguinal ligament. As the sac carries with it a good amount of femoral fat, the sac needs to be separated well and identified from the fatty tissue before closed securely.

In McVay's tissue-based repair, the Cooper's ligament is approximated with the conjoined tendon, through an inguinal incision placed just above the medial side of the inguinal ligament. This type of hernia repair results in an unwanted tension. The Cooper's ligament is though strong yet it lacks the elasticity. Therefore, sutures may cut through the tissues in the postoperative period. McVay's Cooper ligament repair with the advantage of covering all potential hernia sites in the myopectineal orifice has been used to repair the femoral hernias in children. Authors have not experienced any recurrence after surgical repair of the femoral hernia with the approach below the inguinal ligament.

The well-known advantages of tension-free hernia repair led to the development of new techniques for femoral hernia repair using prosthetic material. In 1974, Lichtenstein and colleagues have described 'plug' technique for femoral hernia repair with a recurrence rate less than 2%.

Recently, femoral defect has been repaired successfully in children using a mesh plug. There were no complications after a follow-up period for 2 years.

In a series of 712 inguinal hernias in 542 children, repaired laparoscopically, direct hernias were found in 2.3%, femoral hernias in 1%, hernias en pantalon in 0.7%, and a combination of indirect and femoral hernia in 0.2%.

Laparoscopic groin exploration and femoral hernia repair has some distinct advantages. The procedure is safe and effective even in the pediatric patients. The advantages of the laparoscopic approach include its technical ease, feasibility as an outpatient procedure, cord structures remaining untouched, the superior diagnostic ability, simultaneous repair of the bilateral hernias and clear visualization of the anatomy.

The incidence of postoperative recurrence varies from 0-13% in different series. A correct preoperative diagnosis will lead to appropriate surgical approach and management, thus avoiding the unnecessary morbidity and preventing unnecessary re-operations.

**RICHTER’S HERNIA**

A richter is hernia is defined as a herniation of the antimesenteric border of the bowel through a fascial defect.

As only a portion of the circumference of the bowel is involved, the bowel may not be obstructed, even if the hernia is incarcerated or strangulated, and the patient may not present with obstructive symptoms. Richter’s hernia can occur with any of the various abdominal hernias and is particularly dangerous, as a portion of strangulated bowel may be reduced unknowingly into the abdominal cavity, leading to perforation and peritonitis. The patient may complain of pain or have tachycardia and fever due to the strangulation.

**LITTRE’S HERNIA**

This term is given to herniation of the Meckle's diverticulum through an inguinal hernia. It is extremely rare to happen. A Littre's hernia is defined as any hernial sac which contains a Meckel’s Diverticulum. It has been reported in association with inguinal, umbilical, femoral, sciatic, ventral, and lumbar hernias. This hernia is rare, particularly in children, in whom the umbilical hernia is reported to be the most common variety. Littre's hernia is difficult to diagnose, but should be suspected in patients with gastrointestinal bleeding, incompletely reducible hernias, and hernias with fecal fistulae. It may be confused with cryptorchidism when Meckel's diverticulum adheres to and envelops the testicle making palpation of the gonad difficult.

The recommended treatment is resection of the Meckel's diverticulum from within the opened hernial sac followed by herniorrhaphy.
VENTRAL HERNIA

This is commonly seen in children as follow-up of conservatively managed abdominal wall defects. The hernia size may be small or large, with a narrow or wide neck (Fig. 47.1). The contents are small bowel loops but liver may also be projecting out in the sac if the size of the hernia is more than 5 cm in diameter. The contents are usually not reducible completely as there are dense adhesions between the under surface of the skin and liver or the intestine. The rectus muscles are wide apart, thinned out and weak, forming the neck of the hernia. All ventral hernias should be repaired, preferably before 1 year of age so that the contents can be reduced and the rectus muscles can be approximated in the midline. With this, the abdominal cavity also gets a chance to grow with the age of the patient. Various options available to repair the ventral hernia include:

**Primary Repair of the Defect**

after reducing the hernial contents inside the abdominal cavity (Fig. 47.1). In case of difficulty in bringing the muscles together in the midline, additional techniques may be adapted and these include; stretching or the mobilization of the abdominal wall from lateral sides, raising of the anterior rectus sheath vertical flaps on one or both sides and suturing these together in front of the intestine. In cases of anticipated difficulty in closing the hernia, a slow pneumoperitoneum may be introduced to increase the size of the abdominal cavity well in advance.

**Moderate Sized Defects**

Prolene mesh prosthesis may be used to fill the gap between the rectus muscles if these cannot be approximated. The available skin is used to cover the mesh. If the same is not sufficient to cover the defect, alternate materials like dura, pericardium, cultured skin are used till the complete healing of the wound takes place. The mesh is removed after many months or years when the abdominal cavity has grown in size and the rectus muscles can be brought together in the midline.

**Phantom Hernia**

The size of the ventral hernias may be so huge that the abdominal cavity never got a chance to grow, and all the abdominal contents remained in the sac and grew outside the abdomen. It is thus impossible to reduce the hernial contents into the abdominal cavity due to lack of space (Figs 47.2A and B). Such cases should first be investigated for evaluating the position of great vessels, the kidneys and the liver by CT/MRI and nuclear scans. The management should be staged; first allowing the skin from lateral abdominal wall to enlarge in size with the use of tissue expanders, then the hernia is repaired with or without the mesh to bridge the gap between the rectus muscles.

In neglected cases, a severe lumbar lordosis may well become an alternative factor to produce visceroadominal disproportion observed before surgery, and its correction after surgery may well induce the abdominal cavity to rapidly enlarge. It may be speculated that the dehiscence of abdominal rectus muscles associated with omphalocele causes the tension of ventral muscles to decline and then, imbalance in tension between ventral (abdominal) and dorsal (back) muscles causes the lumbar lordosis to increase. Thus, during the staged procedure, the prosthetic sheet should be attached under moderate tension, and its plication should be carried out at regular intervals to maintain the tension of abdominal rectus muscles.

**INCISIONAL HERNIA**

Iatrogenic hernia in general, occurs in 2-10% of all abdominal operations secondary to breakdown of the
fascial closure of wound to the prior surgery. Even after repair, recurrence rates approach 20-45%. However, its incidence of incisional hernia in children is much lower due to good muscle strength, better wound healing ability and the routine practice of skin crease incisions.

While having an access to the kidneys, the intercostal nerve which lies posteriorly immediately below the last rib in between the internal oblique and the transverse abdominal muscles, an effort should be made to spare this nerve by dissecting both proximally and distally, enabling careful padding and traction of the nerve out of the operative field. The division of the nerve leads to muscle denervation and lumbar hernia. Postoperatively, the muscle denervation leading to the flank bulge must be differentiated from the flank incisional hernia, which is rare. In the later instance, a fascial defect is usually palpable. Most importantly, wound infection accounts for the majority of incisional hernias.

**SPIGELIAN HERNIA**

This rare form of abdominal wall hernia occurs through a defect in the spigelian fascia, which is defined by the lateral edge of the rectus muscle at the semilunar line (from costal arch to the pubic tubercle).

**LUMBAR HERNIA**

Lumbar hernias are also known as posterior body wall hernias (Figs 47.3 and 47.4). Congenital lumbar hernia is a rare anomaly with only 45 cases reported in the English-language literature. Hernias in the lumbar region are classified as; (1) Those through the superior lumbar triangle (of Grynfelt-Lesshaft) and (2) Those through the inferior lumbar triangle (of Petit). Superior lumbar hernias are more commonly reported. However, some series have reported a relatively high incidence of inferior lumbar hernia.

**Hernia through the Superior Lumbar Triangle (of Grynfelt-Lesshaft)**

It is an inverted triangle, larger in size, more constant, most common site of lumbar hernia, contains T12 and L1 nerves and is avascular. A superior lumbar hernia is a protrusion of preperitoneal fat or peritoneum with sac formation or a viscus through the lumbar area just below the 12th rib.

The base of the triangle is the 12th rib and serratus posterior inferior muscle. The anterior boundary is the posterior border of the internal oblique muscle, posterior boundary is the anterior border of the sacrospinalis muscle. The floor of the triangle is formed
Fig. 47.4: The lumbar hernia in a child, with a circular defect in the abdominal wall muscles. The defect was repaired primarily with success by the aponeurosis of the transversus abdominis muscle arising by fusion of the layers of the thoracolumbar fascia formed by the external oblique and latissimus dorsi muscles.

**Hernia through the Inferior Lumbar Triangle (of Petit)**

The base of the triangle is the iliac crest. The anterior (abdominal) boundary is the posterior border of the external oblique muscle. The posterior (lumbar) boundary is the anterior border of the latissimus dorsi muscle. The floor of the triangle is formed by the internal oblique muscle with contributions from the transversus abdominis muscle and posterior lamina of the thoracolumbar fascia and the internal oblique muscle. The triangle is covered by superficial fascia and skin. This is smaller in size, least common site of lumbar hernia, contains no nerves but is vascular. If the hernia through this triangle is small the ring is formed by the thoracolumbar fascia and fibers of internal oblique muscles. If it is large, the ring may include the boundaries of the whole inferior triangle. Enlargement of the ring is by section of the fascia.

**Associated Anomalies**

Congenital variants have been described, frequently associated with musculofascial and skeletal abnormalities, specifically “lumbocostovertebral syndrome” and/or meningomyelocele (Figs 47.5A and B).19 The defect results from a single somatic defect occurring during the third to fifth week of embryonal development. As there are various reports on its association with the lumbocostovertebral syndrome, a spinal X-ray and/CT scan may be done to rule out the additional defects.20-22

Meningomyelocele may predispose to lumbar herniation secondary to abnormalities in muscular innervation related to nerve entrapment in the spinal dysraphism.19

The lumbar hernias may also be associated with the defects in the thoracic cage. The associated anomalies of the ribs and the vertebrae may be extensive and large enough for the liver, lungs, kidney and spleen (left sided) to herniate outside. There may
be paradoxical breathing resulting in respiratory distress, especially in the newborns (Figs 47.6A and B). The large defects involve absence, deficiency, twisting, widening, deformity and the fusion of the remaining ribs. On the right side, the defect may be covered with a large right lobe of the liver and may remain asymptomatic. However, as the important structures in the hernia sac remain unprotected and remain at risk to trauma, a surgical repair at an appropriate time is warranted. The closure of the defect involves approximation of ribs and the muscles as much as possible it could be done comfortably. The remain defect should be closed with a mesh. If the defect is small and less than 5 cm in diameter, there is no problem with the paradoxical breathing and no stabilization is required. However, large defects, more than 5 cm in size require stabilization of the chest. This could be accomplished by utilizing the available deformed, flat and fused ribs to shape them appropriately by splitting, twisting or angulating them to support the mesh graft.

The hernia may be an isolated defect in the lumbar region, well circumscribed or it may be associated with hydrometrocolpos, meningomyelocele, anorectal malformation, undescended testis and multiple other anomalies. The diagnosis of the hernia may be delayed due to its juxtaposition to a posterior meningomyelocele and may result in incarceration. Acquired lumbar hernia generally can be attributed to surgery.
infection, or trauma. Localized neuropraXis, temporary or permanent, may be the underlying factor, common to all these defects. Lumbar hernia associated with intrathoracic neuroblastoma have also been reported. The lumbar hernia is also reported to have resulted from neuropraXis secondary to intrathoracic paravertebral tumor and its management. In both cases, this deficiency was temporary and resolved without specific therapy. These cases suggest a role for conservative treatment for the hernia itself, when the neural impairment resulting in the defect is of a temporary nature.19

Investigations for a lumbar hernia include ultrasonography, barium enema and small bowel contrast studies to rule out hydronephrosis or renal lump; bowel content, etc. A dorsal and lumbosacral X-rays may be done to rule out vertebral pathology.

REPAIR

Early operation is the treatment of choice, and repair with local tissues is preferable.17 The need for prosthetic material arises when the size of the defect is more than 5 cm in diameter and the defect cant be closed primarily.17 A successful operation by mobilization and approximation of the muscle edges offers a good quality of life.17 Operative repair is recommended for these patients before 12 months of age.18

The repair is done with the patient in the lateral kidney position with the hernia side up. The affected flank is extended by extension of the ipsilateral lower extremity and flexion of the opposite extremity at the knee. The choice of the repair material depends upon the size of the defect. For small defects, the defect in the thoracolumbar fascia and muscles is repaired with nylon. For large hernias, a flap graft or a mesh (single or double) or both may be used. The authors have rotated the distal ends of the 10th and 11th ribs to support the thin muscular repair in a case of large defects.

Dowd-Ponka Repair of Lumbar Hernia23

An oblique or vertical incision is given over the hernia site. In superior hernia, the sac lies beneath skin, superficial fascia, and latissimus dorsi muscle. In inferior hernia, there is no layer of muscle. The hernial sac, if present, is ligated with silk (3-0) and replaced in the abdomen. If a large lipoma is present, a purse-string suture or several interrupted sutures will keep the fat down. A Marlex or Prolene patch is placed over the defect and sutured to the external oblique and latissimus dorsi muscles and lumbar periosteum using interrupted nylon/prolene.

The external oblique and latissimus dorsi muscles are approximated over the Marlex patch as far as possible without tension. A flap of gluteal fascia is turned up to cover the remaining defect and secure it with interrupted nylon sutures to the muscles present. A large hernial ring may require a second layer of Marlex mesh sutured to the muscles.

INTERNAL HERNIAS IN THE ABDOMEN

Internal abdominal hernias are uncommon varieties of hernias. These are difficult to detect and also remain mostly asymptomatic. They have confusing anatomy and obscure etiology. They account for about one percent of all cases of intestinal obstruction.

Two types of internal hernias may be encountered:
1. The passage of a viscus through a defect either in a mesentery or the omentum.
2. Protrusion of a viscus through an opening formed by a fold of peritoneum.

Hernias through Mesenteric or Omental Defect

These have been called ‘false hernias’ as there is no hernial sac. All mesenteries in the abdominal cavity are subject to defects through which herniation may take place. These defects may be developmental or as the result of trauma. The chief locations are through the mesentery, greater omentum, sigmoid mesocolon, broad ligament of the uterus or the falciform ligament. Paraduodenal herniation is the most common.24 These hernias are asymptomatic unless incarcerated. The frequency of internal herniation is given in Table 47.1.

mebooksfree.com
The hernia may start in the relatively avascular areas of the mesentery. The defect then enlarges until at least one free edge is formed by an important artery. It is usually a branch of the superior or the inferior mesenteric artery. In many cases, an intestinal loop may pass freely through the defect without any strangulation. However, adhesions may develop between the hernial ring and the herniated intestinal loop, making it vulnerable to symptoms due to strangulation.

Omental herniation can occur between arc of Barkow and any of the descending arteries. For the repair, the ring is enlarged between clamps. The omentum is incised and the bowel is freed. The hernia is reduced and the clamped tissue is suture ligated. The defect in the omentum must be closed with continuous or interrupted sutures to prevent recurrences. Decompression of the proximal intestine without incising the ring may also permit reduction of the herniated loop and closure of the omental defect.

Rarely the loops of the small bowel, appendix, cecum, and the ascending colon may be placed within the anterior and posterior leaves of the un-fused greater omentum. Appendectomy and the resection of the sac should be performed to achieve successful outcome. Embryologically, anatomically and clinically, the intra-mesenteric hernias may take place in any part of mesentery that has congenital openings or pouches. Hernia at the terminal ileum (pouch of Treves’) is one such example. It may enlarge to house the intestinal loops in the pouch.

Mesenteric herniation takes place through defect in mesentery of small intestine, transverse mesocolon and most commonly the sigmoid mesocolon. At least one free edge of the ring is usually formed by a branch of the superior mesenteric or the inferior mesenteric artery. Since there is no sac, the obstructed loops are clearly visible. Any injury to the vessel at the edge of the defect must be avoided. The dilated loop needs to be decompressed first before reducing the hernia. The vascular injury must be avoided.

**Hernias beneath a Mesenteric or Peritoneal Fold**

In this second group of internal hernias there is no break in the peritoneum, the herniated viscus enters and enlarge a naturally occurring fold or pocket of peritoneum. A sac is always present.

A. **Hernia through the epiploic foramen of Winslow**: For unknown reasons, this hernia is extremely uncommon in children despite of the fact that the epiploic foramen is normally open. The boundaries of the foramen are; superiorly the caudate process, anteriorly the hepatoduodenal ligament containing portal triad, posteriorly the inferior vena cava and inferiorly the first part of the duodenum and the transverse part of the hepatic artery. The neck of the ring should not be incised under any circumstances. To reduce the hernia, the hepatogastric ligament is opened and the incarcerated intestine is decompressed carefully taking all care not to allow contamination. After the decompression of the bowel has been achieved, the aspiration site is closed with a purse string suture. The hernia is reduced and the defect in the hepatogastric ligament is closed. Fixation of an abnormally mobile cecum or right colon may be helpful to avoid recurrences.

B. **Hernia through the transverse mesocolon**: The herniated loop enters lesser sac to the left of the middle colic vessels called space of Riolan.

C. **Paraduodenal hernias**: Abdominal cavity is full of pouches and fossae. Moynihan in 1889 described nine fossae or peritoneal pockets which form potential spaces for internal herniations. Only five of these fossae are constant enough to be of clinical importance and have been outlined below in Table 47.2. These hernias, though rare, have been reported in children.

Paraduodenal hernias are formed during the period of fixation of colon (by 5th month of the fetal life). They are known by the direction of the herniated loop, if the loop passes to the right, it is a right paraduodenal hernia; without reference to the midline of the body or to the specific fossae concerned. Paraduodenal sacs usually contain...
small intestine, though rarely may contain cecum, ascending colon or sigmoid colon. The surgical treatment of strangulated paraduodenal hernia includes the reduction of the hernia and the eradication of the fossa. This may be performed either by closing the neck of the fossa or by enlarging the orifice so that there are no chances of the pouch formation. Injury to major blood vessels must be avoided. Enterostomy may be required for decompression of the contents of the hernia. The herniated contents should be looked carefully for the viability and an appropriate action should be taken if the need be.

D. The paracecal hernias: Six fossae are related to the cecum.
   1. Superior ileocecal fossa
   2. Inferior ileocecal fossa
   3. Retrocecal or retrocolic fossa
   4. Hartmann’s fossa
   5. Paracolic fossa
   6. Iliaco-subfascialis.

Out of these, first two are important. Superior ileocecal fossa is formed by superior ileocecal fold of ileocolic mesentery and contains the anterior branch of the ileocolic artery. The inferior ileocecal fossa has an anterior prominent ileoappendicular fold which occasionally contains the ileoappendicular artery. The hernial sac may be found under the cecum.

COMPLICATIONS

Rare hernias through narrow necks like femoral hernia and internal hernias are prone to complications if not identified and treated in time once the symptoms appear. The reason being rarity of the lesion, the abnormal sites and the difficulty in making the diagnosis without surgery. Hernias visible outside the abdominal cavity may be examined for risk of complications. Reducible hernia refers to the ability to return the contents of the hernia into the abdominal cavity, either spontaneously or manually. An incarcerated hernia is no longer reducible. The vascular supply of the bowel is still not compromised, though the symptoms due to bowel obstruction are common. A strangulated hernia when the vascular supply of the bowel is compromised secondary to incarceration of hernia contents, poses a serious challenge.

Complications following repair of the hernia are many and most are avoidable. These include;

1. Vascular complications like seroma or hematoma formation though uncommon in children, still can happen rarely. Main vessel may also be injured if it is included in the clamp while widening the neck of the sac.
2. Neurological injury of the nerves may occur in the close proximity, e.g. T12 or L1 nerves during repair of a lumbar hernia through the superior lumbar triangle.
3. Injury of the hollow viscus (most likely the colon) is likely to happen if the hernia is incarcerated or is of a sliding type. This is likely to happen during the opening of the sac, or by taking deep bites of the protruding fats.
4. Recurrence of the hernia is likely to occur if the anatomical details have not been kept in mind while making a diagnosis or repairing the defect.
5. Infection of the wound or even peritonitis, is a serious threat if the bowel gets injured during surgery.

REFERENCES

Intra-abdominal infections have been well recognized throughout the history of medicine and are very commonly encountered in pediatric surgical practice. This is especially so in developing countries like India where the incidence of infective gastrointestinal diseases and their sequelae is very high. Improvement in outcome and reduction in mortality to 10-20% today is largely due to better supportive care, improved and effective antibiotics, widespread application of ultrasonography and computed tomography to localize intraperitoneal collections and improved interventional techniques. However, mortality persists with patients succumbing to the effects of sepsis and eventual multisystem organ failure (MSOF). The single most influential factor in successful treatment of intra-abdominal infections is early prompt diagnosis and effective treatment, and for this, a thorough knowledge of the pathophysiology of peritonitis and the application of the various diagnostic and therapeutic options available is essential.

**ANATOMY AND FUNCTION OF THE PERITONEAL CAVITY**

The peritoneal cavity consists of the greater and lesser sacs, which communicate via the foramen of Winslow. Within the greater sac, compartmentalization by various ligaments and retroperitoneal attachments creates sites of fluid accumulation and subsequently, abscess formation. These include the right subhepatic space, the right and left subphrenic spaces, the paracolic gutters, and the pelvis (Fig. 48.1). Posteriorly, the right subhepatic space opens into the Morrison's pouch, one of the most dependent spaces in the peritoneal cavity, making it a likely site of fluid accumulation and abscess formation.

The peritoneum consists of a single layer of mesothelial cells, with a basement membrane supported by an underlying layer of highly vascularized connective tissue. The total area of the peritoneum is approximately 1.8 m² in the adult; proportionately lower in the child. The mesothelial cells contain microvilli 1.5 - 3.0 μm in length, which greatly increase the surface area of the mesothelial cells. A 1 mm increase in thickness of the peritoneum by fluid can result in sequestration of large volumes of fluid, explaining the massive fluid shifts associated with diffuse peritonitis. The peritoneal membrane can be divided into two parts: *visceral*, surrounding and lining the viscera and *parietal* which lines the posterior peritoneum.
aspect of the anterior abdominal musculature and also lies superficial to the retroperitoneal viscera, including the aorta, vena cava, ureters and kidneys. The parietal portion is richly supplied with nerves and when irritated, causes severe pain localized to the affected area. The visceral peritoneum in contrast is poorly supplied with nerves and its irritation causes vague pain which is usually located to the midline.

One half of the peritoneum, about 1 m², functions as a passive semipermeable membrane to the diffusion of water, electrolytes and macromolecules. Under normal circumstances, the peritoneal cavity is largely a potential space, as only a thin film of lubricating fluid separates the parietal and visceral layers. This fluid itself closely resembles lymph fluid and has a low specific gravity, protein content of about 3g/dL and < 3000 cells/cu mm. This fluid is circulated through the peritoneal cavity and this movement of fluid is largely produced by the creation of a negative pressure area in the subphrenic space by diaphragmatic motion. This upward movement of peritoneal fluids is responsible for the occurrence of many subphrenic abscesses. Most of the peritoneal fluid is absorbed into the lymphatic circulation via the mesothelial lining of the parietal peritoneal surfaces, with the remainder absorbed through diaphragmatic lymphatics. Mesothelial cells also absorb solutes by the continuing process of endocytosis. Exchange of solutes across the peritoneal lining is the basis for peritoneal dialysis. The clearance of particulate matter, cells and microorganisms contained in peritoneal fluid may however be largely dependent upon diaphragmatic lymphatics. In the peritoneum overlaying the muscular portion of the diaphragmatic surface, intercellular gaps or stomata are present between peritoneal mesothelial cells. The diameter of these stomata varies from 4 - 12 μm depending on diaphragmatic stretching and contraction. Fluid as well as particulate and other substances are channeled via the stomata through fenestrations in the basement membrane and carried to specialized diaphragmatic lymphatics called lacunae. During the respiratory cycle, relaxation of the diaphragm in expiration opens the stomata and promotes rapid filling of the lacunae. At inspiration, contraction of the diaphragm empties the lacunae into efferent lymphatic channels and ultimately to the central circulation via the thoracic duct. As shown by animal experiments, this process of fluid movement and particulate clearance via the diaphragmatic lymphatics is rapid.

Several factors can influence the diaphragmatic clearance mechanism or “pump”. Animal experiments show that introduction of platelets or other agents into the peritoneal cavity can occlude the stomata. Body positioning can also influence the effectiveness of diaphragmatic clearance and the head-up position has been found to delay the appearance of bacteria in the circulation after intraperitoneal injection. Reducing spontaneous respiration by the application of muscular paralysis and mechanical ventilation has been observed to decrease particulate clearance from the peritoneal cavity and lower the incidence of bacteremia. These effects result from chemical paralysis of the diaphragm and elimination of the “pumping mechanism”, as well as the application of positive intrathoracic pressure that impairs thoracic lymphatic flow. Although this diaphragmatic “pump” mechanism is an effective local defense mechanism, its benefit in terms of host survival is uncertain. Both animal and human studies have shown that the incidence of bacteremia and mortality were reduced when the diaphragmatic clearance of bacteria was impaired. It is possible that the local clearance and carriage of bacteria into the systemic circulation may overwhelm systemic defenses and paradoxically increase mortality.

LOCAL RESPONSE TO PERITONEAL INJURY OR INFECTION

The objective of the local response to infection is the removal or containment of microorganisms from the peritoneal cavity. This response however, can be initiated by any noxious stimulus that causes mesothelial or vascular endothelial cell injury. It has been shown that similar local physiological effects can be produced by endotoxin as well as by organisms such as gram-positive bacteria, Bacteroides species, and yeasts that have no endotoxin, or only biologically inactive forms of endotoxin. It is likely that the overall inflammatory response, both local and systemic is a general one, and not specific for any single infective agent. The systemic response is mediated by cytokines such as tumor necrosis factor (TNF) and interleukin-1 (IL-1). A similar sterile peritonitis can in fact, be initiated by noninfective agents such as gastric juice, pancreatic juice, bile salts or meconium.
In addition to mechanical clearance of bacteria via lymphatics, the local peritoneal inflammatory process consists of (i) changes in blood flow and vascular permeability with influx of fluid, (ii) cellular immune response, and (iii) fibrin deposition and mechanical sequestration.

**Changes in Blood Flow and Vascular Permeability**

The earliest physiological changes are an increase in blood flow and an influx of fluid to the foci of inflammation. These are mediated by histamine released from tissue mast cells and basophils, and later by bradykinin. Both histamine and bradykinin cause pain, vasodilatation and increased permeability of the small peritoneal blood vessels. Other vasoactive substances such as prostaglandin E2α (PGE2α) and leukotriene C4 (LTC4) also contribute to the observed vascular changes. The initial fluid that accumulates is a transudate with low protein content. Later however, with increasing vascular permeability, there is exudation of large volumes of fluid rich in immunoglobulins, complement factors, coagulation factors and cytokines. This massive third space fluid-shifts and loss of plasma proteins can lead to hypovolemic shock and in addition, may impair bacterial phagocytosis by diluting opsonins and impeding neutrophil mobility and migration.

**Cellular Response**

Several major cell types play key roles in the inflammatory response. These include resident and recruited macrophages, mesothelial cells, adjacent capillary endothelial cells, and recruited neutrophils. Several humoral mediators are involved in activating both macrophages and neutrophils, modulating leukocyte metabolic activity, chemotaxis, and opsonization of bacteria. The first step in the response to contamination is probably induced by a host response to microbial cell products. In the case of gram-negative organisms, this is most likely lipopolysaccharide (LPS). For gram-positive organisms, the cell wall product teichoic acid and specific cell wall glycans induce a macrophage response. Macrophages serve as an early line of cellular defense and coordinate the inflammatory response. Macrophage products include IL-1, IL-6, IL-8, IL-10, IL-12, TNF-α, GM-CSF, granulocyte colony-stimulating factor (G-CSF), monocyte chemoattractant protein-1 (MCP-1), monocyte inflammatory protein a (MIP-a), and several eicosanoids. These molecules recruit and activate mesothelial cells as well as mediate macrophage microbicidal activity. Mesothelial cells produce a variety of inflammatory molecules that recruit additional cells to the peritoneal cavity and activate them there. These cells also secrete IL-8, a neutrophil chemoattractant and activator as well as various adhesion molecules.

Neutrophils are the key effector cells in the inflammatory response and possess an array of granular enzymes that are capable of digesting basement and interstitial proteins, facilitating directed migration and allowing for digestion of injured tissue. Although C5a anaphylotoxin possesses the most potent neutrophil chemoattractant properties, C5a, C567 complex, kallikrein, IL-1, IL-8, and platelet aggregation factors (PAF) also have chemotactic effect. By 4 to 6 hours following injury, significant neutrophil influx has occurred and is peaked at about 8 hours. Several substances influence leukocyte metabolism and the production and release of lysosomal enzymes. These include anaphylotoxins, and kallikrein, which induces superoxide anion generation and lysosomal enzyme release in neutrophils.

Capillary cells adjacent to the site of injury can be activated by the injury or humoral mediators and produce a variety of adhesion molecules as well as IL-8 and platelet-activating factor (PAF). Thus, activation of vascular endothelium is a key mechanism of inflammation. Activated PAF also stimulates platelet aggregation, which may play a role in the platelet sequestration and thrombocytopenia observed in septic shock.

**Fibrin Deposition and Mechanical Sequestration**

Normally, intact mesothelial cells maintain fibrinolytic activity within the peritoneal cavity by the secretion of tissue plasminogen activator (t-PA). With mesothelial cell injury and inflammation, local fibrinolytic activity is suppressed due to the loss of plasminogen activator. As high concentrations of fibrinogen are present, fibrin deposition readily occurs by activation of the intrinsic pathway.
The role of fibrin deposition in the local inflammatory response is to isolate or contain contamination and thereby prevent widespread dissemination. Fibrinous adhesions cause the adherence of loops of intestine and omentum to one another as well as the parietal peritoneal surface, thus creating physical barriers against the spread of bacterial contamination. Fully developed fibrous adhesions are seen at 10 days and become maximal 2-3 weeks after peritoneal injury. It is worthwhile to remember that small children have a poorly developed omentum, and thus, there are more chances of rapid progression to diffuse peritonitis.

In some patients, the development of an intraperitoneal abscess is the culmination of the sequestration process described above. Within the adhered mass of viscera, fibrin and bacteria, liquefaction develops from the release of proteolytic enzymes from perishing leukocytes and the action of bacterial exozymes. The resultant tissue damage and liquefaction results in abscess formation.

**Peritoneal Healing**

The peritoneum appears to heal rapidly after injury. It appears that the replacement of the injured mesothelium occurs over the entire wound simultaneously and the rate of healing is independent of the size of the peritoneal wound. Within 3 days after injury, the wound is covered by connective tissue cells, and by day 5, these new cells resemble normal mesothelium. However, as noted above, peritoneal injury in the presence of inflammation and infection results in adhesion formation. With time, fibrous adhesions undergo remodeling and usually become progressively attenuated. However, in the setting of severe peritoneal injury or persistent infection, filmy fibrinous adhesions are transformed into dense fibrous adhesions by the ingrowth of fibroblasts, capillaries and the deposition of collagen.

**Bacterial Virulence**

Although more than 500 species of bacteria are normally present in the colon where there are between $10^{10} - 10^{12}$ bacteria/mm$^3$, the vast majority of these are anaerobic species which contribute little to clinical intra-abdominal infection. Despite the massive contamination and complexity of the microbial spectrum that occurs with fecal contamination, within 48 hours, only a few isolates are recovered in peritoneal fluid culture. The most common facultative gram-negative bacteria isolated in clinical infections are species of *Escherichia coli*, *Klebsiella*, *Proteus*, *Pseudomonas* and *Enterobacter*, which make up less than 0.1% of the normal colonic flora. Even the most common obligatory anaerobic pathogen, *Bacteroides fragilis*, accounts for only 1% of the colonic flora. Commonly isolated gram-positive species include *Enterococci* and *Staphylococci* and *Streptococci* species. This indicates that only a few pathogenic bacteria survive to propagate the infection.

Innate virulence factors also play a role in the pathogenesis of infection. It has been shown in experimental models that *E. coli* and *Enterococcus* were the predominant organisms during the peritonitis phase, while *B. fragilis* predominated during the abscess phase. The presence of capsular polysaccharide in the case of *B. fragilis* is strongly associated with abscess formation. Extracellular products such as coagulase and catalase secreted by *Staphylococcus aureus* enhance its virulence. The size of the bacterial inoculum also influences the virulence, both the ability to produce infection as well as the severity of the disease. The ability to adhere to the mesothelial surface may also enhance the virulence of organisms such as *Enterobacteriaceae* (in the early phase), and *Bacteroides fragilis* (8 hours or more after infection). Such organisms are resistant to mechanical removal by saline lavage.

Bacterial *synergism* also potentiates the virulence of a single organism. Polymicrobial infections, specifically combinations of aerobic and anaerobic species, exhibit significantly greater lethality than comparable infections involving a single species of pathogenic bacteria.

**Adjuvant Factors**

The simultaneous presence of various adjuvant substances increases bacterial virulence and/or
interferes with host defenses. Such adjuvant substances are invariably present following gastrointestinal perforation, trauma or a surgical procedure (Table 48.1). These adjuvant substances may be endogenous or foreign materials.

Blood is the most important adjuvant substance. The lethality of \textit{E. coli} is enhanced \textit{in vitro} by hemoglobin.\textsuperscript{25} Although it is not clear whether it is due to the liberation of iron, an essential growth factor for \textit{E. coli}, or depression of neutrophil migration and phagocytic function.\textsuperscript{26-28} The presence of both fibrin and platelets within the peritoneal cavity also may impair physical bacterial clearance by blockade of the diaphragmatic lymphatics.\textsuperscript{8} Other substances originating from the gastrointestinal tract itself like bile salts, gastric mucin, pancreatic secretions as well as chyle and urine have been shown to have adjuvant activity.\textsuperscript{1,3}

Foreign materials such as barium sulfate, talc or cellulose probably also impair phagocytosis by causing the premature activation of neutrophils and release of lysosomal enzymes.\textsuperscript{29,30} Retained suture materials and drains may have a similar effect. It is therefore important that during surgical intervention, attention should be paid to meticulous hemostasis, copious lavage to remove adjuvant material, the thorough evacuation of intraperitoneal fluid, and minimizing the use of foreign material such as hemostatic agents and suture material.\textsuperscript{1}

### Table 48.1: Adjuvant substances for peritoneal infection

#### Endogenous factors
- Blood, ferrous iron
- Platelets
- Fibrin
- Intraperitoneal fluid
- Necrotic tissue
- Gastric juice, pancreatic juice, urine, meconium, chyle
- Bile, bile salts

#### Foreign material

- **Macroscopic foreign material**
  - Suture material, surgical clips
  - Prosthetic implants
  - Sponges
  - Hemostatic pads/powders
  - Surgical drains

- **Microscopic foreign material**
  - Barium sulfate
  - Talc powder, other glove powder
  - Clothing fibers

The systemic response to peritoneal infection is similar to the response of the body to other forms of injury and includes the release of catecholamines, glucocorticoids, aldosterone and antidiuretic hormone.\textsuperscript{3} The systemic response is best studied under three broad headings, namely hypovolemia and its consequences, pulmonary complications, and effects on tissue metabolism.

#### Hypovolemia and Hemodynamic Changes

The development of hypovolemia is central to the systemic response and is largely due to the fluid influx, often copious, occurring in the peritoneal cavity. The reduction in intravascular volume reduces venous return and cardiac output. Systemic hypotension may also be the result of secretion of TNF, IL-1, platelet activating factors, and nitric oxide, which have vasodilatory effects and may reduce systemic vascular resistance.\textsuperscript{13,14} Diminished urine flow develops as a result of the effects of increased aldosterone and antidiuretic hormone secretion. Thus, a clinical setting of hyperdynamic or “warm” septic shock may be created, characterized by tachycardia, fever, oliguria, hypotension, and warm extremities. There is increased cardiac output, low peripheral vascular resistance, low arteriovenous oxygen difference, and high mixed-venous oxygen content.\textsuperscript{1}

#### Effects on Pulmonary Function

Abdominal distension secondary to fluid accumulation within the peritoneal cavity as well as within the bowel reduces diaphragmatic mobility and decreases ventilatory volume, producing eventual atelectasis.\textsuperscript{1} Beta-adrenergic stimulation leads to intrapulmonary shunting while increased pulmonary vascular permeability also develops as a result of a number of inflammatory mediators.\textsuperscript{1} Fluid accumulates in the pulmonary interstitium and decreases pulmonary compliance. Early manifestations of these changes include hyperventilation and the development of respiratory alkalosis. With worsening
peritoneal inflammation can cause the peritoneum. Peritonitis can be categorized into three main divisions. **Primary peritonitis** refers to an infection of the peritoneal cavity that has no intrabdominal source. **Secondary peritonitis**, the most common in clinical practice, is defined as peritonitis resulting from an intra-abdominal source, most commonly, the perforation of a hollow viscus. **Tertiary peritonitis** develops following the treatment of secondary peritonitis and represents either a failure of the host inflammatory response, or a superinfection.

**Clinical Presentation of Peritonitis**

The clinical presentation of peritonitis is fairly similar in the various pediatric age groups, although the diagnosis is considerably more difficult to make in the newborn and small infant as will be discussed later.

The history and physical examination are pivotal in deciding the need and urgency for intervention and the use of diagnostic techniques. A brief history of the duration of illness, the presence of fever and its nature, as well as previous hospitalizations and surgery is important. Especially in the older child, abdominal pain is usually the predominant presenting symptom. The pain of fully established peritonitis is constant, burning and aggravated by motion or movement. The extent of pain may be localized or diffuse depending upon the area of parietal peritoneum that is inflamed. Visceral peritoneal irritation, usually from distension of a hollow viscus, causes dull, poorly localized, often periumbilical crampy pain. Anorexia, nausea and possibly vomiting, as well as thirst and oliguria are frequently present.

**Physical Examination**

Important physical signs include fever, tachycardia and tachypnea or labored breathing. If septic shock is present, there may be tachycardia, hypotension, and warm, pink extremities. Patients prefer to remain still and supine, so that there is minimal exacerbation of pain. Gentle percussion followed by direct palpation will show as well as localize tenderness. With generalized peritonitis, abdominal tenderness is diffuse and is often maximal at the site overlapping the region where the peritonitis originated. Bowel sounds are usually markedly diminished or absent. Abdominal wall rigidity due to voluntary guarding and reflex muscle spasm can be extensive. In localized peritonitis, tenderness is focal, and the remainder of the abdomen may be relatively soft and nontender. A rectal or vaginal examination may also be performed in order to localize pelvic tenderness or intrapelvic collections.

Physical signs may be minimal or absent in patients receiving corticosteroids, or with altered consciousness from head injury or encephalopathy. In these cases, the diagnosis may rest upon other diagnostic modalities.

**Clinical Presentation in Infants and Small Children**

It is considerably more difficult to make a diagnosis of peritonitis in infants, including newborns, as well as in small children. A small infant with far advanced peritoneal inflammation may only wince or draw up the legs in response to abdominal palpation, whereas an older child will respond more decisively to the resultant tenderness. Bowel sounds are also difficult to assess in newborns or small infants.

A newborn with spontaneous gastrointestinal perforation and peritonitis may present at an early stage with refusal of feeds and evidence of physiological instability. This includes lethargy, temperature instability, recurrent apnea, episodes of bradycardia and evidence of poor capillary circulation, such as delayed capillary fill. Gastric retention and
vomiting may be marked and the progress of abdominal distension is often very rapid. A history of rectal bleeding and diarrhea may be present, especially where the perforation follows inflammatory bowel disease. Metabolic acidosis and oliguria may develop very rapidly. Edema and erythema of the abdominal wall is a cardinal sign of underlying peritonitis in the newborn and small infant, and is often accompanied by scrotal edema. Purulent fluid may sometimes track down a patent processus vaginalis and present with unilateral or bilateral scrotal abscess or collection.

**LABORATORY AND RADIOGRAPHIC INVESTIGATIONS**

In general, laboratory tests may not be very specific. Leukocytosis, with a predominance of immature neutrophil forms is almost always present. It should be remembered however, that newborns with abdominal sepsis and peritonitis usually have neutropenia, thrombocytopenia, and metabolic acidosis. A neutrophil count of less than 6000 cells/mm$^3$ is most commonly associated with gram-negative neonatal septicemia. Thrombocytopenia is nearly universally present and levels of C-reactive protein may be elevated. It is essential in newborns, and probably also in small infants, to take specimens of blood, both peripheral and from indwelling cannulas, urine, and if necessary, cerebrospinal fluid, for culture studies.

Plain radiographs of the abdomen may reveal obliteration of the peritoneal fat lines and the psoas shadow indicating the presence of peritoneal edema (Fig. 48.2). Fluid in the peritoneal cavity along with fluid-filled bowel loops may result in the abdomen appearing almost completely opaque on a plain skiagram (Fig. 48.3). Free air may be visible on an upright abdominal film. The erect radiograph should be obtained with the beam centered at the level of the diaphragm and a waiting period of at least 5 minutes. As little as 3 - 5 ml of subdiaphragmatic air can be detected in this fashion in a small child. In neonates with gastrointestinal perforation, a massive hydro-pneumoperitoneum or pyopneumoperitoneum may be recognized by the presence of an air-fluid level, which is too great in length for even an obstructed segment of colon (Fig. 48.4). If the child is unable to assume the erect position, a lateral decubitus film with the patient’s left side down should be requested. Air-filled loops of bowel, with thickened opaque walls may be found when bowel edema and paralytic ileus is present. Other findings that support the diagnosis of intra-abdominal infection include pneumatosis intestinalis, air in the portal vein, a mass effect or extraluminal gas collections suggestive of an abscess. These findings are more characteristic of neonatal
Peritonitis in Children

necrotizing enterocolitis (NEC), a topic that is covered elsewhere.

The role of more elaborate diagnostic studies in peritonitis is limited to those patients presenting with abdominal pain who have no immediate compelling indication for abdominal exploration and in whom the diagnosis may be in doubt. In general, ultrasoundography, computed tomography (CT) and especially magnetic resonance imaging (MRI) should not be routinely used in patients with acute peritonitis. However, imaging experience has shown that many of the morphological changes of peritonitis, such as thickening of the visceral and parietal peritoneum, inflammatory changes in the omentum and mesentery, and free or loculated fluid collections often with higher density than bland ascites are well shown with CT. The source of the peritonitis, such as a perforation of bowel, is often apparent as well.

PRIMARY PERITONITIS

Primary peritonitis, also known as idiopathic peritonitis, represents peritonitis occurring without any intra-abdominal source of infection. According to the Western literature, the incidence of primary peritonitis has decreased in recent decades, and at present represents less than 1% of all cases of peritonitis. This condition is primarily treated without surgery. Although previous studies suggested that the incidence of primary peritonitis is highest in girls 4 to 6 years of age, recent studies suggest that there is an equal distribution between boys and girls.

Most commonly, primary peritonitis is seen in children with nephrotic syndrome, systemic lupus erythematosus, or hepatic dysfunction with cirrhosis and ascites, or in those undergoing peritoneal dialysis.

Apart from the open ends of the fallopian tubes, the peritoneal cavity is a closed space. Therefore, the means by which bacteria gain access to the peritoneal cavity is difficult to understand. At present, the most likely explanation is the hematogenous route as in some series; the organism cultured from the peritoneal fluid has also been found in other sites, such as the mouth or the urinary system. Lymphatic spread as well as ascending genitourinary routes has been implicated. It is possible that ascending infection from the genitalia may occur in girls as the fallopian tubes open into the peritoneal cavity. The theory of translocation of enteric bacteria is less favored now, although the predominant pathogens in primary peritonitis, at least in adults today, are coliform bacteria.

Clinical History and Investigations

The history in children is usually acute with acute abdominal pain, fever, nausea, vomiting and lethargy. Abdominal distension may be present and there is usually diffuse tenderness and "rebound" tenderness. The most important differential diagnosis is perforated acute appendicitis, although with primary peritonitis, the disease usually develops faster and presentation and pain is more acute. The total leukocytic count is raised, with relative neutrophilia. Plain abdominal radiographs should be obtained in order to rule out the presence of pneumoperitoneum.

Diagnostic paracentesis is of value if ascites is present, for example in nephritic syndrome and cirrhosis with ascites. In primary peritonitis, > than 500 WBCs/mm³ are present, and granulocytes predominate. The pH is less than 7.35 and lactate levels more than 5 mg/dL. If the gram stain or culture yields a mixed flora of both gram-positive and gram-negative organisms, or else the presence of gross feces, bile or blood, it is more likely that intestinal perforation is the cause of peritonitis. In these cases, immediate exploratory laparotomy is indicated. In cases where
differentiation from perforated acute appendicitis is difficult, computed tomography (CT) scan may be of help.

A classification of primary peritonitis in children is shown in Table 48.2.

In the case of primary peritonitis occurring in children who are otherwise normal, the incidence has shown a marked reduction over the past few decades, perhaps related to the widespread availability and early use of oral antibiotics for a variety of respiratory tract infections, dental diseases or urinary tract infections. Since then, however, sporadic reports of Group A streptococcal peritonitis with an association with simultaneous positive cultures from the trachea, pharynx or tonsils in otherwise healthy patients have been noted. Similar infection due to Streptococcus pneumoniae, often penicillin resistant, has also been reported. Blood cultures should therefore always be obtained and may also be positive for Strep. pneumoniae. If the peritoneal fluid examination confirms the diagnosis of primary peritonitis, antibiotic treatment, usually with a sulbactam-ampicillin and gentamicin combination or a third-generation cephalosporin is usually effective. Laparoscopy or laparotomy is indicated only if the peritoneal fluid is not accessible or the patient does not improve with intravenous antibiotics. Following surgery, intravenous antibiotics and nasogastric aspiration is continued until the white cell count is normal and the ileus resolves.

Peritonitis in Children with Nephrotic Syndrome and Hepatic Cirrhosis with Ascites

Peritonitis is a known complication of nephrotic syndrome (NS) in childhood. Increased susceptibility to peritonitis in these patients may be related to reduced cellular immunity and chemotaxis, impaired opsonization, and decreased levels of immunoglobulins. Loss of complement proteins I and B of the alternative complement pathway in urine in patients with NS may also be responsible for the increased susceptibility. The most commonly documented causative organism is Streptococcus pneumoniae, although gram-negative organisms have also been reported. In 79% of cases, steroids were being used to treat the NS or relapse was diagnosed. The most common presenting symptoms are diffuse abdominal pain, fever, rebound tenderness, nausea and vomiting. Fifteen to twenty-seven percent of children may experience more than one episode of peritonitis during the course of NS. Treatment is directed towards antibiotic coverage to include both gram-positive and gram-negative organisms until the results of peritoneal, blood and urine cultures are available.

In children with hepatic dysfunction and cirrhosis with ascites, primary peritonitis is more frequently due to the gram-negative organisms that colonize the intestinal tract, such as E. coli or Klebsiella pneumoniae. This is probably because of reduced hepatic clearance of bacteria from the blood as well as the lymphatic system, thus increasing the opportunity for bacteria to persist in ascitic fluid. In addition, patients with cirrhosis and ascitis have reduced amount of protein in ascitic fluid, correlating with decreased levels of opsonin and complement.

Peritonitis in Children Undergoing Peritoneal Dialysis

Peritonitis is a major complication of peritoneal dialysis in patients of end-stage renal disease and is more often seen in patients undergoing continuous ambulatory peritoneal dialysis (CAPD) rather than in patients undergoing intermittent peritoneal dialysis. Most cases are caused by catheter contamination. The incidence is an average of 1.3 episodes per patient per year. It has been shown that rates are lowest with use of a double-cuffed catheter with a downward directed tunnel. Use of exit-site mupirocin and antibiotic prophylaxis during catheter insertion and other invasive procedures also lowers the risk. Usually the infection is monomicrobial and fungal infections are more common. The most common infecting organism
is a gram-positive coccus, usually Staphylococcus aureus or Streptococcus epidermidis. Occasionally, Pseudomonas, yeast and atypical tubercle bacilli may be recovered. The clinical presentation includes abdominal pain, fever, and a high neutrophil count in the cloudy dialysate fluid. The fluid should be cultured and intravenous or intraperitoneal antibiotic therapy started. The options include ceftazidime and vancomycin or aminoglycosides. A recent report suggests that a combination of intraperitoneal ceftazidime and cefazolin is very effective and avoids the renal toxicity, which may be seen with use of aminoglycosides. Clinical improvement is usually seen after 24 to 36 hours. Removal of the catheter is indicated only if there is no improvement after 4 to 5 days of antibiotic therapy, the presence of fungal or tubercular peritonitis, or a severe skin infection at the catheter site. The increased risk of intraperitoneal hypercoagulation and hypofibrinolysis in these patients may also explain the blockage of the peritoneal catheter, which may be seen in some patients.

A similar form of peritonitis may also be seen in patients who have a ventriculoperitoneal shunt. Shunt-induced peritonitis should be suspected in any child who has a ventriculoperitoneal shunt and abdominal symptoms.

**TUBERCULOUS PERITONITIS**

Abdominal tuberculosis and tuberculous peritonitis are extremely common in developing countries like India. In recent years however, an upsurge in incidence has also been reported in the West. Typically, tuberculous peritonitis is believed to be caused by hematogenous spread, although the primary source of infection (lungs, intestine) may no longer be clinically apparent. Some cases may be the result of reactivation of latent peritoneal tuberculosis established by hematogenous spread from a pulmonary focus during an earlier episode of acute disease. Otherwise infection could result from spread from tuberculous mesenteric lymph nodes, transmurally from tuberculosis of the ileocecal region, or a tuberculous pyosalpinx.

**Clinical Manifestations**

In the early phase, the manifestation may be acute with rapid development of increasing abdominal distension and pain. Usually however, the symptoms consist of progressive abdominal distension and ascites (100%), fever (27%), and loss of weight (18%). A “doughy” feel of the abdomen may be present and rolled-up omentum may be palpable. Ascites may sometimes be loculated. The tuberculin test is usually positive. Pulmonary tuberculosis is concomitantly present in 50% cases. Concomitant tuberculosis involving other organ sites, e.g. meningitis may sometimes be present.

The "dry" or chronic form of peritoneal tuberculosis may also be seen when there is resolution of ascites and formation of dense adhesions and matting of bowel loops. Acute or subacute intestinal obstruction may be present. Clinical manifestations of generalized tuberculosis may be present in at least a third of these patients, and consist of anorexia, weight loss and night sweats. Occasionally, a "purulent" form of peritoneal tuberculosis may be seen where a mass of omentum, bowel and caseating lymph nodes form an abscess which may occasionally burst leading to a spontaneous fecal fistula. Peritonitis may also occur in patients with primary intestinal tuberculosis in whom a bowel perforation may occur proximal to a tubercular stricture of the intestines.

In the ascitic stage, the diagnosis of peritoneal tuberculosis can be made by paracentesis, which would yield fluid with elevated protein content, lymphocyte pleocytosis and glucose concentration below 30 mg/dL. Acid-fast bacilli (AFB) are detected in the peritoneal fluid cultured conventionally in 80% cases, although according to other sources, the yield may not be so good. Mycobacterium tuberculosis may also be detected in ascitic fluid by the polymerase chain reaction method, or by the finding of high interferon gamma and adenosine deaminase activity. Recently, ultrasonography (US) and computed tomography (CT) scan of the abdomen have been reported to be effective in the diagnosis of peritoneal tuberculosis. According to Demirkazik et al peritoneal and omental thickening detected by CT and ascites with fine mobile septations shown by US strongly suggest the ascitic type of peritoneal tuberculosis. The two modalities should be used together for accurate diagnosis of tuberculous peritonitis. Ozates et al also found that US and CT findings of high density ascites contributed well to the diagnosis of peritoneal tuberculosis.
Diagnostic laparoscopy, using the open technique of trochar insertion is recommended if diagnosis cannot be made by paracentesis or other diagnostic modalities. \(^1,59,60,62\) Laparoscopic findings include complete studding of the visceral and parietal peritoneal surfaces as well as the omentum with small, whitish tubercles. \(^1\) Stalactite-like fibrinous masses hanging from the parietal peritoneum may be present. Other findings include dense adhesions between abdominal viscera and inflamed hemorrhagic areas on the peritoneum. \(^64\) Laparoscopy combined with peritoneal biopsy or biopsy of nodules gives the diagnosis in 75 to 85% of cases. \(^60\) As a last resort, open laparotomy with peritoneal biopsy may be performed; the placement of drains or bowel exteriorization is best avoided. \(^3\)

**Management**

It is essential that as soon as secondary peritonitis is diagnosed, aggressive preoperative resuscitation and antibiotic therapy is instituted. The primary principles in the management of secondary peritonitis are: (i) resuscitation, (ii) initiation of antibiotic therapy, (iii) surgical management, and (iv) continued post-operative metabolic support.

**Resuscitation**

All cases of secondary peritonitis are accompanied by significant "third space" losses of extracellular fluid, which can at times be immense. This includes fluid accumulating in the peritoneal cavity, fluid exuding from the surface of the abdominal viscera as well as fluid that may collect inside the lumen of dilated intestinal loops in the presence of ileus. Hypovolemia, which often develops rapidly, can have serious consequences in neonates and infants. Major fluid deficits and metabolic derangements should be corrected before surgery, although surgery for acute perforations of the gastrointestinal tract should not be inordinately delayed on this account. In these cases, resuscitation should continue during surgery. \(^3\) The type of fluid used for resuscitation depends upon the level of gastrointestinal perforation. In general however, in cases of intestinal perforation and peritonitis, replacement with adequate volumes of lactated Ringer's solution is necessary and should be accompanied by transfusion of plasma or salt-free albumin to restore both intravascular volume and colloid osmotic pressure. Infusing low doses of dopamine may help in patients with significant hypotension as it improves blood flow and reduces the incidence of acute renal failure. \(^3\) Vital signs—temperature, blood pressure, pulse rate, respiration rate are continuously recorded. The effectiveness of fluid resuscitation efforts can be judged by the restoration of pulse rate and arterial blood pressure to normal levels. Placement of a urinary catheter is essential since restoration of urine output to levels of at least 1 - 1.5 ml/kg/hour is a reliable indicator of adequate restoration of intravascular volume. Insertion of a central venous pressure (CVP) line and the use of invasive peripheral arterial and central cardiac pressure-monitoring lines may help provide
more precise estimation of intravascular volume and cardiac output. However, these invasive monitoring techniques are often difficult to install and maintain in infants and small children.

Supplemental oxygen is essential, especially in the newborn or small infant with gross abdominal distension and in more extreme situations, endotracheal intubation and mechanical ventilation may be needed to preserve oxygenation.

Nasogastric intubation is essential and serves to reduce abdominal distension and prevent pulmonary aspiration. H-2 blocking agents such as ranitidine or famotidine should be administered to prevent stress-related gastric ulceration.

**Antibiotic Therapy**

Antibiotic therapy is begun along with the initial resuscitation, and the initial selection of antibiotics is empiric. It has recently been reported that 76% of patients with peritonitis had peritoneal fluid cultures with mixed aerobic and anaerobic bacteria, with *Escherichia coli* and *Bacteroides fragilis* the most common combination. Presumptive antibiotic therapy should therefore include coverage for both aerobic gram-negative rods and anaerobic organisms. For most cases of secondary bacterial peritonitis, a single antibiotic agent with both aerobic and anaerobic activity is preferred. Second or third-generation cephalosporins or beta-lactamase inhibitor combinations are satisfactory. Alternatively, a combination of a monobactam and metronidazole yields cure rates of 80-90%. However, for cases of hospital-acquired or severe secondary peritonitis, potent broad-spectrum agents should be selected. Effective regimens include carbapenem, or a combination of an aminoglycoside with metronidazole (or clindamycin) and ampicillin. The selection of antibiotics should definitively be influenced by consideration of institutional antibiotic-resistance patterns when treating complex bacterial peritonitis.

Once antibiotic therapy is begun, changes in the antibiotic regime should be based primarily on the clinical progress. As a general rule, infections should show definite evidence of response within 72 hours of initiation of treatment. The duration of antibiotic therapy is determined by the clinical circumstances. The judgement of stopping antibiotic therapy should be made based on the indicators of temperature, white blood cell count (WBC) and the differential leukocytic count. It should also be realized that the absence of response is not an automatic indication that the wrong antibiotic was selected. In most cases, the same antibiotic should be continued and a search made for a localized septic anatomic focus requiring drainage, debridement or excision.

**Surgical Management**

The mainstay of surgical treatment consists of source control, peritoneal toilet and prevention of recurrent infection. Control of the source of infection involves resecting, excluding or patching the diseased viscera at laparotomy, or more recently, laparoscopic methods in selected cases. It is essential to evacuate all purulent collections, with particular attention to subphrenic, subhepatic, interloop and pelvic collections.

The second goal is to minimize the risk of recurrent sepsis. Standard intraoperative techniques to achieve this goal include intraoperative debridement with removal of fibrin, blood and necrotic material, and copious irrigation of the peritoneal cavity with saline. Addition of antiseptics or antibiotics to the irrigating fluid is of doubtful help in reducing mortality, but may help reduce the incidence of postoperative wound infection.

Certain nonstandard surgical techniques have been described to prevent recurrent sepsis but there benefit remains controversial. These include radical peritoneal debridement, continuous postoperative lavage, and planned repeat laparotomy. *Radical peritoneal debridement* implies the removal of all fibrin and necrotic tissue including abscess cavity walls, which may act as foci and media for bacterial growth. However, this technique may itself cause significant bleeding and fibrin deposition and at present is not recommended. *Continuous postoperative irrigation of the peritoneal cavity* with large volumes of crystalloid solution via multiple catheters placed in the peritoneal cavity at the time of surgery has not conclusively been proved to be of significant benefit. *Planned repeated laparotomy* is a technique developed to prevent recurrent sepsis by repetitive abdominal exploration to debride necrotic material and drain abscesses. Several studies conducted in adults have shown encouraging results with this technique. However,
in a study of peritonitis in childhood, Haecker et al.\textsuperscript{72} found that radical adjuvant surgical measures were not necessary and hypothesized that during peritonitis, compartmentalization of the focus of infection prevents further systemic reactions and ultimately leads to removal of the infectious agents by endogenous mechanisms.

**Postoperative Peritonitis**

Postoperative peritonitis is usually the result of anastomotic leakage and is often discovered on the fifth to seventh postoperative day. Early diagnosis is essential as delay contributes greatly to increase in mortality. This is especially true for most centers in India where intensive care facilities or facilities for administering total parenteral nutrition may be lacking. In the newborn who develops an anastomotic leak following a bowel anastomosis, the first signs may be reduced spontaneous activity, lethargy, temperature instability, increased gastric aspirate and abdominal distension. An erect radiograph of the abdomen may be very helpful in diagnosing an anastomotic leak in these situations (Fig. 48.5). Drainage, controlled fistula formation, exteriorization, repair or resection and reanastomosis are performed as indicated.\textsuperscript{3}

**MECONIUM PERITONITIS**

Meconium peritonitis occurs due to contamination of the peritoneal cavity in utero or in the immediate perinatal period and usually results in severe peritonitis, often with intraperitoneal calcification. Meconium is first formed in the 3rd month of intrauterine life and consists primarily of amniotic fluid, squamous cells, bile salts and pigments, and pancreatic and intestinal enzymes.\textsuperscript{73,74} Sterile meconium in the peritoneal cavity excites a strong fibroblastic response. This has been shown to be due to a marked proinflammatory response in the peritoneal macrophage with elevation of both procoagulant activity (PCA) and tumor necrosis factor alpha (TNF-alpha).\textsuperscript{75} Foreign body granulomas and calcification due to deposition of calcium salts develops by the fourth day.\textsuperscript{76} In most cases, the perforation seals spontaneously.

According to the Western literature, this condition is usually due to perforation of the obstructed bowel in complicated meconium ileus.\textsuperscript{76,77} However, in Asian countries like India, meconium ileus is uncommon. Intestinal atresia or stenosis, volvulus, internal hernia, congenital peritoneal bands, ruptured Meckel’s diverticulum or appendicitis may also lead to perforation and meconium peritonitis.\textsuperscript{76} In a review of 32 cases of meconium peritonitis, Niramis et al found that the obvious causes were ileal atresia in 4, jejunal atresia in 3 and appendiceal perforation in 1. In the other 23 patients, no apparent cause of perforation was noted.\textsuperscript{78}

The clinical presentation of meconium peritonitis in the newborn has been classified into four types:\textsuperscript{26}

1. A meconium pseudocyst is formed by meconium leakage over an extended period. There may be a calcified fibrous cyst wall, which may be formed entirely from neighboring loops of intestine.

2. Adhesive meconium peritonitis with numerous inflammatory adhesion bands and matted bowel loops. This results from widespread peritoneal contamination and may be associated with bowel obstruction.

3. Meconium ascites results from bowel perforation occurring at term or immediately after birth. Meconium-stained ascitic fluid fills the peritoneal cavity. Intraperitoneal calcification may be absent or of the fine, stippled variety.

![Fig. 48.5: Gas under the diaphragm and a large air-fluid level in a neonate with an anastomotic leak following surgery for ileal stenosis](image-url)
4. *Infected meconium peritonitis* results from a perforation that as not sealed before birth, allowing bacterial contamination of the peritoneal cavity. This is the most serious form of meconium peritonitis.

Antenatal diagnosis may be made during maternal ultrasound examination. Clinical presentation of meconium peritonitis includes gross abdominal distension, an edematous, erythematous abdominal wall, a palpable abdominal mass, and features of bowel obstruction. Niramis et al found plain abdominal X-rays to show abnormal calcification and mass lesion in the peritoneal cavity in 71.9 and 46.9% respectively (Fig. 48.6). Scrotal calcifications due to calcification of meconium tracking down the processus vaginalis may be noted, and in one report, abdominal, scrotal and thoracic calcifications due to healed meconium peritonitis were noted. Rarely, disseminated intravascular meconium may complicate meconium peritonitis and have devastating consequences.

Patients who have an incidental finding of abdominal or scrotal calcifications do not require surgery. Surgery is primarily required for intestinal obstruction or persistent bowel leak. Surgical options include resection of the pseudocyst and devitalized intestine with either a primary anastomosis or a temporary enterostomy. Surgery is often very difficult due to the presence of dense vascular adhesions and matting of the bowel loops. A large series showed that partial resection of the cyst and bowel exteriorization yielded better survival figures than primary anastomosis after resection of all diseased bowel. Simple drainage, bowel rest, total parenteral nutrition and administration of antibiotics followed by definitive surgery after 2 to 3 weeks has also been shown to be successful. Recent studies show that with proper management, survival should be expected in virtually every case.

**TERTIARY PERITONITIS**

Tertiary peritonitis, also known as persistent diffuse peritonitis (PDP) is a condition that may follow initial successful, usually operative, treatment of secondary peritonitis. This may represent both a failure of host response, as well as superinfection.

The clinical picture mimics that of occult sepsis, consisting of low grade fever, leucocytosis, elevated cardiac output and general hypermetabolism. Both CT and laparotomy usually fail to identify a focal source of infection. In adults, if superinfection is present, culture data may yield two distinct categories of microorganisms: (i) highly virulent gram-negative aerobic bacteria such as *Pseudomonas* or *Serratia* species which have extensive resistance to antibiotics, and (ii) low virulence organisms such as *Staphylococci epidermidis* and *Candida* species which are resistant to the initial antibiotic therapy. Treatment is based on sensitivity information and operative management has very little role.

A study of peritonitis in children found that PDP is a distinct form of peritonitis even in children, accounting for approximately 25% of cases. The authors emphasized that rates of host defence affecting disease, extra-appendicular origin, and mortality were markedly higher in children with PDP, and that survival could be improved by the choice of more conservative treatment options, avoiding unnecessary operations in some instances.

**PERITONITIS IN CHILDHOOD: AN INDIAN PERSPECTIVE**

In developing countries like India, the causes, epidemiology and presentation of peritonitis are quite
different from those described in the Western literature. This is true, both for newborns and infants as well as older children. This is largely because a very large percentage of the population lives in poor socio-economic conditions, with very little access to proper sanitation and hygiene. In this scenario, diarrheal diseases and other infections of the gastrointestinal tract are very common, increasing the risk of secondary peritonitis due to perforations of the gastrointestinal tract. There is often a substantial delay before patients are brought for treatment and often, the child has been inadequately treated by several local doctors before finally being referred to a tertiary care center in a precarious condition. In addition, diseases like abdominal tuberculosis, enteric (typhoid) fever with its sequelae, amebic colitis, and helminthic diseases like roundworm infestation are extremely common. The following section briefly describes our recent experience with peritonitis in newborns and older children at the Department of Pediatric Surgery, Lady Hardinge Medical College and associated Kalawati Saran Children’s Hospital, New Delhi. Kalawati Saran Children’s Hospital (KSCH) is a very busy children’s hospital catering to a large population derived from Delhi and neighboring North Indian states. The vast majority of patients belong to the poor socio-economic strata of society.

Peritonitis in Newborns—the KSCH Experience

During a study carried out from March 1998 to October 2000 (2 ½ years), 85 newborns with peritonitis were admitted to the Pediatric Surgery ward of Kalawati Saran Children’s Hospital, New Delhi. Fifty-nine were males and 26 were females. The largest number was made up of patients with necrotizing enterocolitis (NEC) of the small and/or large bowel, comprising 43 patients (50.6%); there were 11 patients with spontaneous gastrointestinal perforation without gangrene (SIP) (13%), and 9 patients with meconium peritonitis (9.5%). The etiology of peritonitis in these 85 patients is shown in Table 48.3, and the various features that these patients presented with and their demographic characteristics are summarized below.

Of the 85 patients, 8 were brought on the first day of life, 41 between 2 - 7 days after birth, and 36 neonates were 8-30 days old at presentation. Four patients weighed less than 1000 g at admission, 34 patients weighed between 1000-2000 g, 34 patients between 2000-2500 g, and 9 patients weighed more than 2500 g at admission.

The most commonly seen clinical signs and symptoms were abdominal distension in 82 patients (96% of patients), bilious vomiting/nasogastric aspirate in 81 patients (95%), constipation 76 (89%), abdominal wall erythema 32 (37.6%), an abdominal mass 10 (12%), gastrointestinal bleeding 12(14%), and overt neonatal sepsis in 45 patients (53%). Abdominal guarding and tenderness was seen in 30 patients (35%). Significantly, in 33 patients, there was a history of diarrheal disease preceding the abdominal distension. Thirty-eight patients (45%) had been receiving top-feeds while the remaining 47 patients were on breast-feeds alone.

A study of the data tabulated above reveals certain interesting facts. 43 patients had NEC with perforation and 11 patients had spontaneous intestinal perforation (SIP), i.e. intestinal perforation in the absence of gross intestinal gangrene or necrosis. The etiopathogenesis of NEC in newborns has been studied extensively and is the subject of numerous articles in the literature. Spontaneous gastrointestinal perforations in the newborn have also been studied and are thought to be due to the undesirable side effects of an asphyxial defense mechanism, known as selective circulatory ischemia which is activated by perinatal stress, hypoxia or shock. Redistribution of blood flow during hypoxia, hypovolemia, or other stress states, with shunting away from mesenteric vascular beds,

is thought to result in microvascular injury, and subsequent loss of mucosal integrity. The ultimate result may therefore be extension of microvascular thrombosis with transmural necrosis and intestinal perforation. As with NEC, multiple factors are responsible, including bacterial colonization of the gut, presence of a hyperosmolar luminal substrate such as carbohydrate, and immaturity of the immune system. The neonate also has an immature immune system, and prematurity is associated with deficiencies in complement, opsonization, phagocyte function, immunoglobulin A (IgA) and immunoglobulin M (Ig M), and the function of T lymphocytes.

In the West, SIP is predominantly seen in premature infants 4-5 days old, with a perinatal history of stress and asphyxia. In contrast however, our data shows that most newborns with NEC or SIP are of normal birthweight or of borderline low birthweight. Most of these children are born at home and have been doing well for anywhere from 2-20 days when they develop abdominal symptoms. Many of these children also have a prior history of infective diarrheal disease and/or 'ghutti' intake. Ghutti is an indigenous substance containing opioids and is often given by poor working women to their infants to keep them quiet. Excess administration of ghutti causes a form of paralytic ileus due to the overdose of opioids and predisposes to infective gastrointestinal diseases. One fact that is almost universal is the poor socio-economic status of our patients and the poor hygiene in which these newborns are nurtured indicating that morbidity and mortality is largely preventable. It is obvious that a stress state with hypovolemia, hypotension and diminished resistance to infection is also an additional contributing factor in patients with infective diarrheal diseases who develop NEC or SIP.

A variety of operative procedures were performed on the patients in our series, including resection and primary anastomosis or primary closure of perforations in 54 patients. There were 47 deaths, overall a mortality of 55.2%. These included 13 out of 15 patients who were admitted in very poor general condition and often were premature or of low birthweight. Many of these newborns had evidence of severe neonatal sepsis. These patients were thought to be in too poor a general condition to withstand major surgery and intraperitoneal drains were inserted under local anesthesia. Overall, most deaths were due to the consequences of severe overwhelming neonatal sepsis.

Peritonitis in Children Aged 1 Month to 12 Years

During the period from February 1999 to March 2001, 90 patients in the age group of 1 month to 12 years were admitted with peritonitis in the pediatric surgery ward of Kalawati Saran Children’s Hospital, New Delhi. The etiology of peritonitis in these 90 patients is shown in Table 48.4. There were 55 male and 35 female patients, (a male: female ratio 1.57:1). Of the 12 patients with primary peritonitis however, 7 were girls and 5 were boys.

A study of Table 48.4 reveals certain interesting facts. According to the Western literature, the majority of cases of childhood peritonitis are due to perforated appendicitis. In contrast, in our series, tuberculous peritonitis, peritonitis due to non-specific perforation(s) of the intestine with/bowel gangrene, enteric (typhoid) perforations, and roundworm infestation with intestinal perforation were frequent causes of peritonitis (Fig. 48.7).
Tuberculous peritonitis was seen in as many as 18 patients (20% of the total). In 2 of these patients, primary peritoneal tuberculosis was absent, the peritonitis being secondary to intestinal tuberculosis with a bowel perforation proximal to a stricture. The early or ascitic form of tuberculosis was seen in only 3 patients, the remaining patients presenting with the chronic form of peritoneal tuberculosis with matted bowel loops and features of intestinal obstruction. 4 patients presented with an umbilical fecal fistula secondary to perforation of matted, edematous intestinal loops. This is likely to be a consequence of delayed presentation and/or inadequate primary treatment.

In 20 patients, peritonitis was due to a single or multiple perforation(s) of the small or large intestine with/without the presence of associated gangrene of the bowel. Significantly, out of these 20 children, 10 were in the age group of 1 month to 1 year. In this particular group, 6 children (60%) had a history of gastroenteritis with vomiting and diarrhea or diarrhea alone, immediately preceding the presentation with peritonitis. In 2 patients, there was a history of respiratory tract illness, and in 1 child a history of high-grade fever for a few days prior to the development of peritonitis. Four patients (40%) were malnourished with weight less than the 50th percentile of normal for the age. Thus, in a large percentage of these small infants, predisposing factors and stress in the form of infective gastroenteritis/enterocolitis, other infectious diseases and malnutrition were present. It is likely that in these infants, the etiopathogenesis of intestinal perforation, gangrene, and peritonitis is similar to that described earlier for the majority of newborns presenting with SIP/NEC and peritonitis at our institution. Postoperative mortality in this group was high, as many as 6 infants (60%) succumbing to varying combinations of severe sepsis, persistent peritonitis, dyselectrolytemia, poor general condition and malnutrition.

There were 17 older children (age group 1 year to 12 years) in whom peritonitis was due to intestinal perforation with/without gangrene of the bowel. In 7 of these children, the clinical history, investigations and operative findings suggested that intestinal perforation was due to typhoid enteritis, while in the remaining 10 patients, no specific cause of bowel perforation or gangrene could be found.

Miscellaneous causes of peritonitis included blunt abdominal trauma with jejunal perforation (2 patients), perforated ileal duplication cyst (1), ileal volvulus around a chylolymphatic cyst with proximal perforation (1), acid ingestion with intestinal perforation (1), and perforation of Meckel’s diverticulum (6).
perforation (1), perforation of the gall bladder (1), foreign body perforation (1), ruptured liver abscess (1), ruptured perinephric abscess (1) and a trichophytobezoar with jejunal perforation in 1 patient.

The overall mortality in this series of 90 patients was 10% (9 patients). Significantly, all the 9 patients who died had peritonitis as a consequence of SIP or NEC with gangrene and bowel perforation, 6 in the age group of 1 month to 1 year, and 3 who were 1-12 years old at presentation. It is clear therefore, that peritonitis and its consequences are more severe in this vulnerable group of patients. The illness often pursues a very fulminant course and morbidity and mortality may be very high.

REFERENCES

HISTORY

Hildanus in 1627, was the first author who described what was thought to be a case of infantile hypertrophic pyloric stenosis (IHPS). However, the history does not fit with the usual evolution of the IHPS, as the child recovered spontaneously, and no pathological proof is provided with the case. It is likely that it was a case of overfeeding.

Patrick Blair in 1717, described a more typical clinical and postmortem finding of IHPS, and presented it to the Royal Society in London. The first complete description was by Harald Hirschsprung, a Pediatrician from Copenhagen, in 1888, and established the clinical and postmortem findings as a new, specific entity, and named it Angeborener Pylorusstenose (congenital pyloric stenosis) because he believed that this pathology was congenital, by failure of the involution of the fetal pylorus.

Use of atropine remained at the center of the medical management, till the surgical treatment was established. Cordua performed jejunostomy in 1892, Lobker attempted gastroenterostomy in 1898, and, 1899 Nicoll tried pyloric dilatation via gastrostomy. Pyloroplasty and extramucosal pyloroplasty was then described by Dent, Nicoll, Fredet, and Weber.

On 23 August 1911, Wilhem Conrad Ramsted first performed his pyloromyotomy without transversal suture. On 18 June 1912, he successfully repeated his new technique on another male patient; and reported these two cases to the Natural Science Assembly at Munster. The Ramsted operation is nowadays a standard surgical technique for the IHPS.

ANATOMY

There is a pyloric obstruction caused by hypertrophy of the muscle, involving the internal circular layer on gastric side.

The enlarged pylorus has an olive shape measuring usually 2-2.5 cm in length and 1-1.5 cm in diameter. The “olive” is pale, contrasting with the pink color of the duodenal cul-de-sac.

Histologically, the mucosa and adventitia are normal. The edematous mucosa is seen as a longitudinal fold at the contrast study. The stomach is distended and frequently hyperkinetic.

ETIOLOGY

Etiology is unknown. Whether the condition is congenital or acquired is debated. Thompson Benson in 1897, described it as a neurologic dysfunction at the stomach and pyloric level leading to uncoordinated and sometimes antagonistic contractions. Therefore, the hypertrophy is a consequence of this hyperactivity.

There has been lot of research on this subject and various factors associated with this pathology namely are: decrease in ganglion cells in hypertrophic pyloric muscle, immature ganglion cells; pyloric ulcer leading to antropyloric spasm and muscular hypertrophy; hypergastrinemia; substance P causing chronic pylorospasm followed by a hypertrophy of the pyloric muscle.

Studies investigating the role of encephalin, neuropeptide Y, vasoactive intestinal polypeptide and gastrin releasing peptide shows reduction of immunoreactivity in intramuscular nerve supporting cells and lack of nitric oxide synthase have been suggested as a factor in the pathogenesis of IHPS.
Ultrastructural abnormalities of enteric nerves and the interstitial cells of Cajal have been implicated. Increased insulin-like growth factor and platelet derived growth factor system in the pyloric muscle in IHPS have also been noted. The Neuronal cell adhesion molecule (NCAM) plays an essential role in the development and function of the peripheral nervous system. It has been reported that NCAM, NADPH diaphorase and neurofilament immunoreactive fibers were absent or markedly reduced within the hypertrophied circular and longitudinal musculature. It suggests that this condition may be a consequence of a developmental deficiency preventing the proper innervation of the pyloric muscle layer. Genetic mutations involving the production of nitric oxide may be responsible for many cases of IHPS. An association between systemic erythromycin in infants and subsequent IHPS, with the highest risk in the first 2 weeks of age, has been reported.

ASSOCIATED ANOMALIES

Some associations are genetically X-linked described by Spicer, including esophageal atresia, and neuronal dysfunction. Other non-genetic malformations are: inguinoscrotal pathology, encephalocele, hydrocephalus, cardiac malformations, gastroesophageal reflux, and hiatus hernia are well known.

Jaundice, described with IHPS, usually resolves after pyloromyotomy.

INCIDENCE

It is 1.5-4 in 1000 live births amongst whites but is less in Africans and Asians.

The highest incidence is in the north of Europe, and incidence is increasing with an increased number in the spring and autumn.

It has been observed that there is male predominance with familial predisposition. If mother had the pathology then 19% of the male and 7% of the female offspring are likely to be afflicted. Only 5% of the male and 2.5% of the female offspring of a father with pyloric stenosis will develop the disease; environmental and seasonal variations have been described.

DIAGNOSIS

The infant with hypertrophic pyloric stenosis often starts vomiting at 3-4 weeks of life, and sometimes earlier. The vomit contains milk or curds and is non bilious; it can have a brownish discoloration or have coffee-ground appearance, caused by chronic gastritis. The vomiting is always forceful and may be abrupt or insidious in onset. The vomiting occurs shortly after feeding, and the infant remains hungry. A delay in the diagnosis may result in pronounced malnutrition and severe electrolyte imbalance.

IHPS has been diagnosed in premature debilitated infants; at birth, and even in utero.

The diagnosis of IHPS is made by physical examination in 75%; it should start by a feeding of formula if the infant state allows it (infant alert, active). This makes visible gastric peristaltic waves that progress successively from the upper left to the mid right of the abdomen.

The examiner should stay on the left of the patient while baby is supine in mother's arms, relaxed, warm and reassured. The left hand is placed at the epigastrium with the mid-finger tip just above and to the right of the umbilicus. The right hand is beneath the infant for support, giving a slight extension to the back in order to ease the palpation of the "olive" which is pushed forward by the vertebrae. If it is not palpated, then the test is repeated just after an episode of vomiting.

Some may suggest surgery after confirming the presence of pyloric "tumor" by test feed but authors recommend ultrasound confirmation of the pathology to avoid negative laparotomy. Demonstration of pyloric muscle thickness of 4 mm or more by ultrasound and pyloric channel length of 16 mm or more increases the specificity of the test to 100% (Fig. 49.1).

Earlier, an upper gastrointestinal examination with the barium was recommended, which is replaced by ultrasound examination to confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS

This includes primary medical and surgical conditions that result in projectile non-bilious vomiting such as pylorospasm, gastroesophageal reflux, gastric atony, metabolic disorders and increased intracranial pressure. Other surgical causes of non-bilious emesis
include gastric antral web, pyloric atresia, pyloric duplication cyst and ectopic pyloric pancreas.

**PREOPERATIVE MANAGEMENT**

The longer duration prior to presentation to a hospital and the frequent vomiting can lead to severe dehydration with electrolyte imbalance. Vomiting of gastric contents leads to depletion of sodium, potassium and hydrochloric acid, resulting in hypokalemic, hypochloremic metabolic alkalosis. The kidneys conserve sodium at the expense of hydrogen ions, leading to paradoxical aciduria. In more severe dehydration, in an attempt to retain fluid and sodium, renal potassium losses worsen. The renal and the gastric loss of $K^+$, will not be reflected in the serum level until the intracellular $K^+$ is severely depleted.

The hypokalemia and acid urine are late signs of metabolic alkalosis.

**Preoperative Fluid Resuscitation**

- **Type of fluid:** 5% Dextrose with 0.45% Saline. Add 2 mmol of KCl in each 100 ml of fluid.
- **Volume:** 150 ml per kg of body weight per 24 hours.
- **Investigation:** Serum electrolytes every 12 hours.
- **Nasogastric loss:** Replace ml for ml by normal saline.
- **The most important factor is serum HCO$_3$ level, 25-28 mEq/l denoting a safe correction of alkalosis before proceeding to surgery.**

**OPERATIVE MANAGEMENT**

Patient is operated after correction of fluid and electrolytes, under general anesthesia in a warm theatre.

Since the initial description of pyloromyotomy as the curative procedure for infantile hypertrophic pyloric stenosis, it has been achieved through diverse upper abdominal approaches to pylorus. The supraumbilical incision was described by Tan and Bianchi in 1986 with the intention of achieving an unscarred abdomen (Figs 49.2 and 49.3). Since the original publication various authors have described some modifications. We have described a modification and have used our approach successfully in more than forty patients with no complication of perforation, wound dehiscence or conversion to right hypochondrial incision.
SURGICAL TECHNIQUE

All patients are fully resuscitated pre-operatively. Separate gentle cleaning of umbilicus is performed followed by standard preoperative cleaning. A supra-umbilical skin incision is made around one-half of the umbilicus and carried down to the abdominal wall fascia with sharp dissection as shown in Figure 49.4.

The incision is modified at the level of the rectus sheath. A midline vertical incision is made up to the tip of the xiphisternum and a 4/0 vicryl (ethicon) stitch is placed at the cephalic end of the incision as a landmark. At the umbilical end the incision is converted in the shape of an inverted T. The transverse incision through the sheath needs to be longer on the right side of the midline, approximately double the size as compared to its arm on the left side. Two stay sutures are placed at the corners of the transverse incision.

The pylorus is delivered easily and pyloromyotomy performed (Figs 49.5 and 49.6). We use the back of the scalpel handle to split pyloric muscle after making a very superficial incision on pyloric swelling.

Before returning the pylorus to the peritoneal cavity, a perforation should be carefully looked for, and if there is one, it should be closed with an omental patch. A meticulous closure of the fascial wound is done by 4/0 vicryl (ethicon) stitch. Hemostasis is achieved before skin closure and a sterile dental roll is used for pressure dressing for forty-eight hours.

Laparoscopic Pyloromyotomy

Alain et al first described Extramucosal pyloromyotomy by laparoscopy in 1991. This has gained popularity in recent years. A 5 mm port is placed in the umbilicus under direct vision (Fig. 49.7) and the abdomen is insufflated with carbon dioxide. Two 3 mm stab incisions using a No.11 scalpel blade, are made, 1 in the epigastrium and another in the right mid-abdomen (Fig. 49.8). The grasper inserted through the right mid-abdomen incision, stabilizes the pylorus and the serosal surface of the hypertrophied pylorus is incised using a pylorotome, inserted through the epigastric incision. The pylorotome is then removed and pyloromyotomy completed using a pyloric spreader.
A meta-analysis of studies comparing laparoscopic versus open pyloromyotomy found 8 studies comparing the 2 methods from 1966-2002 and included 595 patients (355 open and 240 laparoscopic). Four studies were retrospective reviews, 3 were prospective and only 1 study was a randomized controlled trial. Mucosal perforations and incomplete pyloromyotomy were both more common with laparoscopic pyloromyotomy, although not significantly so. Compared with open procedure, laparoscopic pyloromyotomy is associated with similar operating time, shorter time to full feeds and shorter postoperative length of stay. A retrospective review in 2004, comparing 232 laparoscopic pyloromyotomies with 225 open procedures, showed no significant difference in rate of complications. Van Der Bilt JDW et al, has reported decreased complication rates from laparoscopic pyloromyotomy with increased experience.31

POSTOPERATIVE CARE

Maintenance intravenous fluids are continued postoperatively until the infant is feeding satisfactorily. The timing of reintroduction of feeds continues to be controversial. We recommend feeding the infant from the following morning and increase the volume of feed as tolerated.

COMPLICATIONS

Pyloromyotomy is associated with a low incidence of morbidity and mortality.

Mucosal perforation is usually because of excessive dissection on the side of duodenum. It should be recognized and closed with one or two sutures and a patch of omentum tied over it. Other complications include incomplete pyloromyotomy, hemorrhage, wound infection and dehiscence. Postoperative vomiting usually improve with time.

OTHER TECHNIQUES AND NONOPERATIVE TREATMENT

Balloon dilatation of pylorus has been tried with discouraging results. It has been described to perform pyloromyotomy with exteriorization of the pylorus.

Non-surgical treatment by frequent small feeding has been described. Medical treatment involving intravenous and oral atropine in addition to fluid and electrolyte replacement has also been reported. However, these are not preferred approaches in most countries.

Gastric Volvulus

Shilpa Sharma, D K Gupta

50

Volvulus is derived from the Latin word volvere, that means 'to roll'. Gastric volvulus is usually a disease occurring in adults with only about 10-20% of cases occur in children, usually before age 1 year, but cases have been reported in children up to 12 years age.

Though the number of cases reported was only just over 300 cases till 1991, yet a high index of suspicion has helped to identify more cases recently.1-5 Gastric volvulus in children is thus a rare surgical emergency. However, it may be an important cause for mortality if diagnosis is delayed and gastric perforation occurs. Chronic gastric volvulus could also be responsible for many incidences of apparent life-threatening event in infancy.6

Berti first described gastric volvulus in 1866.7 Berg performed the first successful operation on a patient with gastric volvulus in 1896. Borchardt described the classic triad of severe epigastric pain, retching without vomiting, and inability to pass a nasogastric tube in 1904.8

DEFINITION

Gastric volvulus is an abnormal degree of rotation of one part of the stomach around another varying from 180 degrees to 360 degrees.9 The abnormal rotation creates a closed loop obstruction that can result in incarceration and strangulation.

According to the axis of rotation of the stomach, 3 types of gastric volvulus have been described:

i. Organoaxial volvulus: Stomach rotates about its longitudinal axis.9,10 The antrum rotates in opposite direction to the fundus of the stomach. This is the most common type in both children and adults and is usually associated with diaphragmatic defects. Strangulation and necrosis commonly occur with this type and have been reported in 5-28% of cases.

ii. Mesenteroaxial volvulus: Stomach rotates about a line perpendicular to the cardiopyloric line. The rotation is usually incomplete and occurs intermittently. Vascular compromise is uncommon. Patients usually have chronic symptoms. It is more often seen in young children than in adults and is associated with ligamentous laxity but not with diaphragmatic defects.

iii. Combined form: Stomach rotates on both its long and short axes. This form is usually observed in patients with chronic volvulus.

PREDISPOSING FACTORS

Gastric volvulus may be primary (idiopathic) or secondary depending upon the absence or presence of associated anomalies.

Type 1—Primary Gastric Volvulus

The stomach is anchored at the esophageal hiatus by the peritoneal reflection, gastrophrenic, gastrocolic, gastroplenic and gastrohepatic ligaments (Fig. 50.1). In neonates, absence or attenuation of these ligaments predisposes to gastric volvulus. Acute idiopathic gastric volvulus is relatively rare in children.3,11

Type 2—Secondary Gastric Volvulus in Presence of Associated Anomalies

Associated anomalies include:

1. Congenital diaphragmatic hernia3,12,13
2. Traumatic diaphragmatic hernia14
Gastric Volvulus

3. Eventration of the diaphragm
4. Wandering spleen
5. Asplenia-polysplenia syndromes
6. Parahiatal hernia
7. Morgagni hernia

Miller et al reviewed the anatomic defects associated with this type of gastric volvulus, as diaphragmatic defects - 43% Gastric ligaments - 32% Abnormal attachments, adhesions, or bands - 9% Asplenia - 5% small and large bowel malformations - 4% Pyloric stenosis - 2% Colonic distension - 1% Rectal atresia - 1%. There may be a combination of associated anomalies.

CLINICAL PRESENTATION

Gastric volvulus has been described as acute or chronic depending upon the mode of presentation. The symptoms depend on the degree and rapidity of twisting. Symptoms may range from mild abdominal pain and vomiting, when no or partial outlet obstruction is present, to severe pain and retching, when there is complete obstruction and ischemia. Chronic gastric volvulus is more common than acute gastric volvulus.

The gastric volvulus in children is usually associated with other anomalies and is thus secondary. The most common association is with diaphragmatic hernia and thus the volvulus is intrathoracic. Intrathoracic gastric volvulus usually presents in infancy. Intrathoracic gastric volvulus may present as an acute case or as a chronic case.

In chronic cases, the patient may complain of non-specific symptoms, intermittent episodes of abdominal pain, abdominal fullness following meals and dysphagia. The child with chronic type of gastric volvulus may present with recurrent chest infections and weight loss. There are few abdominal signs because the stomach is in the thorax. Chronic volvulus may be detected incidentally on plain chest radiographs or on upper gastrointestinal (GI) series.

Acute Intrathoracic gastric volvulus manifests as sharp chest pain radiating to the back and rarely dyspnea. Occasionally, some patients present with hematemesis secondary to mucosal ischemia and sloughing. This can rapidly progress to hypovolemic shock from loss of blood and fluids. Acute intrabdominal gastric volvulus presents as the sudden onset of severe epigastric or left upper quadrant pain. In acute cases, the child may present with symptoms of acute intestinal obstruction. A case of perforated stomach may present with pyoperitoneum. In a series, 8 cases with organoaxial volvulus had presented with acute apnea associated with pallor, cyanosis, and hypotonia.

The typical features described in adults include Borchardt’s triad of epigastric pain, retching with no vomiting, and difficulty or failure to pass a nasogastric tube as an acute presentation. These are however not seen frequently in children. None of the patients in a series of 18 patients had Borchardt’s triad. When acute GV in children fails to exhibit the full gamut of Borchardt’s triad, the diagnosis may be delayed. Upper GI series can be diagnostic during an acute attack.

COMPLICATIONS

Gastric volvulus may be complicated with ulceration, perforation, hemorrhage, pancreatic necrosis, omental avulsion and rarely splenic rupture.

Organoaxial volvulus is more commonly associated with strangulation. Because of the rich vascular supply of the stomach, strangulation occurs in only 5-28% of cases. Increased pressure within the hernia sac associated with gastric distension can lead
to the ischemia, necrosis and perforation. Gastric perforation can result in sepsis and cardiovascular collapse.

**INVESTIGATIONS**

**Plain Radiograph**

Plain radiograph may suggest the diagnosis of gastric volvulus which can be confirmed with a contrast study. A single large air-fluid level or a single bubble without additional bowel gas seen on plain abdominal radiography may indicate gastric volvulus. A retrocardiac gas-filled viscus in cases of intrathoracic stomach confirms the diagnosis. The diaphragm should be seen for evidence of any herniation or eventration. Bilateral eventration of the diaphragm with perforated gastric volvulus in an adolescent has been reported. Pneumoperitoneum should be looked for as an evidence of perforation. If a nasogastric tube is passed, it may be seen to coil at the esophagogastric junction that may be inferior to its normal location. Plain radiographic findings that are suggestive of gastric volvulus should be confirmed with a barium study.

**Ultrasonography**

The ultrasonographic features consist of a constricted segment of stomach, with 2 dilated segments located above and below the constricted part, akin to a peanut. However, most report normal findings on ultrasonography, thus an upper GI series should be used to confirm the diagnosis if suspected.

**Contrast Studies**

If barium moves past the esophagogastric junction, the upside-down configuration of the stomach and the degree of obstruction can be documented organoaxial volvulus is demonstrated as reversal of greater and lesser curvatures with two air fluid levels. In mesentericoaxial volvulus, the stomach may be seen in inverted position with pyloroantral obstruction showing a beaked appearance.

The combination of an abdominal radiograph and upper gastrointestinal contrast study usually allows an unequivocal diagnosis in all cases. The barium study is highly sensitive and specific for gastric volvulus (Figs 50.2A and B). However, the diagnosis may be missed in cases of intermittent torsion. The upper GI series may show only a paraesophageal hernia or eventration of the diaphragm during a symptom-free interval, leading to a false-negative diagnosis. A study has demonstrated the peanut sign on ultrasonography in a case of chronic gastric volvulus.

**Other Investigations**

The computed tomography (CT) scanning and magnetic resonance imaging (MRI) appearance of gastric volvulus can be variable. The extent of diaphragmatic herniation, the points of torsion, and the final position of the stomach determine the appearance (Figs 50.3A and B).

Gastric volvulus may be discovered during scintigraphic examination for chronic GI bleeding, sometimes incidentally, as an intrathoracic stomach with the greater curvature superior to the lesser curvature. Similarly angiography for massive or refractory GI hemorrhage has shown displaced gastroepiploic arteries are high beneath the left hemidiaphragm in gastric volvulus. The angiographic appearance is sensitive and specific during an acute episode.

Fiberoptic endoscopy has a limited role in the diagnosis of gastric volvulus because the twist precludes passage of the endoscope. Laboratory studies are generally unrewarding, although levels of amylase and alkaline phosphatase may be increased.
DIFFERENTIAL DIAGNOSIS

In acute gastric volvulus, the differential diagnosis includes acute gastric dilatation, gastric outlet obstruction like prepyloric mass and pyloric web, perforated peptic ulcer, ruptured gallbladder.

MANAGEMENT

Reduction of acute gastric volvulus may be attempted with nasogastric decompression though it is often unsuccessful. Nonsurgical treatment has been described for primary gastric volvulus by few authors but secondary gastric volvulus needs immediate surgical intervention to minimize the risk of infection and perforation which may lead to mortality. The treatment for chronic idiopathic gastric volvulus may be based on the age at diagnosis, the severity of symptoms, and how patients are expected to comply with conservative measures.

Emergent surgical intervention is indicated for acute gastric volvulus. With chronic gastric volvulus, surgery is performed to prevent complications.

Although the treatment of gastric volvulus is surgical, endoscopic reduction can be attempted in selected patients of acute and chronic cases with multiple comorbid conditions who are poor candidates for surgery. The scope is advanced beyond the point of torsion, then rotated to untwist the stomach. However, there is a risk of gastric perforation and should not be attempted in patients who appear to have vascular compromise. Failure to reduce the twist necessitates surgery. Percutaneous endoscopic gastrostomy can be performed after reduction of the volvulus to reduce the incidence of recurrence. Some authors argue that surgical intervention is necessary in these cases only when endoscopic management fails or when the volvulus recurs.

Surgical goals of treatment include:
1. Reduction of the volvulus
2. Prevention of recurrence
3. Repair of predisposing factors.

Most cases of acute and chronic gastric volvulus can now be approached laparoscopically. A combined laparoscopic and endoscopic approach has also been used to better assess the intraluminal and intra-abdominal status of the stomach as well as its position before, during, and after fixation.

Laparoscopy assisted anterior gastropexy may be performed to fix the stomach in its anatomically correct position. Some authors feel that routine gastropexy for all patients with a radiologic diagnosis of gastric volvulus is not mandatory. Prophylactic gastropexy should be mandatory in patients developmental anomalies of the ligamentous connections.

Gastrostomy may be done in older children with adequate stomach size to prevent recurrence, help in decompression and for feeding later on. An anterior gastropexy with associated antireflux fundoplication may be performed. Diaphragmatic defects may be repaired. Plication of the diaphragm and gastropexy is needed for cases associated with eventration of the diaphragm.
Patients with signs of acute peritonitis are better explored through a midline laparotomy incision. Partial or total gastrectomy is required in the setting of necrosis. Peritoneal lavage is done for cases with gastric perforation after gastrectomy of the involved segment or repair of the perforation. The healing is poor in these patients after stranulation and a re-exploration may be required.

Gastric decompression with either a nasogastric tube or gastrostomy is maintained until the return of bowel function.

**MORTALITY**

The mortality rate for acute gastric volvulus is reportedly 42-56% in general with a nonoperative mortality as high as 80%. The patients have a higher mortality if gastric perforation has occurred. Almost the whole stomach is ischaemic with poor healing after gastrectomy. The mortality rate for chronic gastric volvulus is 10-13%.

**REFERENCES**

Gastrointestinal bleeding (GI bleeding) is a common condition encountered in children. Sometimes it occurs in patients undergoing treatment for other disease. Others present with gastrointestinal bleeding as the first manifestation of an underlying disease. The patient may be vomiting of blood (site of bleeding is usually above the ligament of Treitz) or may be passing blood per anus (site of bleeding is below the duodeno-jejunal flexure). In either situation the blood passed may be fresh or altered. The bleeding may be severe enough to necessitate admission and treatment of hemorrhagic shock before initiating investigations toward a specific etiology and its subsequent treatment. Fortunately in most children the bleeding ceases spontaneously, giving us ample time to investigate and home in on an accurate diagnosis. The search for an etiology is however considerably influenced by the age of the child as is evident from the list of conditions in Table 51.1. For the benefit of readers an empirical approach to diagnosis has however been included in Table 51.2.

**GI BLEEDING IN THE PEDIATRIC POPULATION—AN OVERVIEW**

As stressed above, the approach to children with GI bleeding is distinct in different age groups. Certain underlying similarities however can not be overlooked. Questioning the parents on the amount of blood loss, assessing the vital parameters and hemoglobin estimation are essential in gauging the hemodynamic status of the child. If bleeding is severe and is estimated to be greater than 15% of the blood volume then resuscitation must precede investigation for specific diagnosis. A patient in shock is initially treated with crystalloids like Lactated Ringer’s solution followed by blood or packed cell transfusion depending on the hemoglobin level and the hematocrit. Once the patient’s hemodynamics gets stabilized, investigations are initiated toward a specific etiology (Table 51.2) and the treatment started.

In a newborn, assessment of the coagulation status for bleeding disorders, Roentgenogram of the abdomen for NEC or volvulus neonatorum, examination of the perineum for anal fissure and examination of stool to exclude infective diarrhea are useful.

In infants and older children upper or lower GI endoscopy, Roentgenogram of the abdomen for intestinal obstruction or isotope tagged RBC scans are useful. Angiography becomes imperative in patients where the site of bleeding remains elusive in spite of the usual imaging investigations. In some patients, endoscopy of the upper or lower GI is performed on the operation table and sometimes passage of the endoscope through the enterotomy wound becomes necessary.

**GI BLEEDING IN NEONATES**

A newborn with GI bleeding having history of perinatal stress may be suffering from *erosive gastritis*. A newborn being treated for septicemia may develop GI bleeding as a consequence of *consumptive coagulopathy* (or DIC). Bleeding from the GI tract along with bleeding from sites in an otherwise normal newborn may be due to *hemorrhagic disease of the newborn.* It is important to enquire about administration of vitamin K to the newborn. *Maternal
performed to detect maternal blood in the newborn’s vomitus. A change in the color of a sample of vomitus following treatment with sodium hydroxide, confirms the presence of maternal blood.

Saline lavage (a cold saline lavage may cause hypothermia) antacid, H₂ receptor antagonists (1-3 mg/kg/day over 4 days), coating agents like sucralfate usually cures erosive gastritis. If continuous bleeding lowers the hemoglobin level to below 12 g/dL fresh blood should be transfused immediately. In patient with septicemia, a proper microbiological screen is instituted and appropriate antibiotic administered.

intake of drugs like sulphonamides may interfere with vitamin K absorption in newborn or cause derangement of liver function and lead to bleeding in newborn. When coagulopathy is suspected in a newborn assessment of the bleeding time and coagulation profile (prothrombin time and activated partial thromboplastin time) is advised. Ap. test is performed to detect maternal blood in the newborn’s vomitus. A change in the color of a sample of vomitus following treatment with sodium hydroxide, confirms the presence of maternal blood.

A change in the color of a sample of vomitus following treatment with sodium hydroxide, confirms the presence of maternal blood.
Gastrointestinal Bleeding

An upper GI bleed of more than 20 ml of blood is sufficient for the appearance of altered blood in stool. A patient with malrotation of gut with volvulus will have bilious vomiting with altered blood per anum. The vomitus may also contain blood. A straight radiogram of the abdomen will show a paucity of gas in the bowels. Treatment of midgut volvulus requires urgent resuscitation and prompt laparotomy for division of the Ladd’s bands (the Ladd’s procedure). Contrary to popular belief anal fissures can result following either loose motion or constipation. Stools are streaked with blood. Nappies may be spotted. The treatment includes regulation of stool to normal soft consistency and local application of anesthetics.

In NEC the stool is mixed with blood, which may be altered or bright red. There is more often than not, a history of perinatal stress. Features of septicemia may be obvious. Early in the disease the abdomen will be tender. As the disease progresses, features of peritonitis appear. Investigations include full septic screening and straight radiogram of the abdomen to detect the presence of gas in the bowel wall (pneumatosis intestinalis), gas in the portal vein or pneumoperitonium appear.

GI BLEEDING IN INFANTS

Infants with IHPS rarely present with blood tinged vomiting. They usually present with nonbilious vomiting, show visible gastric peristalsis and may have a palpable pyloric tumor. Ultrasonography has been very helpful in the diagnosis of pyloric tumors, which are not clinically palpable. Straight radiogram of the abdomen or contrast study of the upper gastrointestinal tract are rarely necessary to demonstrate gastric hold up or string hold up or string sign at the pylorus. The treatment is surgery following resuscitation.

Another cause of nonbilious vomiting mixed with streaks of blood is Reflux esophagitis. Upper GI contrast study, esophageal pH monitoring, esophageal manometry, technetium milk scanning and perhaps endoscopy help in reaching a diagnosis. Treatment consists of antacids, thickening of feeds, maintenance of upright posture, small frequent feeds and prokinetic agents. Rarely antireflux surgery is necessary.

An important cause of lower GI bleeding between 2 months and 2 years is intussusception. Prior to bleeding which is classically described as “red current jelly”, the child has episodic abdominal pain. A sausage shaped lump in the abdomen is easily palpable. Ultrasonography examination is of great help in the diagnosis of a lump in the restless child. Single or double contrast enema study also helps in diagnosis and treatment of the condition. Cases in which hydrostatic reduction fails, surgery is necessary.

In tropical countries infants often present with infective dysentery. In such cases, stool is mixed with blood and mucus. Such a patient will have no feature of intestinal obstruction. Stool examination and culture will help in diagnosis and treatment.

GI BLEEDING IN OLDER CHILDREN

Peptic ulcers: in older children can develop acutely following burns (Curling’s ulcer) head injury
(Cushing’s ulcer), malignancy and sepsis. They are promptly diagnosed by endoscopy and treated with cold saline lavage, antacid, H₂ receptor antagonists and treatment of the primary disease. They rarely require surgery.¹

**Erosive gastritis:** following ingestion of drugs is another cause of massive upper GI bleeding in children. Such bleeds may be fatal. Prompt diagnosis is possible by eliciting a history of drug intake and performing endoscopy. Treatment follows the principles of peptic ulcer management. The offending drug must be identified and withdrawn.

**Portal hypertension:** in children can cause alarming upper GI bleeding. The common causes of portal hypertension in our country are extrahepatic portal obstruction, non-cirrhotic portal fibrosis and biliary or postnecrotic cirrhosis. Patients usually present with massive bleeds and have a palpable spleen. Upper GI endoscopy will confirm the diagnosis. Ultrasonography, Doppler study of portal circulation and splenoportovenogram help in diagnosing the site of obstruction and size of the portal vein. Present day therapy include variceal sclerotherapy, banding or injection of gel foam. Rarely, surgery for devascularization or shunting the portal blood into the systemic circulation is performed.

**Arterio-venous malformation:** in the stomach or in the intestine can give rise to alarming bleeding. Diagnosis may be made by isotope tagged RBC scan or by angiography. At operation the mesentery adjacent to the malformation is usually abnormal.⁷,⁸

**Tropical jejunitis:** is a disease of tropical countries. Patients of tropical jejunitis present with features of intestinal obstruction and GI bleeding. At laparotomy segments of small intestine are found to be in various stages of necrosis.

Patients with **Meckel’s diverticulum:** have episodic, maroon colored massive bleeding. The diverticulum is lined by ectopic gastric mucosa. Acid secreted from the ectopic mucosa cause peptic ulcer on the adjacent alkaline mucosa. Similar bleeding can occur in patients or tubular duplication containing ectopic gastric mucosa. Such patients are usually older. At times a tender spot can be found in the abdomen. In 90% of cases the diverticulum can be picked up by Tc 99m Pertechnitate scan.⁹,¹⁰ Wedge resection of the diverticulum is performed if the adjacent ileum is healthy. Resection and anastomosis with adjacent ileum becomes necessary when the adjacent bowel is abnormal.

The most common cause (80%) of rectal bleeding in older children is an isolated rectal polyp. A rectal polyp is often single in the rectum in 40% of cases. They are easily picked up by per rectal examination and are treated by excision. Some polyps may occur at higher levels requiring colonoscopy or double contrast study. At these polyps may be two or three in number. These polyps are inflammatory in origin and are considered to be retention polyps. Since, these polyps have normal colonic tissue arranged in haphazard way they are also regarded as hamartomatous polyps.¹² Polyps can easily be removed during sigmoidoscopy or colonoscopy. If the polyps are more than five in number, periodic colonoscopic surveillance is mandatory.

Juvenile polyposis syndrome is an uncommon condition and can occur in infancy or in older children. These patients present with features of rectal bleeding and protein loosing enteropathy. Morphologically these polyps resemble juvenile polyps but are multiple in number and can involve the entire GI tract. In older children the involvement may be limited to varying portions of the colon and rectum. In localized disease, limited resection of the colorectum and regular colonoscopic surveillance is an option. Some authors recommend prophylactic colectomy, mucosal resection of the rectum and ileoanal anastomosis.¹²

Patients of **Peutz-Jeghers syndrome** have hamartomatous (hamartoma of muscularis mucosae) polyps in the intestine along with pigmentionst around buccal mucosa, conjunctiva and rectal mucosa (Fig. 51.4).¹３ They are most commonly found in the small intestine (Fig. 51.5).¹⁴ It has an autosomal dominant inheritance. Patients may present with colicky abdominal pain, features of intestinal obstruction or anemia. Patients with this syndrome may develop intestinal and extra-intestinal malignancies. Such patients need regular follow-up to detect signs of early malignancy. If a laprotomy is performed, conservative surgery for intestinal obstruction along with intraoperative endoscopic removal of larger polyps is the preferred mode of treatment.¹ Rarely a lymphoid polyp in young children present with recurrent severe bleeding. They are usually diagnosed by colonoscopy and require surgery.
Familial adenomatous polyps usually involve colon and rectum of patients in their teens. It has autosomal dominant transmission and the patients develop cancer of colon at an early age. There is a deletion in the long arm of chromosome. The polyps can occur anywhere from stomach to anus. Patients present with diarrhea, bleeding per rectum and anemia. Many patients are diagnosed during surveillance of relatives of diagnosed patients. The investigations are the same as for juvenile polyposis syndrome. Total colectomy with rectal mucosectomy and ileoanal pull though with or without a reservoir is the preferred method of treatment in all symptomatic patients. All these patients need regular endoscopic follow-up.

Some recent publications mention hookworm infestation as a cause of massive gastrointestinal bleeding. In tropical countries amoebic colitis and tuberculosis of large gut may present with recurrent severe bleeding. Repeated stool examination for parasites and acid fast bacillus is necessary to arrive at a correct diagnosis. Colonscopic biopsy also helps in the diagnosis. Medical treatment with anthelmentics, antiamoebic and anti tubercular drugs is usually sufficient to control the bleeding.

Idiopathic Primary Intussusception

Essam El-Sahwi

DEFINITION

Intussusception means telescoping of one segment of the gastrointestinal track into the other, usually the proximal segment goes into the distal.

Intussusception is the most common cause of intestinal obstruction in children under the age of two. The most frequent occurrence of intussusception is in midsummer and midwinter. The ratio of males to females is 3:1. The peak is seen in an infant 5-9 months of age and 80% of patients are under the age of two.1,2

TYPES

The terminal ileum usually telescopes into the right colon producing the following types of intussusception:

Ileocolic, ileo-ileocolic, or colocolic, may occur if the right colon goes into the transverse colon, or cecocolic if the cecum invaginates in the ascending colon.3

ETIOLOGY

Primary Intussusception

In 95% of infants and children, primary intussusception has no obvious cause. Some factors incriminated include

A- Disordered peristalsis due to weaning.
B- Preceding attack of gastroenteritis.
C- Adenovirus infections leading to hypertrophy of the Peyer’s patches which act as a leading point in intussusception.
D- Mobile ileocecal junction.
E- Long bloodless fold of Treves.

Secondary Intussusception

- In a minority of cases, intussusception is secondary to an obvious cause such as Meckel’s diverticulum, submucous lipoma. Inverted appendix or polyps, intramural hematoma (Henoch-Schoenlein purpura), or intestinal lymphoma.3

PATHOLOGY

The mass of intussusception is composed of the following layers: entering layer and returning layer which constitute the (intussusceptum), and the receiving layer (the intussuscipiens). Early in the disease, the intestine is viable, but if the case is neglected, the bowel becomes gangrenous due to composition of the blood supply in the squeezed mesentery between the layers of intussuscipiens leading to perforation and peritonitis.1

CLINICAL PICTURE

It is imperative to differentiate intussusception into early and late cases, as this will have clinical, and therapeutic implications.1 Intussusception may present as an emergency or even in postoperative cases.4,5

Symptoms

Early Cases

Intermittent colicky pain in a previously healthy robust active baby. The exception is a child with cystic fibrosis, Henoch-Schonlein purpura who may fail to thrive. Pain may cause the baby to draw his legs up to the Abdomen. Pallor and sweating are seen during the attack of pain. Reflex vomiting (nonbilious) is a
frequent early sign and is due to traction on the mesentery dragged by intussusception. Passage of blood or mucus unmixed with stools per rectum is a common symptom.

Neglected Cases

In neglected cases prolonged ischemia produce infarction of the bowel with subsequent peritonitis, and abdominal distension absolute constipation, and cessation of passage of blood per rectum. Vomiting is copious and might be feculent.

Signs

Early Cases

Pallor and sweating are common signs during the attack of colicky pains palpable sausage shape mass many be felt in the different quadrant of the abdomen palpation of the right iliac fossa palpation feels empty (sign D’ance). Rectal examination will reveal the passage of blood and mucus on withdrawal of the finger.

Neglected Cases

On physical examination, the abdomen is often distended, the right lower quadrant may feel empty, and a sausage -shaped mass may be palpable in the upper right to midabdomen (65%). The apex intussusception can sometimes be palpated on rectal examination (Figs 52.1A and B). The child is often febrile, and the blood count may show a leukocytosis. (A diagnostic barium enema may demonstrate the intussusception with a coil-spring sign at the point of bowel invagination).

The general condition deteriorates due to electrolyte imbalance and peritonitis.

INVESTIGATIONS

In early cases, sonography is helpful in the diagnosis of intussusception 75% of the cases (Target sign) (Figs 52.2A to D).

In doubtful cases, barium enema will show obstruction of the flow of the barium and the typical meniscus sign or cobra head sign (Figs 52.3A and B). Only in late cases plain X-ray anteroposterior and decubitus radiographs of the abdomen may demonstrate dilated loops of small intestine, air-fluid levels, or a soft tissue mass in the right upper quadrant.

Plan X-ray anteroposterior and decubitus films will show absence of intestinal gases from the ileocecal junction, also it may visualize the soft tissue shadow of the mass of the intussusception.

TREATMENT

An infant with intussusception is managed by insertion of a nasogastric tube, intravenous fluid resuscitation, and antibiotics. After rehydration, the child is taken to the radiology suit for an attempted hydrostatic reduction of the intussusception under sonographic guidance.6

A sedative should be administered prior to the examination once hypovolemia has been corrected. The surgical staff should be in attendance for the attempted reduction, with the anesthesiologist and

operation room staff alerted and standing by should reduction be unsuccessful.

Hydrostatic barium enema reduction has been the main stay of non-operative treatment. The enema is performed with 13-foot column and limitation of continuous hydrostatic pressure 5-minute time frames. Reduction is considered satisfactory when the intussusceptum is reduced through the ileocecal valve and the contrast material refluxes into multiple small bowel loops. Air reduction of intussusception was introduced in a large number of cases in China.

This technique is now commonly performed in the United States and Canada. Report suggests that this technique is as effective as barium enema reduction. The air pressure must be monitored, with a maximum of 110 mm Hg in children and 80 mm Hg in infants. This perforation occurs more commonly in babies less than 6 months of age with symptoms present for more than 3 days.

The procedure is performed under fluoroscopic control, and it is safe to make two to three attempts at reduction. The perforation rate is similar to that observed with hydrostatic barium enema. The rate of successful reduction varies from center to center but is in the range of 50-75%. Some centers do not attempt reduction if the infant has had symptoms for longer than 72 hours and has a server obstructive bowel pattern on plain abdominal X-ray. Unsuccessful reduction is followed by an immediate trip to the operating room.

The Alexandria University Experiment in Hydrostatic Reduction of Intussusception

The study was divided into two 8-years phases for comparison: phase I from 1983 through 1990 and phase II from 1991 through 1998.

During phase I, we started HR under US guidance in 1984 with a small number of cases and generally increased after gaining confidence and experience with the technique. Exclusion criteria from a trial with HR included any of the following: tender abdomen, bilious vomiting, abdominal distension, fluid levels on X-rays, and age less than 3 months.

Diagnosis and reduction were initially done by the first author—subsequently the technique was taught to pediatric surgical residents routinely. We do not have access to a 24-hour service for barium reduction, however’s we had 50 cases during phase I that had undergone a trial of reduction with barium under fluoroscopy. The diagnosis was made by finding the typical target appearance in transverse section and the pseudokidney in longitudinal scans. In phase II, in suspicious cases a diagnostic saline enema was given to provide contrast and enhance diagnostic accuracy.

HR was done using a worm saline reservoir at a height of 1 mm above the level of the patient, introduced through a 10-18 Fr Foley catheter after strapping the buttocks, monitoring progress by US (Aloka SSD- 650, Tokyo) with a 5 MHz sector transducer. Cases initially reduced on US (disappearance of the mass) were re-examined after 1 and 4 h for confirmation of reduction. Cases for surgery. Details of reduction and/or surgery were accurately recorded and analyzed.

Results

A total of 489 cases were studied in phase II. The diagnostic accuracy of US in detecting intussusception was 474/489 (96.9%) in phase I and 572/572 (100%). Table 52.1 shows the details of trials of reduction and success rates.

The duration of symptoms before presentation is shown in Table 52.2. The rate of successful reduction was reduced with delayed presentation (Table 52.3).

Unreduced cases were admitted for emergency surgery; the findings at exploration were recorded in operative records. These ranged between negative explorations where a reduced intussusception was found, indicated by a congested ileum and cecum, primary intussusception, either ileo-colic or ileo-ileocolic, and secondary intussusception, and the cause was reported (Table 52.4) shows the details of findings at operation for unreduced cases.

Cases of primary intussusception found at surgical exploration were treated by simple reduction with milking; when irreducible or gangrenous, resection anastomosis was performed. Table 52.5 shows the incidence of resection: 25% in phase 30.4% and I in phase II. The complications encountered included recurrence, perforation, and negative exploration. Table 52.6 shows the details of complications encountered during HR.

Among 50 cases that underwent barium reduction, 31 were reduced (62%) with recurrence in 3 and perforation in 2. Perforation resulted in barium peritonitis, the patients had a stormy postoperative course, and one of them eventually died.

Operative Intervention

In cases of failed hydrostatic reduction or in the presence of peritonitis or if the duration has been for more than 24 hours, an operative intervention is indicated with initial resuscitation. The various surgical techniques range from the manual reduction to the resection of the gangrenous bowel with end-to-end anastomosis (Figs 52.4A to 52.5C). Warm compression of the intestinal segment involved intussusception is helpful not only in reduction of the intussusception but also prevent further damage of the intestine by reducing the edema. It also helps to identify the area of demarcation between the healthy and unhealthy segment of the intestine. After reduction the intestine, it is vital to look for any.
Neglected Cases

Resection of the gangrenous bowel is required in neglected cases that might even amount to right hemicolecctomy or subtotal colectomy and restoration of the bowel continuity by an end-to-end anastomosis in 2 layers.

PROGNOSIS

In the hands of an experienced surgeon the mortality rate should approach zero. Deaths do occur if treatment is delayed. This shows the importance of early diagnosis of intussusception and it is always safer for the practitioner to refer any case of bleeding per rectum in the suspected age group to a pediatric surgical center.^

HISTORY AND INCIDENCE

In 1809, in the fifth volume of *Beiträge zur vergleichenden Anatomie*, John Friedrich Meckel identified the omphalomesenteric duct as the origin of the small bowel diverticulum that was later to bear his name.\(^1\) The first documented report of this anomaly was over 200 years earlier by Fabricus Hildanus and Littre reported its appearance in a hernia in 1745.\(^2,3\) Salzer is credited for first identifying heterotopic mucosa within the diverticulum.\(^4\)

Although it is widely accepted that Meckel’s diverticulum is the most common congenital anomaly of the gastrointestinal tract, the incidence is unclear. Traditional teaching has concentrated on the much-quoted “rule of two’s” (2% incidence, located within 2 feet of the ileocecal valve, 2 inches in length and usually symptomatic before 2 years of age). There is much evidence that this adage, albeit useful for teaching purposes, is outdated. All reports quoting incidence are confined to either autopsies or incidental finding at laparotomy, neither being representative of an otherwise healthy population. The incidence quoted in the literature varies from 3-4%.\(^5-10\) In asymptomatic patients the male to female ratio is nearly equal (1.3:1) but males are more likely to suffer complications (3.3:1).\(^5\)

An increased incidence of Meckel’s diverticulum is seen in association with other conditions including esophageal atresia, anorectal malformations and exomphalos.\(^11,12\) There also appears to be an estimated three-fold increase in incidence in Crohn’s disease.\(^13\)

ANATOMY

Meckel’s diverticulum is an example of a true diverticulum in which all normal intestinal layers are present. It is, by definition, situated on the antimesenteric border of the ileum, usually within 100 cm (rather than 2 feet) of the ileocecal junction and length varies between 1-8 cm. The blood supply to the Meckel’s diverticulum is characteristic. During development of the embryo, the paired vitelline arteries pass on either side of the mesentery to ramify over the yolk sac. The left vitelline artery normally disappears and the proximal section of the right persists as the superior mesenteric artery. The Meckel’s diverticulum is supplied by the distal section of the right vitelline artery, which persists as an end-artery branch of the superior mesenteric artery. Occasionally remnants of the vitelline vessels can result in bands connecting the diverticulum to the anterior abdominal wall or the mesentery, both scenarios potentially causing intestinal obstruction.

The Meckel’s diverticulum can invert and in this form is more likely to cause an intussusception.\(^14,15\) A rare anatomical variant is the so-called “giant” Meckel’s diverticulum. There is controversy regarding the distinction between this lesion and segmental
dilatation of the ileum and ileal dysgenesis. However, as with all vitellointestinal remnants (Fig. 53.1), the identification of the vitelline artery supplying the lesion is characteristic.\textsuperscript{16}

**HISTOLOGY**

**Heterotopic Mucosa**

Heterotopic mucosa (Fig. 53.2) of gastric, pancreatic and duodenal origin can be present within a Meckel’s diverticulum and the presence of such mucosa is more likely in symptomatic cases.\textsuperscript{5,17-23} There is great debate as to the incidence of heterotopic mucosa with widely varying figures quoted in the literature (Table 53.1). However, there is unanimous agreement that in cases with heterotopic gastric mucosa \textit{Helicobacter pylori} has no part to play in the symptomatology.\textsuperscript{19-21}

**Tumors**

Various series have reported malignant change within a Meckel’s diverticulum. Given the different heterotopic mucosa that can be found, it is not surprising that a wide range of malignancies have been reported in adults including carcinoid tumors, leiomyosarcoma and adenocarcinoma.\textsuperscript{24-27} Tumors reported in children include lymphoma, adenomyoma and nesidioblastosis.\textsuperscript{23,28,29}

Like carcinoid tumors found in the appendix, those found in a Meckel’s diverticulum are usually small, solitary and asymptomatic. However, they have a greater potential to metastasize than appendiceal carcinoids but there have been no cases reporting carcinoid tumors arising from a Meckel’s diverticulum in children.\textsuperscript{25}

**CLINICAL PRESENTATION**

Most published series have reported that approximately half of children with a symptomatic Meckel’s diverticulum present under the age of 2 years though that has not been our experience in Glasgow. Between 1946 and 1991, 281 Meckel’s diverticula were resected and less than one-third were in children less than 2 years of age (Fig. 53.3).

Meckel’s diverticulum can present with gastrointestinal bleeding, intestinal obstruction, perforation or inflammation. A Meckel’s diverticulum can also be found incidentally during laparotomy or laparoscopy. Each method of presentation will be discussed and the management options explored.

**Gastrointestinal Bleeding**

Painless gastrointestinal bleeding is the commonest presenting complaint in most reported studies of Meckel’s diverticulum. It usually occurs in children less than 5 years of age and can present with melena (black, tarry stools) or hematochezia (fresh red blood per rectum). The blood loss can vary from chronic insidious bleeding leading to anemia to acute massive blood loss presenting with shock.

On presentation, if there has been significant blood loss, the patient may require fluid resuscitation. The volume required should be estimated on the basis of the examination and should not be delayed until laboratory data are available. Intravenous access should be obtained early, and blood can be sent to establish the full blood count, hematocrit, platelet count, coagulation studies and for cross-match. Initial resuscitation with crystalloid or colloid is appropriate until blood is available (if indicated). Salient points in the history are previous episodes of bleeding, family history of bleeding disorders, and medications that may alter hemostasis. An accurate history taken from the parents or carer can usually distinguish between upper and lower GI bleeding although, due to the cathartic action of blood, vigorous upper GI bleeding can produce bright red blood per rectum. In such a situation the child is likely to have had a major bleed and is likely to be profoundly shocked. Examination should be directed toward estimating blood loss and establishing a diagnosis. A nasogastric tube should be passed; the aspirate should clarify whether the bleeding point is pre- or post-pyloric in origin. In the pediatric patient these steps are nearly always possible before planning surgery, and it is unwise to rush an unstable, hypovolemic child to the operating room (OR).

Investigations of the child with lower GI hemorrhage should not delay resuscitation. Stable patients with resolution of symptoms who have a positive 99mTc Technetium-pertechnetate scan (Meckel’s scan) should be prepared for resection of the diverticulum on a semiurgent basis. In patients where the Meckel’s scan is negative but have evidence of repeated hemorrhage, further investigation is indicated. 99mTc Technetium-labelled red cell scans can detect bleeding at a rate of over 0.1 ml/min. Angiography requires a bleeding rate of over 0.5 ml/min. A child who presents with ongoing bleeding or presents with repeated episodes sufficient to drop the hemoglobin concentration to less than 9 g/dl should be explored by laparoscopy or laparotomy. Endoscopy does not often show bleeding points in children, although it is often performed to exclude other causes before laparotomy is performed.

**Obstruction**

Meckel’s diverticulum can precipitate intestinal obstruction in a number of ways, the most common being intussusception and volvulus. These will be discussed in turn, followed by some more unusual examples reported in the literature.

**Intussusception**

Most cases of intussusception are idiopathic. In older children and adults it is more common for a lead point to cause the intussusception. In our 17-year series of intussusceptions, which included 255 cases undergoing laparotomy, there were 21 cases with lead points identified of which the commonest was a Meckel’s diverticulum (Table 53.2). In our experience, as with other series, intussusceptions caused by a Meckel’s diverticulum
diverticulum were not successfully reduced by contrast enema.\textsuperscript{33,34} The ultrasound appearance of the inverted Meckel’s diverticulum causing an intussusception is characteristic (Fig. 53.4). A Meckel’s diverticulum can rarely be identified during attempted air enema reduction (Fig. 53.5).\textsuperscript{15,34}

Children with a Meckel’s diverticulum acting as the lead point of an intussusception are likely to be in need of urgent fluid resuscitation. Following an unsuccessful attempt to reduce the intussusception by contrast medium or air enema, the child should be taken to the OR. Access to the abdomen is through a right-sided transverse incision. Making the incision above the level of the umbilicus offers better exposure. The Meckel’s diverticulum should be excised. It is likely that a more extensive resection will be necessary to ensure both ends of the anastomosis are healthy and well perfused. Primary anastomosis should be possible even in cases of perforation.

**Fig. 53.5:** Attempted air reduction of intussusception with a lead-point (arrow) which was found at laparotomy to be a Meckel’s diverticulum

**Fig. 53.6:** Internal hernia around a patent vitellointestinal duct

### Volvulus and Other Causes of Obstruction

Congenital bands can attach the Meckel’s diverticulum to the umbilicus. This attachment can act a pivot point for axial rotation and resulting volvulus.\textsuperscript{35} Although this is an uncommon complication the results can be devastating if urgent surgery to untwist the volvulus is not undertaken. Bands that run from the Meckel’s diverticulum to the mesentery can cause obstruction of the small bowel. These bands are also a potential site for internal herniae (Fig. 53.6).\textsuperscript{36} A long Meckel’s diverticulum can cause obstruction or ischemia by wrapping around adjacent bowel.\textsuperscript{37}
Meckel’s diverticulitis can be difficult to distinguish clinically from appendicitis. In cases of suspected appendicitis where the macroscopic appearance of the appendix does not correlate with the clinical picture or intraperitoneal findings, the ileum should be followed to at least 100 cm from the ileocecal junction. If an inflamed Meckel’s diverticulum is found (Fig. 53.7), resection should be undertaken.

Perforation can result from diverticulitis and the child may present with generalized peritonitis. Rarely this can mimic necrotizing enterocolitis in neonates. Ulceration can be within the diverticulum or in the adjacent ileal mucosa. At laparotomy the perforation should be sought and the resection margins should include the ulcer. Perforation has also been reported as a result of impaction of a fish-bone in a Meckel’s diverticulum.

INVESTIGATIONS

Technetium Scanning

99mTc pertechnetate scanning was first clinically reported in 1970 by Jewett, Duszynski, and Allen. This technique is useful in identifying heterotopic gastric mucosa and uses the principle that superficial mucous secreting cells of functional gastric mucosa store and secrete intravenously administered pertechnetate ions carrying the 99mTc technetium isotope. Meckel’s diverticula that do not contain gastric mucosa will not be detected. It is less likely these will be symptomatic. Other abnormalities of the small intestine containing gastric mucosa, for example duplications, will give positive scans.

For the first 15 minutes after IV injection of the isotope, anterior views of the abdomen are acquired every minute. Lateral and posterior views are taken 15 minutes postinjection. Repeat delayed views at 30 minutes may be useful. The bladder should be emptied both prior to and at 30 minutes into the study, as renal excretion of pertechnetate into the bladder can obscure a Meckel’s diverticulum. Uptake of radionucleotide is usually less dense than in the stomach, but a Meckel’s diverticulum will be seen most often in the right lower quadrant (Fig. 53.8) although it can change position during the examination.

There are a number of recommendations to optimize the accuracy of this test. The patient should be fasted and the stomach and bladder can be emptied with a nasogastric tube and urethral catheter respectively. Glucagon, pentagastrin, and H2-blockers have been given to augment the sensitivity of the study. Glucagon inhibits intestinal peristalsis and therefore, prevents spillage of gastric contents into the bowel. Pentagastrin increases the uptake of the radionucleotide. Cimetidine, an H2 receptor antagonist that inhibits the secretion of pertechnetate into the gastric lumen can be given orally for 2 days prior to the study. In patients who present as emergencies with gastrointestinal bleeding cimetidine can be given intravenously as a slow bolus 20 minutes prior to the scan.
Despite these measures there is still a considerable error associated with this test. False-positives may have heterotopic gastric mucosa in an alternative lesion as mentioned previously. Cooney et al reported 5 out of 26 patients (19%) who underwent laparotomy following a positive scan with no identifiable pathology. In patients who present with gastrointestinal bleeding, the sensitivity of this test can be as low as 60%. If faced with a patient with recurrent bleeding and a negative scan, surgical exploration is indicated.

Other Investigations

Ultrasonography can be useful in detecting the complicated Meckel’s diverticulum. Angiography can detect the vitelline artery and can be useful even in the absence of active bleeding although the “noise” from surrounding vasculature can make the identification of this artery difficult. Superselective catheterization of distal ileal arteries can overcome this problem.

Laparoscopy has the advantage of offering the opportunity to proceed with diverticulectomy at the time of the diagnostic examination.

SURGICAL MANAGEMENT (DIVERTICULECTOMY)

A Meckel’s diverticulum can be excised at laparotomy, by a laparoscopic-assisted method or by laparoscopy alone. For open excision, access is obtained through a right transverse incision and the ileum is followed proximally from the ileocecal junction. The contents of this segment of bowel may appear dark due to recent hemorrhage. Once the Meckel’s diverticulum has been identified the vitelline artery supplying it should be ligated and divided. The lumen of the small intestine 10 cm to either side of the diverticulum should be occluded using a non-crushing technique. Resection of the ileal segment containing the Meckel’s diverticulum should be performed in all cases (Fig. 53.9). In cases presenting with gastrointestinal hemorrhage, the bleeding may originate from the diverticulum but it is more commonly from an ulcer of the adjacent ileal mucosa (Fig. 53.10). Once resection is performed an inspection of the mucosal surface of the adjacent ileum should be undertaken to identify a bleeding point. More often than not such a lesion is not visible, although if one is seen the resection margin should be extended to include this rather than oversewing the lesion.

Closure of the ileum is performed by an end-to-end anastomosis. Single-layer anastomosis with 4/0 or 5/0 vicryl or PDS on a non-traumatic needle is appropriate. The resected sample should be sent for histological examination. If a resection of the ileal segment is performed it is unusual for there to be extension of heterotopic gastric mucosa beyond the resection margins. If this is found it should be accurately documented and the patient should be made aware, as this may be a potential site for further bleeding in the future.

Laparoscopy is being used more frequently with some success. The advantages of laparoscopic diagnosis include the ability to perform resection at
the time of diagnosis. This can be performed extracorporeally by exteriorization of the bowel through the umbilical port, or in the larger patient a total laparoscopic method can be employed utilizing the endo GIA stapling device. Some authors have reported excision of the Meckel’s diverticulum using an “endoloop” in a similar manner to removal of the appendix.

MANAGEMENT OF INCIDENTAL MECKEL’S DIVERTICULUM

The management of the incidentally discovered Meckel’s diverticulum has been a source of great debate over the years and there have been no guidelines to aid the surgeon in deciding whether or not to resect. The deciding factor is the estimated lifetime risk of complications arising from a Meckel’s diverticulum. Meckel estimated the lifetime risk of complications to be 25% although more recent reports place it at between 4 and 6%. These reports assume an incidence of 2% in the general population. However, if the incidence were lower than this, the rate of complications would be accordingly higher.

Some authors suggest a selective approach, advocating resection of a Meckel’s diverticulum with a narrow neck or macroscopic evidence of heterotopic mucosa. However, the macroscopic appearance is not a good indicator of the potential for future complications. The morbidity associated with resection of the lesion is low, particularly in children. We recommend excision of incidentally discovered Meckel’s diverticula in all patients if the resection can be carried out safely. The very ill patient who would benefit from expeditious surgery, or the neonate where resection and anastomosis can be challenging are not candidates for incidental excision. It is important however to clearly document the presence of the Meckel’s diverticulum for future reference.

OUTCOME

The commonest long-term complication following Meckel’s diverticulectomy is bowel obstruction secondary to adhesions, which is estimated to have an incidence of 5-10%. A large study looking at both children and adults quoted a worse outcome in symptomatic cases with an incidence of postoperative complications of 12% and long-term complications of 7%. The figures for asymptomatic cases were 2% for both groups. In our series of 281 patients over 45 years mortality and complication rates were higher in the symptomatic group. Improvements in intensive care management of the sick infant and child should ensure that mortality in children with a Meckel’s diverticulum is close to zero.

Appendicitis

Although Leonardo da Vinci has already illustrated the appendix in his anatomic drawings in 1492, a first anatomic description of a vermiform appendix was not done before 1521 by Berengario DaCarpi.1

Certainly much more older are descriptions of an appendicitis of an Egyptian mummy from Byzanz. Reports on an appendicitis were first published by Jean Fernel 1544 and von Hilden 1652. These were followed by impressive reports on perforations of the appendix by L Heister, Mestivier and J Hunter in the 18th century. The first appendectomy was performed 1735 by C Amyand on an eleven-year old boy who developed appendicitis in the region of a scrotal hernia. In 1827, F Melier proposed the surgical treatment of appendicitis as standard therapy but was stubbornly ignored. For a long time the treatment of appendicitis remained a domain of internists who treated the patients with opium and bed rest as well as with drainage in case of abscesses. In 1886, Reginald Heber Fitz from Boston, for a short period a scholar also of the famous R Virchow in Vienna, imprinted the term “appendicitis” and also demanded an early surgical treatment and resection of the appendix, respectively. At that time chloroformism as well as Lister’s principles of asepsis have met with approval.

Since it was clear at the end of the 19th century that vermiform appendix was responsible for two-thirds of all cases of fatal peritonitis, a basis for diagnosis and treatment of this disease was rapidly found. Already in 1889, numerous reports on the surgical therapy of appendicitis were published among others also by McBurney. In 1894, he reported on a new surgical method which he had taken over from his colleague JB Murphy and published for the first time, the gridiron.2 This method made it’s way worldwide and is now accepted as standard. Already ten years later Murphy was able to report on 2,000 accomplished appendectomies in the American Journal of Medical Sciences.3 But not till the era of antibiotics in the fifties of our century appendicitis could lose the nimbus of an extremely dangerous disease. In 1910 the operative mortality, for a country like Switzerland, lay in the range of 6.2% compared to a cumulative mortality of 5.7%.4 Appendectomy now represents one of the most important abdominal teaching operations for young surgeons.1,5 Today appendicitis is the most frequent indication for operation in the childhood and in general appendectomy presents the third-most operation worldwide.

EPIDEMIOLOGICAL FACTS

In the USA, about half a million appendectomies are performed every year which accords with an incidence of 260/100,000 inhabitants. There are similar numbers in Europe. For instance, in Austria approximately 20,000 in 1998 and in France about 200,000 appendectomies were performed in 1996 (Table 54.1). Table 54.2 outlines the morbidity and mortality in India.

ANATOMIC AND HISTOLOGIC BASICS

The vermiform appendix develops from a common gemma with the cecum in the distal part of the primitive intestinal loop between the 6th and 8th embryonic week, and exists in this type only in primates. It becomes visible from the 8th week of development; at this time in the child, the appendix has a length of about 10 cm. The appendix is an about
Table 54.1: Appendectomies/100,000 inhabitants in different countries

- Less than the half of these patients do really have appendicitis (110/100,000). Therefore, nearly 50% are so-called “negative” appendectomies - appendectomies without an inflamed vermiform appendix. Especially in young women this rate can be 2.5 times higher than in the respective male population. This can be explained by the insecure diagnostic demarcation to other causes of pain in the right hypogastric zone in women, and by the known increased morbidity and mortality in cases of an overlooked appendicitis. In general the incidence of newly diagnosed appendicitis is slightly but steadily retrograde. This process cannot be explained by now but in the last decades, for some regions there is reported upon a decrease of up to 46%. Apparently also genetic factors seem to play an important role in the disease process. The highest rate of appendicitis is found within the white population, while Black Africans and Asians only suffer half as much from appendicitis. In Africa the incidence of appendicitis is particularly low. To what extent only predisposition or other habits of life are responsible for that cannot be answered yet. A higher frequency of appendicitis has also been described within families. Children whose parents have been appendectomized early during childhood, are also frequently appendectomized early. Whether this is caused by an increased sensibility of parents or by genetic factors is still unclear. There exists a sex-specific distribution, in consequence of, males do have a 1.1-1.7 times higher risk to develop appendicitis. These data comply with a whole life-span risk for men of 8.6-6.7% for women to suffer from appendicitis. On the other hand, women do have a much higher risk to get appendectomized (23.1% of women, 12% of men).

Age shows a distribution with a peak in the age group of 14-19 years. In this group there is a relative disease frequency of 230/100,000 whereas frequency is decreasing to 50/100,000 at the age of 45 and to about 13/1000,000 at the age of 80. These data underline the enormous importance of this disease, especially for pediatric surgery.

2.5-24 cm long (in adulthood about 9 cm) and about 0.5 cm thick, at the beginning of the cecum caudal departing, blind-ending, worm-shaped enteral compartment. In the correct way, one has to say that the cecum departs cranially from the appendix, because the appendix represents the start of the large bowel. But it is—as an blind-ending structure with a comparably narrow lumen (1-2 mm)—turned off for the passage of the bowel movement (feces), and is therefore functionally and anatomically considered an “appendix” of the cecum. The observation that the cecum is only partly and the appendix is not filled with meconium (therefore no growth stimulus is given) explains why the vermiform appendix is so thin in contrast to the colon/cecum. Although the appendix belongs to the colon, it does not form Taenias, because the outer lengthwise-muscle layer of the Muscularis propria builds an even plate at the passage to the appendix, and possibly has a pretty peristaltic movement. This runs in the direction from the tip to the base. At the point at which the Taenias of the cecum converge, one can most easily find the base of the appendix. Histologically it corresponds to the colon. However, the appendix exhibits a high content of defending cells, and several lymphoid follicles lying tightly against one another in the mucosa and submucosa, respectively, underlining its immunological importance. Noteworthy, the number and density of mucosal lymphoid follicles increases during adolescence. This period of enhanced development of lymphoid follicles corresponds exactly with the age range showing the highest incidence of appendicitis.

Blood supply is through the mesenteriolium (mesoappendix) by the appendicular artery originating from the ileocecal artery which in its turn generally originate from the inferior right colic artery coming from the superior mesenteric artery.

The mesenteriolum is an expansion of the iliac mesenterium and passes under the ileum to the appendix. The appendicular artery takes its course along the free edge and works as a functional end artery. Its branches break through the wall until they reach the mucosa. In the luminal area arterioles build a fine reticulum. The base of the appendix may be
supplied by small branches of the anterior and posterior cecal artery. The venous drainage runs and parallel to the arteries, whereby again a basket-like reticulum is formed in the area of the lymphoid follicles. The lymphatic drainage of the cecum passes to the ileocecal lymph nodes along the superior mesenteric artery into the cisterna chyli. There are anastomoses to retroperitoneal lymph nodes. The appendix in its turn does not have an own lymphatic drainage but as a whole is considered, similar to the tonsils, a lymphatic organ. Thereby the often observed contemporarily inflammatory response of tonsils and appendix can be explained. Malformations of the appendix are very rare. Generally, it is a question of either an agenesis or a reflection whereby the cecum can also be involved. While the frequency of this congenital malformation lies in the range of a thousandth part, the diverticulum as acquired dysplasia is more frequent. Diverticula are evaginations of the mucosa through the muscularis propria. A congenital “diverticulum”, also an evagination affecting the entire wall, is added to the rudimentary reflections.

The posteromedial passage about 2-3 cm below the ileac opening into the cecum conforms to the McBurney point at the outer belly. This point lies at the junction between the lateral and the middle third of a line thought of between the anterior superior iliac spine and the bellybutton (Fig. 54.1).

The position of the vermiform appendix lies shortly medial or under the McBurney point in about 59%. In considerable 25% of all cases the appendix is positioned between the anterior superior iliac spine and the bellybutton. 27-65% have a retrocecal position (Figs 54.2 A to D).14-16

This position particularly raises difficulties for diagnosis and surgery. Retroileal or only partly retrocecal (transverse) inflamed appendices usually follow a typical clinical pattern while the symptomatology of strictly retrocecal, cranially directed appendices is rather unspecific. Even with ultrasonography, retrocecal appendicitis is only visible for skilled people and the operation is technically difficult for beginners in the operating room.

**CLINICAL SYMPTOMS AND DIAGNOSIS**

Abdominal pain is a frequent symptom and the cause of up to 20% of all visits. With every fifteenth child there underlies a serious disease. This among others can be an appendicitis. The other diseases with urgent necessity for surgical interventions are rather rare. The appendicitis is clinically recognized by a typical tenderness to pressure, Blumberg’s sign, and the most frequent accompanying symptoms, vomiting and loss of appetite. However, diagnosis is still extremely difficult and only ultrasonography, in the hands of an
experienced physician, is a reliable remedy.\textsuperscript{17} In daily practice new examination methods like MRI, nuclear-medical examinations (autologously marked leukocytes), or CT are, because of their poor availability, only of academic interest.

Appendicitis is a very rare event under an age of 4 and seldom up to 6 years, but if, rather less symptomatic and painful. Unfortunately, just the nearly obligatory perforation with all the signs of a peritonitis leads to the doctor and therefore to a diagnosis in this age group. Peritonitis is still the main cause of the very high morbidity. According to results from great studies the morbidity lies in a range between 5-33\%. Principal causes of a perforated appendix with localized or already generalized peritonitis are local infections especially with adipose children, the occurrence of a paralytic ileus caused by a peritonitis, or an intra-abdominal abscess. Also late complications like adhesions and an adhesive strangulation of intestines are typical consequences of a peritonitis. On the other hand, not surgically treatable diseases like enteritis are – as a differential diagnosis—only difficult to distinguish from an appendicitis. An often similar symptomatology, above all a tenderness to pressure in the hypogastric zone and the, for not skilled persons, complicated examination under the difficult circumstances with children make diagnosis extremely hard. Due to the fear of an overlooked appendicitis a low specificity is tolerated in favor of a high sensitivity. This means that already in case of an insignificant suspicion for appendicitis, the patient is attributed to a surgical department and often also operated. The generally accepted rates for appendectomies in case of a wrong positive preoperative diagnosis are 20-25\%. For the year 1997, large studies within surgical quality-assurance programs state childhood appendectomy-rates with a negative histological finding between 18.6-21.2\%.\textsuperscript{18} In the past years enlarged attention has been drawn to the increase of specificity to say of unerring aim without accepting a low sensitivity, that is an increased overlooked appendicitis-rate and therefore an increased rate of perforation.\textsuperscript{19,20} In addition there are intensive efforts to develop a simple strategy to clarify acute abdominal pain in childhood. In a long-term prospective study together with other hospitals those criteria were proved that usually are referred to for diagnosis and that are also feasible in a consulting room or in basic-care providing hospitals. In contrast to the acute abdominal pain of grown-ups, fewer diseases are of question as differential-diagnostic causes. Thereby the diagnostic pathway is vastly uncomplicated.

In the author’s series collective unspecific abdominal pain and functional discomforts were 40\%, infectious enteropathies 25\%, appendicitis 12\%, and urogenital infections are remarkable 4\%. All other noteworthy diseases were reported in less than 1\% of all cases. From this is experience the following schemes could be deduced.

The two main criteria are the clinical examination and the ultrasonic examination by a physician who is especially experienced in abdominal ultrasonography in childhood and particularly in ultrasonic diagnostics of the appendicitis. In addition, the typical history and the results from laboratory experiments (Table 54.3) are observed. These criteria are assessed individually. If one or both main criteria (clinics, sonography) and at least one accessory criterion (history, laboratory) are met the patient is suspected of having an appendicitis, and will need hospitalization. If no other cause of disease is found and an appendicitis cannot reliably be excluded, the hospitalization either leads to an immediate surgery or to a re-evaluation after two to six hours intervals without food intake and parenteral fluid supply until verification or exclusion of an appendicitis. This is recognizable with a relatively high probability during the further course. If only one main criterion, clinical or sonography, is typical for an appendicitis and the second main criterion as well as both accessory criteria are negative, the child can be discharged under adequate care. Within 24 hours an ambulatory control has to follow. If history and laboratory investigations are positive and both main criteria—clinics and ultrasound are negative, the patient is hospitalized but is allowed to drink clear liquid. IV fluid in these cases is not necessary. If laboratory or history alone is positive, patient is referred back to the practitioner/pediatrician for further control. This procedure is in a more or less structured manner applied in many pediatric clinics, whereas the importance of ultrasonography is definitely greater in European countries in contrast to Asian countries and the United States. This method has especially proved when the pediatric surgeon is
Pediatric Surgery—Diagnosis and Management

trained and experienced in abdominal sonography because the valuation of a nevertheless dynamic examination in combination with the own experience in clinical examination turns out significantly better in contrast to that of a radiologist who does perform this examination without special background. In the USA, the value of sonography is more inferior. In USA and in Asian countries clinic symptomatology and laboratory investigation are the most important criteria. Especially in countries with many children and less good medical care the greater experience of the physician does successfully replace missing technical devices like sonography, laboratory investigation and radiography. On the other hand, in the USA, there exists a more profit-orientated health system where examination methods like ultrasonography are difficult to establish.

Formerly practiced examinations, like the rectal-axillary temperature difference are obsolete for the diagnosis of appendicitis due to the unreliability of the measurement.

The typical symptoms of appendicitis are also apparent abdominal pain, guarding, relaxation-position, nausea or vomiting. These are, especially in childhood, very common symptoms which could appear with various distinctions in many other abdominal and also systemic diseases, and in connection with enteritis. In childhood, abdominal pain along with appendicitis first develop in the region of the bellybutton and then within hours shift to the right lower quadrant where they steadily increase. A primary examination in this early stage makes diagnosis very difficult. Because a high rate of wrong positive diagnoses still leads to numerous unnecessary appendectomies and therefore also to enormous costs, many institutions try to establish clear diagnostic criteria. These criteria should – also without technical resources—enable a prompt (that means before perforation occurs) diagnosis on the one hand and also to prophylactically operate as few as possible children on the other hand. All these efforts have shown that the clinical experience of the examiner is the most important instrument. Also computer-based decision-making systems could not improve diagnosis of appendicitis.25-27

The diagnostic accuracy in fact could be increased through forms which were necessary for the computer presentation but this was mainly due to the forced precision of the surgical examination. All attempts, for instance by entering into scoring systems, to establish standardized diagnostics, following objectively measurable criteria were disappointing (Table 54.4).28

The experience of the surgeon is presently and will also be in the 21st century the most important and safest diagnostic criterion.29 The so called “wait and see” policy has proved helpful. Most hospitals in Europe hospitalize a child with a well-founded

fundamentally it can be written down that diagnosis is based on clinical examination, laboratory analysis and ultrasonography. The algorithm for the management of appendicitis is given in Figure 54.3.

Clinical Examination

A history of abdominal pain for last 12-24 hours without fever or diarrhea migrating from the central area to the right lower quadrant, typical tenderness to pressure above the McBurney Point, and rebound tenderness are frequent. The patient is anorectic and frequently vomits in a relatively early stage. In most cases the last defecation is still normal. The often mentioned rectal-axillary temperature difference of more than one centigrade celsius is unreliable. With children it is often not carried out exactly and moreover only appears in advanced stages. In later stages abdominal guarding is added to distinct pain existing in the right lower quadrant and tenderness to touch. The tongue is coated in nearly all cases and perioral paleness is found. In case of an existing Douglas’ abscess frequent, highly liquid bowel

movement can often simulate enteritis. Besides the obligatory anorexia, a blown abdomen is the most frequent symptom in children under the age of three.

**Laboratory—Chemical Analysis**

If appendicitis is the presumptive diagnosis, an analysis of the urine is obligatory. Usually, the determination of leukocytes, nitrate as well as erythrocytes is sufficient to recognize an urinary tract infection as differential diagnosis. Further helpful information about the hydriational condition of the child is offered by the specific weight and the determination of ketone in the urine (acetonuria).

Blood examination for the red blood count and differential white blood count, and the analysis of the C-reactive protein (CRP) together with the clinical findings reach a high sensitivity and specificity. The laboratory finding is positive, if leukocytosis is of more than 10,000/mm³ or a CRP-level higher than 0.5 mg/dl exists.

**Ultrasonography**

*Appendicitis-criteria according to Puylaert* (Table 54.3): The special power of sonography lies in the plain presentation of typical and important differential diagnoses (Figs 54.4A to D). Ileus, intussusception, enlarged lymph nodes, ovarian cysts, renal and liver affections, tumors, and others cause symptoms mimicking an appendicitis and can be distinguished safely (Figs 54.5A to D). Ultrasonography offers a
sensitivity around 90% and a specificity of nearly 100% for the detection or exclusion of an acute appendicitis. There is a positive predictive value of 92%, the negative predictive value is 99%.

**MRI**

On T2-weighted ultra turbo spin-echo images, acute appendicitis appears with a markedly hyperintense center, a slightly hyperintense thickened wall, and a markedly hyperintense periappendiceal tissue. Unenhanced axial T2-weighted spin-echo imaging is the most sensitive sequence for. MR imaging seems to be a valuable technique for depiction of acute appendicitis (Fig. 54.6). Yet MR, as diagnostic remedy, is not sufficiently evaluated to be able to give a general judgement, but in the future it seems to be able to replace ultrasonography as well as CT as diagnostic resource because of the reproducible presentation of pictures and the missing roentgen burden.

**CT Scan**

Rarely used in Europe and Asia, more frequently applied in the USA, CT together with contrast medium is able to describe the inflammatory altered vermiform appendix (Fig. 54.7). But one has to consider that such
an examination is expensive and complex and also includes burden with X-rays. Its efficacy in childhood is lower than in connection with adults. Due to the above mentioned reasons, CT is generally seen as second choice after ultrasonography.34

Nuclear Medicine

During the past years studies have been published dealing with the detection of inflammation by labeled, autologous leukocytes. With this method a sensitivity of 27-97% and a specificity between 38-94% can be reached. Like for CT, radioactive substances are necessary and an experienced ultrasound-examiner is able to gain the same information without any burden for the young patient. But for the detection of a Meckel’s diverticulum radionuclide imaging can be a very helpful tool (Fig. 54.8).

Diagnostic Laparoscopy

In contrast to adults the diagnostic laparoscopy has only a minor importance for the diagnosis of acute appendicitis in childhood. Exceptions are prepubertal and pubertal girls, for these laparoscopy is an important diagnostic tool.35,36 Otherwise it is reserved to the clarification of chronically recurrent abdominal pain also in connection with a simultaneously planned, concomitant appendectomy (Figs 54.9A and B).37 For this purpose it is an ideal instrument.38

DIFFERENTIAL DIAGNOSIS

Functional discomfort generally manifests within a few hours in a chronic course with a self-limiting character of the single episode. The kind of pain is not leading and the absence of a more exact specification in young children is also unreliable. Often cyclic vomiting is accompanying. Typically, children report upon more pain during examination than objectively can be observed. Attention intensifies symptomatology. The general condition is barely reduced. Also appetite is not reduced. Enteritis as one of the most important differential diagnoses in childhood is most easily recognized by an exact clinical history and
observation. Mainly virally caused, children are suffering from cough or cold, headache, fever and fatigue in the days before abdominal pain appear. Abdominal pain itself is diffuse, cramping and at the beginning associated with episodes of diarrhea. Such episodes occur in advanced stages of an appendicitis only. Nevertheless, a careful observation is important then, because viruses preferentially attack with (Paramyxoviridae-mumps, enteric viruses-Coxsackie B) or without (Adenovirus) viremia-lymphatic organs, to which also the appendix belong. Particularly the intestinal types of the adenovirus group which do not attack the respiratory organs are able to cause swelling of mesenteric lymph nodes for months and can be a trigger for appendicitis. With abdominal ultrasonography, the picture of a mesenteric lymphadenitis is observed which is a frequent finding together with ear-ache and simultaneously appearing abdominal pain in the right upper quadrant. The blood count is rather indicating a leukopenia than a leukocytosis, the CRP level is low. In the differential blood count a lymphocytosis would appear. Bacterial enteritis would appear. Bacterial enteritis is mainly caused by Campylobacter, Yersinia, and Salmonella. Typically diarrhea, in most cases connected with subfebrile or febrile temperatures, is in the foreground whereas abdominal pain is appearing late and seems to be diffuse. Often also family members, friends, or playmates are afflicted. The blood sample shows a strongly increased number of leukocytes, in particular a leftward shift is existing, and the CRP is increased. Bacterial enteritis are also able to initiate appendicitis and the following three germs Campylobacter jejuni, Yersinia pseudotuberculosis and enterocolitica are the most frequent inducers of a bacterial appendicitis. Especially appearing in childhood up to the age of four, an inflamed Meckel’s diverticulum is barely to distinguish from an acute appendicitis. But in general this is only a rare event. The probability that a Meckel’s diverticulum becomes symptomatic is about 2%. Of this percentage only a small part appears as inflammation, another part manifests as bleeding or ileus.

In young women during puberty, diseases of the internal genitalia are more common causes of discomfort. Functional ovarian cysts are very frequent. These typically disappear with start of menses but can also persist for months and therefore cause pain. They are ultrasonographically easy to identify. The treatment, if necessary, is only conservative. If the cysts are larger than 5-8 cm, a laparoscopic enucleation is possible. These, including many small cysts, may lead to a torsion of the ovary and therefore to intensive acute abdominal pain. The torsion of an ovarian cyst is, in any case, an indication for immediate surgery. This is only limitedly valid during neonatal period. At that age, the necrotic ovary may possibly be resorbed. Also without torsion or bleeding, ovarian cysts, predominantly in puberty, are the cause of deep-seated rather chronic, cyclically relapsing abdominal pain. Teratoma, dysgerminoma, and other germ cell tumors but also malformations of the uterus or the vagina (Mayer-Rokitansky-Küster-Hauser syndrome, Uterus dimetria with one-sided vaginal atresia) may cause symptoms of appendicitis. Laparoscopy represents for all of these diseases an essential part of diagnostics.
Also sexual transmitted diseases like PID (pelvic inflammatory disease) are possible differential diagnoses. This disease almost only appears in sexual active girls. The inverted conclusion that an appearance of PID is coupled with a loss of virginity however is not admissible. In most cases the right-sided salpingitis with an abscess in the small pelvis can only be distinguished from an appendicitis by an ultrasonographically skilled examiner, and can also be in connection with an appendicitis ab externis. Furthermore, in sexually mature young women one has to think of pregnancy or ectopic pregnancy.

If the pain is appearing periodically and menarche fails to come, the cause may be a congenital malformation like the Mayer-Rokitansky-Küster-Hauser syndrome (Rokitansky sequence). This syndrome represents a congenital combination of malformations which is characterized by a normal female chromosome complement (46XX), normal secondary sex characters, vaginal atresia, and uterus malformation (bicornuate or bipartite). The vaginal atresia leads to an obstruction of menstrual blood, which increases in consequence of every period and therefore causes pain. During this stage of development, also an endometriosis can get symptomatic although, this is typically causing dysmenorrhea and dyspareunia in young women.

In pre-school children of both gender pneumonias, in particular lobular pneumonias on the right in connection with peritoneal symptoms may simulate an appendicitis. There is a typical retraction of the intercostal space during inspiration, cough, and hyperpyrexia. Sonographically, free fluid is copiously found in the abdomen together with a pleural Winkel’s effusion but there is no indication for an inflammatory event in the right lower quadrant. A pulmonal radiography leads to the right diagnosis.

Urinary tract infection is a frequent, spastic, and painful event in preschool children, can be accompanied by fever and may correspond to the first symptoms of a vesicoureteral reflux. In school-age children, dysuria appears as an accompanying symptom of appendicitis in up to 20%.

A bacterial meningitis starting with abdominal pain and cramps is extremely dangerous. However, in most cases headache, visual disturbance, hyperpyrexia, neck stiffness, diffuse peritoneal guarding, and foudroyant worsening of the general condition of the child exist. In such cases, the lumbar puncture is favored above other diagnostics.

Otitis media may too cause abdominal pain in pre-school children. Abdominal sonography frequently reveals an accompanying mesenteric lymphadenitis. These findings are, in case of a hasty examination, often misinterpreted as appendicitis.

**Pseudoappendicitis diabetica:** In diabetes mellitus right-sided abdominal pain can occur which impose colicky, chronically, and heavily. An unnecessary operation as well as an actual appendicitis recognized too late, lead to the high morbidity among these children. In case of known diabetes and especially of an existing diabetic decompensation, ultrasonography is an helpful instrument.

The idiopathic net torsion as well as the idiopathic segmental infarct of the greater omentum are clinically similar to an appendicitis, in particular if the maximal point lies on the right side. Both events can be diagnosed laparoscopically and treated accordingly. Abdominal lymphangiomas are also sometimes operated as a misdiagnosed appendicitis. With ultrasonographic help, this presumptive diagnosis should be detected preoperatively and therefore, a transverse laparotomy should be chosen. Typhlitis in connection with an acute leukemia is hardly to distinguish from appendicitis. This is a fatal prognosis due to the frequently associated, uncontrollable sepsis.

Furthermore, other differential diagnosis of abdominal pain include clinical history, pancreatitis, cholelithiasis, urolithiasis, peptic ulcer, dyspepsia, amebic abscess, hepatitis, and injuries through anal foreign bodies. These are promptly to distinguish only with a careful clinical history and examination.

In general the following standard is valid: the younger a child is and the more anxious the mother is, the sooner the patient should be hospitalized.

### Most Frequent Misdiagnosis

- Gastroenteritis
- Upper respiratory tract infection
- Sepsis of other origin
- Urinary tract infection
- Encephalitis
- Febrile seizure
- Blunt abdominal trauma.
ETIOLOGY

The etiology of appendicitis is not clarified until now, although two facts are supported by some studies. On the one hand, genetic differences in the development of immunologic protection-factors could be responsible for, on the other hand also environmental and dietary factors seem to play an important role. Striking are variations of sexual distribution, of different populations, and between towns and rural districts. An explanation for the latter distinction could be the higher socio-economic status of the white population in countries like the USA and Europe, or that of inhabitants of large towns. There are also existing seasonal differences with the greatest accumulation of appendicitis during summer season and the lowest appearance in winter.45

Most authors consider the fiber-deficient nutrition of the industrial countries and large towns as the most important etiologic factor. This is supported by the fact that fecoliths, which often occur in consequence of constipation, are also the most frequent starting-point of appendicitis. The association between fecoliths and appendicitis is proved.46 The fecolith leads to an occlusion of the lumen, therefore to a local obstruction, to ischemia, and finally to a local inflammation. The so called appendicitic primary lesion is generated. From these foci granulocytes start migration through all wall layers.

As immunohistochemical investigations have shown, the previously common saying that the vermiform appendix is nothing than a useless, rudimentary organ, is not right. The appendix morphologically and topographically correspond to a GALT (gut associated lymphoid tissue).47 The appendix together with the tonsils, the Peyer’s plaques, and the mesenteric lymph nodes appears responsible for immunoregulatory mechanisms in the lymphatic system. Therein, partial causes of inflammation could be found. Possibly the first step of inflammation, the focal infiltration of the lamina propria, is demonstrably associated with an increase of T lymphocytes (CD3) and plasma cells concerning the whole organ.48 Meanwhile it is known that during inflammations of the appendix different cytokine levels (IL-2, IL-6, TNF-alpha) are increased. These are also used for the detection and proof of chronically relapsing appendicitis.49

The germs which are found with appendicitis generally correspond with the intestinal flora. About 20% are aerobic germs, 20% are anaerobic, and in about 60% aerobic as well as anaerobic germs are found in smears taken during appendicitis.50

The most common germ is *E. coli* followed by *Bacteroides fragilis*, *Peptostreptococcus* and *Pseudomonas sp*. Viral infections with mumps virus, Coxsackie type B, and adenoviruses are frequently seen in appendicitis. The real significance of this observation is still not verified, although in general, the meaning is distributed that, based on a lymphoid hyperplasia appendicitis can evolve. Occasionally, in immuno-suppressed patients (e.g. AIDS patients, patients under chemotherapy) a viral infection with cytomegalovirus (CMV) or Epstein-Barr viruses can act as primary promoter of inflammation. Uncommon causes include yersiniosis, parasites (oxyures), Crohn’s disease, foreign bodies, tuberculosis, volvulus of appendix, intussusception, septa, tumors, and diverticula.51 Necrotizing enterocolitis seems to be responsible for the very rare appendicitis in the neonatal period.52

Eating habits: Absence of dietary fiber.

Fecolith: Occlusion of the lumen – local obstruction – ischemia – local inflammation – migration of granulocytes through all layers.

Yersiniosis: The infection with *Yersinia pseudotuberculotica* and *enterocolitica*, *Campylobacter jejuni*, *Salmonella typhi*, and also the very rare infection with *Mycobacterium tuberculosis* are considered as trigger of appendicitis. The bacterial colonization with *E. coli* is rather a part of an already commenced inflammation than a possible primary cause.

Viral infection or lymphoid hyperplasia: Under chemotherapy, immunosuppression, AIDS

Worms, especially oxyures (*Enterobius vermicularis*) and ascarides are by far the most frequently seen parasites. They are able to induce a lymphoid reaction or cause appendicitis through obstruction. Helminthic diseases are a common incidental finding in histologically not-inflammatory altered appendices. The incidence is, with about 4%, highest in childhood (between the age of 6 and 15).53

Chronic inflammatory diseases (Crohn’s disease): Also Crohn’s disease is able to primarily or secondarily manifest in the appendix and causes an inflammation there. In these cases an ileocecal resection is necessary.
Foreign bodies: Ingested foreign bodies in the lumen like screws, plastic parts, or kernels are inducing an inflamed appendix. But in general it cannot be deduced from these events that swallowing of foreign bodies leads with a higher probability to appendicitis.

Tuberculosis may be the cause of an appendicitis, but is rather simulating one, e.g. with mesenteric expansion (sometimes observed as primary manifestation in pre-school children). Typically, there are multiple, enlarged mesenteric lymph nodes and caseating granulomas in the peritoneum.

Volvulus of the appendix and appendiceal intussusception:

A volvulus of the vermiform appendix is a rare event in childhood. In the literature only a small number of cases are described.\textsuperscript{54-56} It presents itself as an intermittently occurring abdominal pain which acutely exacerbates. Mucoceles, fecoliths (Bonnoud), and idiopathic forms are described as the main causes.

In these situations the color-coded Doppler ultrasonography is useful. Also the intussusception of the appendix into the cecum is a very rare event and is promptly revealed by ultrasonography (beside this, intussusception represents an indirect proof of peristaltic movement). There also exists a congenital form of an inverse appendix.

Septa and atresia are extremely rare, duplications are seen more frequently. They lead to a mucous retention. A septum at the base of the appendix can be simulated by a mucous fold (Gerlach’s valve).

\textbf{APPENDICEAL NEOPLASMS}

Most frequent neoplasms are carcinoids with a frequency of 0.02-1.5% in all histological preparations. In principle, carcinoids are malignant tumors. The appendiceal carcinoid exhibits less DNA-aneuploidy than carcinoids of the ileum and therefore, more frequently shows a benign course.\textsuperscript{57} Due to the risk of metastasis mainly in mesenteric lymph nodes and liver, all carcinoids with an unsteady behavior, those above a diameter of 1 cm, positive lymph nodes, infiltration of the serosa or the mesenteriolum, or a position at the basis should be considered for hemicolecctiony or at least for further clarification with indium\textsuperscript{111}-labeled octreotid. At a size < 1 cm no further therapy is necessary, if appendectomy was carried out and the base lies in the uneffected region. If the tumor is larger than 2 cm, a right-sided hemicolecctiony is indicated. Appendiceal carcinoids emerge from neuroendocrine, subepithelial cells. In contrast to jejunileal carcinoids, the staining with S-100 for appendiceal carcinoids is positive. Rarely, also adenocarcinomas or adenomas are possible. In these cases one has to look for familiar polyposis which is an indication for prepubertal, subtotal colectomy. But adenocarcinomas of the appendix are an extreme rarity in childhood. The age-peak lies in the 6th decade. Rarely lymphoma may also involve the appendix (Fig. 54.10). Benign tumors are mainly asymptomatic mucosal hyperplasias, metaplasias, or adenomas, which, for instance as cystadenomas are producing mucine and can become symptomatic therefore. They form mucoceles which may rupture and cause a peritoneal pseudomyxoma. All, benign as well as malignant tumors of the appendix may, to a significantly higher rate be associated with synchronous or metachronous, gastrointestinal tumors with another localization.\textsuperscript{58}

\textbf{PATHOGENESIS}

In most cases appendicitis follows a cascadic pattern. Fecoliths, helminthes, viral lymphadenitis, or foreign bodies cause an obstruction of the lumen whereby pressure arise to the mucosa and the wall of the appendix which subsequently leads to a venous congestion and arterial hypoperfusion of the distal part of the vermiform appendix. Meanwhile, pathogenic bacteria start to overgrow this area and migrate through the underlying mucosa. The intraluminal increase in pressure develops very rapidly because the
The vermiform appendix is not expansible due to its structural design. Granulocytes migrate through the mucosa, submucosa, muscularis, and finally also through the serosa. Aschoff’s primary complexes are formed which are aggregations of neutrophil granulocytes. On the serosa fibrin is built up and the whole wall slowly becomes necrotic. The base of the vermiform appendix is generally free from inflammation. This may be due to an additional blood supply via branches of the cecal artery at the base, whereas the appendicular artery as an terminal branch is not able to sufficiently ensure the peripheral blood supply during an inflammation. If this process cannot be stopped, perhaps a necrosis develops followed by open ulceration and then perforations results. Unlimited, this may first of all result in local and then in a generalized peritonitis, sepsis and death, or a perityphlitic abscess is formed which breaks through and drains, building a fistula. Whether an arising inflammation always and absolutely leads to the end point gangrene or perforation is questionable. Autotherapy or curing by conservative treatment is also possible. Several studies and investigation indicate that chronically relapsing abdominal pain in the right lower quadrant may be due to afflictions of the appendix. By studying the cytokine expression of the vermiform appendix, nearly identically increased values were found in acute appendicitis and in appendectomies due to chronic recurrent abdominal pain, whereas in elective appendectomies due to other causes expression patterns comparable to those of unaffected appendices were found. Also the fact that many patients are free from pain after appendectomy supports the hypothesis of a recurrently appearing appendicitis.

**CURRENT CLASSIFICATION OF APPENDICITIS ACCORDING TO HISTOLOGICAL BASIS**

*Acute appendicitis* (Fig. 54.11): Thickened, rigidity of wall, injected; mucous membrane defect, neutrophil granulocytes in the mucosa and submucosa; disorder of mucosal epithelium, granulocyte accumulation, extravascular granulocytes, leukocytes in the lumen. *Phlegmonous and ulcerophlegmonous appendicitis* (Figs 54.12A and B): Fibrinously purulently coated, surrounding (mesenteric) phlegmonas; passing through all wall layers, including serosa; fibrinous appositions, defects of the superficial wall layers up to the serosa. After 10–14 hours: transmural granulocytic infiltration; phlegmonous inflammation. After 24 hours ulcers = ulcerophlegmonous inflammation.

*Gangrenous appendicitis*: Necrotic wall areas without opening; gangrene of the whole wall without perforation.

*Perforating appendicitis*: (Figs 54.13A and B) Perforation and outflow of fecal content through defects of the abdominal cavity; defects of the whole wall.

*Neurogenic appendicitis*: Macroscopically nearly not remarkable, obliteration; intramucous or submucous proliferation of nervefibers, possibly with central neurinoma at the peak in case of obliteration.

*Focal appendicitis*: Macroscopically normal; histologically, in case of an extensive incision, inflammation restricted to one area is detectable – if only few incisions are carried out, not visible “normal” histology.

*Recurrent appendicitis*: Macroscopically, frequently thickened, partly whitish glittering, or totally normal. Increased fat tissue. Frequently coproliths in the lumen. Histologically rare lymphocytic infiltration, extensively multiplied reactive lymph nodes, lymphoid hyperplasia. Sometimes fibrotic reconstruction.
COMPLICATIONS OF APPENDICITIS

1. Diffuse peritonitis.
2. Perforation with stercoral abscess, covered with the greater omentum or ileal loops, in case of a retrocecal position through the cecum or open with Douglas’ abscess and diffuse peritonitis, respectively. At an age of 0-4 the frequency of perforations is at least 40%.
3. Thrombophlebitis of the appendicular vein with propagation and septic liver abscesses.
4. Healing with scar formation and relapsing appendicitis at the base of scar obliteration.
5. Adhesive strangulation of the intestines.
6. Appendicular mucocele: Obstruction of secretion in case of an over-wounded appendicitis and allantoid distension of the thinned appendix distally from the obliteration (scar, coprolith, foreign body, etc.) with recurrent pain symptomatology.

THERAPY

Surgical Therapy
The surgical excision of the inflamed vermiform appendix is the commonly accepted treatment. The McBurney’s incision (gridiron incision) as it was introduced by McBurney and Murphy 1894, is the
method of choice. Since 1983 the first laparoscopic appendectomy was reported by K Semm, a Munich gynecologist, this surgical method has developed into an accepted alternative.63

Gridiron incision: This operation method starts from an access in the right lower quadrant, which crosses the McBurney point in the main cleavage line. After discission of the subcutis, the external oblique aponeurosis is cleaved along the strands, the underlying musculature is extensively bluntly separated, and finally the peritoneum is incised following the craniocaudal direction. By luxating the cecum, the base of the appendix can be presented. The vascular supply is interrupted by clinging ligations of the mesenteriolum. A contusion mark is set at the base, where the appendix will be ligated and above be abscised. After disinfection with iodine the stump is sent to the bottom of a cecal purse string suture. Originally, this was also covered by serous tunic fixed with suture. In France, it is not usual to sink the stump. Also in case of a laparoscopic surgery no stump-sinking is performed. Some centers prefer a drainage in case of a perforation or an intra-abdominal abscess.

MINIMAL INVASIVE TECHNIQUES
The Laparoscopic Appendectomy
The minimal invasive surgery has helped to reduce the complication rate in cholecystectomy (the second in frequency operation after appendectomy), the stay in hospital, and the duration of pain. In 1893 Semm, for the first time, has also successfully described appendectomy via laparoscopy. In some pediatric surgery centres, nearly all cases of appendicitis are endoscopically operated (e.g. University hospital Jena, Germany; university hospital Utrecht, Netherlands). Today, 80% of all appendectomies are performed conventionally, 20% laparoscopically (laparoscopic appendectomies in 1996: in Switzerland about 30%, in France and Austria about 7-9%, in the Netherlands 4%, and about 20% in the USA). This is, even though several studies not only have shown no disadvantages of the minimal invasive technique but more or less significant advantages.64 But, a final, statistically really unobjectionable comparison does not exist yet. In the author’s series there were advantages in favor of the laparoscopic technique in inflamed appendicitis and especially in the group of perforating appendicitis.65

The causes of the delayed popularity of the laparoscopic appendectomy are various. The gridiron incision is not only an established technique, but also the most frequent teaching operation. In addition, the laparoscopic operation is technically much more pretentious and therefore the learning process is slower and the fear of complication higher. Also for the non-medical staff, the expenditure in the operation room is much higher. The minimal invasive technique is especially device-depending and therefore much more expensive. Considering the epidemiologic importance of the appendicitis, this cost factor may be crucial.66 In general, a better diagnostic view, a lower wound-infection rate, a shorter postoperative pain phase, a shorter duration of hospitalization, and a better cosmetic result are the stated advantages of the minimal invasive technique in contrast to an open appendectomy (Fig. 54.14A and B).67 But in fact, there are no prospectively randomized studies in childhood and only a small number in adults which statistically
unobjectionably investigate the benefit of both methods for the patients.68 Other differential diagnosis can easily be identified and tackled (Fig. 54.15).

In acute appendicitis a very small skin incision in case of a conventional appendectomy is, in general only possible with a loss of view and with an increase in risk. Especially in case of generous indications in the conventional technique and therefore a high percentage of appendectomies with a histologically unaffected appendix, the portion of very small skin incisions is high. As a result, the difference to minimal invasive surgery is not so clear considering the postoperative recovery period and the cosmetic result. But in case of a histologically verified appendicitis, there is a significant difference in favor of the laparoscopy considering the dimension of the skin incision (particularly, if devices of the new generation with 1.2-5 mm optics and instruments are used).

The disadvantages of laparoscopy are a prolonged duration of operation and the non-sinking of the appendiceal stump associated with an increased incidence of abscesses. Meanwhile, the latter is considered as a typical complication of laparoscopic appendectomy. The endoabdominal abscess seems to be caused by an unclean excision of the appendix or by a local distribution of previously encapsulated abscesses, respectively. To avoid this reliably, a mechanical clamp-suture instrument should be used. A further technical advantage is the possibility of a carefully directed aspiration of pus with the help of an endobag (plastic recovery-bag) whereby the appendix can be removed from the abdomen without contamination of the abdominal wall. In principle, the removal of the appendix is easier because it can be worked in situ and the basis is hardly affected from the inflammatory process.69 In particular in case of a perforation, the noticeable advantages are a shorter, postoperative duration of pain and a shorter resting period.

Delayed Resection

In case of an existing perforation with local peritonitis or perityphlitic abscesses, a drainage with antibiotic protection as initial treatment, alone can make cure possible. Some weeks later the elective stump appendectomy follows.70 Thereby, the morbidity of peritonitis and abscess formation could be decreased.71

The drainage is performed under ultrasonographic control or CT directed and therefore is often carried out in the interventional center of the radiologic department. But this can, in no case prevent the patient from being appendectomized.

NON-SURGICAL THERAPY

Antibiotic Therapy in Appendicitis

The antibiotic therapy ranks high in the treatment of appendicitis.72 An antibiotic therapy without surgery is only suggestive in case of insufficient possibilities for surgery or perforation in combination with drainage (delayed surgery). In such cases, drainage is performed under ultrasound- or CT-directed control. If the acute inflammation is abated and the drainage is removed, resection of appendix via laparoscopy or gridiron incision is necessary. But this treatment option has only a rare importance in childhood. It is mainly important for the treatment of appendicitis in adults.

The germ-spectrum in appendicitis which is found in the lumen primarily shows *E. coli*, *Bacteroides fragilis*, *Enterobacter*, and *Pseudomonas*. In the course of inflammation anaerobic germs increasingly colonize appendix and ileum.73,74 Interestingly, there are also found seasonal differences of the germ-spectrum. There are numerous recommendations concerning the question whether antibiotics are necessary in principle as well as the correct selection of the right antibiotic. From all these studies, it finally can be concluded that the administration of a broad-spectrum antibiotic at least half an hour before skin incision leads to best
results. Whether the postoperative antibiosis has to be continued, depends on the surgical finding, local circumstances, and additional risk factors like diabetes mellitus as concomitant disease.

**Recommendation**

*Perioperative prophylaxis:* Single dose of cephalosporin, e.g. Cefoxitin, amoxicillin + clavulanic acid, piperacillin, or clindamycin/gentamicin; also metronidazole alone is an possible alternative.

*Postoperative treatment:* Gangrenous or perforation: broad-spectrum antibiotic for 3-5 days.

*Peritonitis:* Broad-spectrum antibiotic + metronidazole for 5-10 days.

**POSTOPERATIVE CARE**

Postoperative care is confronted with two fundamental problems. Cure shall proceed without further infections and normal feeding shall quickly be possible. Both aims are not difficult to reach in childhood because in case of a technically troublefree appendectomy – no matter which technique is used – a rapid cure (within one or three days) is the rule. Especially the degree of inflammation and to a minor extent age and the anesthetic procedure are crucial for cure.75 The duration of hospitalization are strongly reflecting cultural and health-political circumstances. So in Europe, the patient with a common health insurance is generally nursed in the unit for one week and is then discharged in healthy condition. In America, the patients is often discharged on the same day because the costs are extremely high for the family and not always covered by the insurance company. Despite this, the complication rates are comparable. These facts show that not the postoperative care in an unit but the perioperative and operative care are the most crucial components for a rapid recovery. In case of appendicitis without complications the patients is already allowed to drink water after 6-8 hours, and if this is tolerated well it is started with a pasty diet. In most cases the patients are allowed to take regular food after three days. During the first days sufficient fluid intake is important, but fresh fruits and vegetables, sweets, and flatulent food should be avoided for at least 10-14 days. In case of peritonitis or an intensive manipulation of the cecum (perhaps with intramural hematoma) a paralytic ileus may occur postoperatively. In these cases, it is better to adhere to food withdrawal and parenteral fluid supply, as well as electrolyte substitution. A temporary stomach tube often simplifies the situation. Fever can persist for some days but is not always associated with the need for antibiotic therapy. But if the fever reappears several days after surgery, one has to think of a subcutaneous or intra-abdominal abscess. If there is no bowel evacuation after three to four days, stimulation with a small clyster, in case of preschool children with the help of an intestinal tube, has a relieving effect. But it is always to think of a fluid deficit which has to be corrected. Bed rest is only necessary as long as the patient himself wants to stay there. Also younger children are able to walk without pain after surgery. The pain situation itself is very individual. In general in young patients a single dose of a nonsteroid antirheumatic like paracetamol or metamizole (in most cases given as suppository on the operating table or on the first postoperative day) is sufficient for pain relief. All complicated cases with median laparotomy, intraperitoneal or subcutaneous drainage, or generalized peritonitis are, of course exceptions. For these cases an additional intravenous dose of opiates with fewer side-effects (e.g. tramadol or nubain) is often necessary.

**POSTOPERATIVE COMPLICATIONS**

The complication rates after appendectomy are still lying between 5.1-33%, whereby the highest proportion is found in the group of the perforating appendices. In spite of a drastic improvement after the introduction of antibiotic therapy, the mortality rate lies, mainly due to multimorbid patients, still between 0.001-0.5%. Complications can be classified into early, that means immediately occurring after surgery, and late complication. Early complications are first of all peritonitis, the intra-abdominal abscess, the disturbance of wound healing, and the paralytic ileus. They nearly always occur due to a perforating appendicitis. The causes of perforation are first of all associated with a delayed start of treatment and a history anamnesis of more than 36 hours (in > 65% of all perforations).76 Precautions to avoid these complications are a perioperative antibiotic prophylaxis, clean and fast surgery, lowest possible contamination of the abdominal wall, adequate
preoperative fluid replacement, and careful lavage with normal saline. Drainages, which are not unusual in adults, are very controversial in children.\textsuperscript{77} Most hospitals also refuse drainage in case of a multiquadrant peritonitis. One exceptions might be the primary drainage without resection of the appendix in case of an extremely progressive appendicitis. Appendectomy is performed as described above, after the abatement of inflammation. If an intraabdominal abscess is existing, there are again two treatment options. In most cases, a complete resolution of the abscess can be achieved and therefore a relaparotomy be avoided by intravenous administration of antibiotics and temporary food withdrawal.\textsuperscript{78} The second option is surgery. Either a relaparotomy is performed or a laparotomy is carried out to clear or drain the abscesses. The process can be followed by ultrasonography.\textsuperscript{79}

Late complications are ileus, caused by adhesions, and stump appendicitis. Also chronic pain may occur as a consequence of nerve lesions, consecutive development of neurinomas, or scar pain. The adhesive strangulation of intestines is typically taking place after a peritonitis and nearly always requires relaparotomy or laparoscopy.

Perioperative complications are a rupture of the appendix, possibly a cecal lesion, a erroneous opening of the bladder, or bleeding due to an insufficient ligation of the appendicular artery. In case of minimal invasive surgery technical complication are added. These are injuries of blood vessels with severe bleeding due to the first trocar or the Veress’ needle, and injuries of abdominal organs also due to trocar insertion or through monopolar coagulation, resulting in a leakage current. Perforations of intestinal loops, liver, spleen and bladder as well as thermic damages of cecum or ileum are occurring.

**PROGNOSIS**

The operative treated appendicitis is considered as cured after wound healing. A relapse is only possible, if a residual stump was left. Indigestions or immunological deficiencies in cases of a premature appendectomy were not observed till now. Although, all possible functions of the appendix are only partly clarified.

Since the notion appendicitis exists, also the conception of chronic appendicitis is known. Although, the existence of such a chronic course is denied by the vast majority of surgeons. On the other hand, the recurrent appendicitis is accepted and proved by several studies.\textsuperscript{80} It has been shown that patients who are again and again suffering from more or less typical discomforts are not operated until the clinically clear picture of an acute appendicitis is observed. The diagnosis is objectively verified by adequate studies. That means that there exists a milder course of the disease which sooner or later ends up in a complicated appendicitis in most cases. In these cases the early appendectomy is an advantage and often the diagnostic laparoscopy is the better operative access.

**FUTURE ASPECTS AND RESEARCH**

The vermiform appendix is increasingly confronted with new scopes for instance as conduit or replacement in operations of the lower urinary tract. There are also new indications like PFIC (progressive familial intrahepatic cholestasis), where the appendix is needed as diversification between gallbladder and skin. Therefore, the indication for appendectomy has to be more precisely in the future. Due to the better diagnostic situation today, fewer false positively diagnosed patients are appendectomized.\textsuperscript{81}

Appendicitis is one of the most discussed topics of surgical research. Clinical investigation about diagnostic criteria, especially the attempt to establish computer-based systems, are supported by the OMGE. Until now these efforts were disappointing. Clinical history and examination should be structurally recorded. Therefore, large prospective studies are necessary to answer the questions whether it shall be operated early or only actively be observed, or whether technical developments like ultrasonography are able to replace the active observation. Due to these and other studies, progress has been made in the establishment of objective parameters for the recognition of appendicitis which are now a part of our evidence-based medicine. Immunocytochemical and immunohistological investigations are carried out in many centers. The role of cytokines for the development of appendicitis is a large chapter of the surgical research. The key-words are among others Pgp 9.5, nerve growth factor, and growth-associated protein 43. One part of research is dealing with neuroimmunological processes within the appendix. Thereby specific neuropeptides like SP are investigated.
referring to their importance for the immune system and the appendicitis, respectively. It is postulated that up to a fourth of all appendectomies, in which a histologically unaffected appendix was found, are cases of neuroimmunoappendicitis, which are based on an increased density of nerve fibers sensitive to two neuropeptides.82 Currently, a meta-analysis has revealed that appendectomized patients less frequently fall sick with ulcerative colitis. Also nothing is known about the responsible immunological processes.83

Short bowel syndrome (SBS) continues to be one of the most challenging problems in pediatric surgery. SBS is a state in which small intestine length is inadequate to digest and absorb nutrients for normal growth and development. Though various forms of treatment have been experimented with, yet there is none ideal. Patients with short bowel syndrome present with diverse derangements in the initial disease with a complex array of secondary problems. Conscientious decision making and judicious planning right in the beginning can go a long way in improving the quality and quantity of life in children suffering from this formidable disorder. Though an intestinal transplant may be the best form of treatment for this pathology, the majority feel it is much more expensive than the present scheme of treatment.1

**ETIOLOGY**

The causes of SBS may be divided into congenital and acquired (Table 55.1). The most common causes in order of frequency of occurrence are; Necrotising enterocolitis, Intestinal atresia, Midgut volvulus, Gastrochisis and Long segment Hirschsprung’s disease.2

*Congenital short bowel syndrome* is a very rare condition of the newborn with total length of small bowel being short, with several reports demonstrating high mortality.3,4 This is always associated with malrotation. The baby may present with chronic diarrhea and failure to thrive. An upper gastrointestinal endoscopy will show a straight duodenum.4 The small bowel biopsies are histologically normal parenteral nutrition is recommended. Enteral feeding with an amino acid-based formula containing long-chain fatty acids may be introduced early and gradually advanced.4 The follow-up reported at 24 months is a regular diet, with normal growth and development of the child. The introduction of early enteral feeds promotes intestinal adaptation, with subsequent weaning off parenteral nutrition.4

Short bowel syndrome can also result from Continence-preserving operations like proximal ostomy performed for either ulcerative colitis or familial polyposis. The postoperative complications of these procedures include obstruction or mesenteric ischemia requiring resections. These are prone to form desmoid tumors and adenocarcinoma. SBS related to desmoid tumors has been reported to have a poor prognosis in patients undergoing resection alone. A more aggressive approach to intestinal transplantation in these patients may thus be warranted.

**Clinical sequelae of SBS**

Loss of a significant length of the small bowel results in interrelated physiologic events as a result of decreased small intestinal mucosal absorptive cell mass. Nutritional and metabolic effects ensue from diminished intraluminal digestive capacity and rapid intestinal transit leading to an excessive loss of fluids, nutrients, electrolytes and bile salts. The loss of a significant bowel length also affects enteroendocrine system profoundly impairing local hormonal reflex loops.

The following clinical sequelae are seen:

1. *Malnutrition:* This results following grossly impaired absorption of all nutrients. The child becomes cachexic with time.

2. *Diarrhea:* The inadequate absorptive surface leads to a lesser fraction of ingested food and intestinal secretions getting absorbed thus causing an excessive volume loss and diarrhea. There is a rapid intestinal transit across a shortened intestinal length. Gastric hypersecretion, a transient phenomenon, most commonly seen with proximal and midgut resections complicates the initial phase in SBS. Increased gastric secretions and excessive salt load thus secreted compounds the diarrhea. The pH in the proximal small intestine is lowered leading to inactivation of digestive enzymes and reduced digestive capability. Thus, a beneficial effect of histamine receptor blockers has been seen in controlling the diarrhea. Loss of cholecystokinin and secretin secondary to loss of enteroendocrine cell mass leads to impaired gallbladder motility, decreased bile secretion and decreased pancreatic secretions.

3. *Malabsorption:* This is a key finding in patients with short-bowel syndrome. Malabsorption of nonessential and essential nutrients, fluids, and electrolytes, if not compensated for by increased intake, leads to diminished body stores and subclinical and (eventually) clinical deficiencies. After intestinal resection, adaptation (a spontaneous progressive recovery from the malabsorptive disorder) may be evident. Growth hormone and glucagon-like peptide-2 have been reported to facilitate a condition of hyper-adaptation in short-bowel patients. Decreased output of brush border disaccharidases results in carbohydrate malabsorption producing reducing substances in stools. Malabsorbed fats and carbohydrates pass into colon and are fermented by colonic bacteria into volatile short chain and hydroxylated fatty acids which also contribute to diarrhea. Malabsorption of proteins also accompanies bile salt malabsorption resulting from extensive ileal resections produces diarrhea, steatorrhea and loss of fat soluble vitamins. Loss of enterohepatic circulation resulting from deceased ileal absorptive surface area leads to depletion of bile acid pool which can’t be compensated even with increased hepatic synthesis. Bacterial overgrowth is also a contributing factor towards diarrhea. Malabsorptive diarrhea due to short bowel syndrome results in nutrition compromise, often requiring parenteral nutrition. Crohn’s disease was the most common cause of SBS in a series. Most subjects with Crohn’s disease undergo surgeries, resulting in loss of the ileocecal valve. Loss of ileocecal valve permits reflux of colonic bacteria into small bowel and increased bacterial counts in small bowel lumen. Adaptive processes may lead to dilated dysfunctional loops with poor motility susceptible to bacterial overgrowth. The endotoxins of these bacteria damage mucosa, affect motility, deconjugation of bile salts and aggravate stasis. Bacterial translocation can further enhance endotoxic shock, septicemia and bowel necrosis.

4. *Vitamin deficiencies:* Impaired fat absorption leads to deficiency of fat soluble vitamins. Rickets can occur due to impaired vitamin D absorption. Vitamin deficiency states can be potentiated by
cholestyramine if it is used to bind the bile salts to
decrease the secretory diarrhea associated with bile
salt malabsorption. Vitamin B₁₂ deficiency can
result due to loss of ileal absorptive surface as well
as due to excessive consumption by bacterial
overgrowth.

5. Cholelithiasis and renal stones: Massive ileal resection
disrupts the enterohepatic cycling of bile salts and
depletes the bile pool rendering the bile
lithotropic.¹⁴ Deficiency of taurine also predisposes
to cholelithiasis. Decreased secretion of cholecysto-
kinin interferes with the gallbladder contractility
adding an element of stasis. These factors
predispose the patients to gallstone formation.
Children with short bowel syndrome have a
propensity to develop hyperoxaluria and oxalate
renal stones. This is a result of metabolism of
increased carbohydrate load that generates excess
of oxalate and unabsorbed fatty acids binding
calcium more avidly than oxalate, leaving oxalate
free for absorption into circulation leading to
hyperoxaluria.¹⁵

6. D-lactic acidosis: D-lactic acidosis is a rare and severe
complication of short bowel syndrome in children.
Some children with SBS develop recurrent episodes
of metabolic acidosis associated with altered
sensorium sometimes even progressing to coma
resulting from the colonization of bowel with
lactobacilli that converts excess carbohydrate to
D-Lactate via enzyme D-lactate dehydrogenase.
This enzyme is not present in the human beings.
D-lactate is then absorbed but it can’t be
metabolized leading to severe metabolic acidosis.¹⁶
Intestinal flora (Lactobacilli) is responsible for the
production of d-lactic acid after fermentation of
food carbohydrates. The patient may present with
acute neurological symptoms including dysarthria
and disorientation.¹⁷ Biological analysis may reveal
metabolic acidosis, increased plasma d-lactic acid
assessed by organic acid chromatography analysis
and a very important increase in expired hydrogen
during glucose breath test. Lactobacillus
fermentum may be isolated in the gastric liquid and
rectal swabs. The treatment consists of intravenous
sodium bicarbonate, antibiotic therapy and
interruption of enteral nutrition. d-lactic acidosis
should be suspected when neurological symptoms
occur in a child with short bowel syndrome. They
can be prevented by treating intestinal bacterial
overgrowth.¹⁷

7. Complications: All patients with true short bowel
syndrome will require total parenteral nutrition
(TPN) is associated with a host of acute and long-
term complications. The overall morbidity and
mortality is extremely high with complications like
sepsis; hydroelectrolyte imbalances secondary to
loose stools; thrombosis or infection of the catheter;
TPN-related cholestasis, weight/age deficit greater
than 40%, rickets and malabsorption syndromes.¹
Multiple central venous accesses need to be
performed in these patients. The use of catheters
in patients requiring short/medium- term
parenteral nutrition has less complications than
patients on home long-term parenteral nutrition.¹⁸
TPN related complications especially CVP line
related sepsis and cholestasis are the leading
causes of morbidity and mortality in children with short
bowel syndrome. CVP line sepsis episodes are more
common in patients with a shorter bowel length
supporting the general principle that bacteriemia
leading from increased intestinal permeability is a
causative factor. TPN associated cholestasis is
defined as a cholestatic state associated with a
prolonged course of TPN. A conjugated bilirubin
level greater than 2.0 mg/dl may be the criteria
after other causes have been ruled out.¹⁹ The exact
etiology of TPN associated cholestasis has not been
definitely established. The clinical implications of
TPN associated cholestasis include increased rates
of sepsis, cirrhosis and increased mortality.¹⁹

PHYSIOLOGICAL CHANGES

Adaptation

Adaptation is a compensatory response by the residual
small bowel after a sudden reduction in mucosal
surface area characterized by increased cell turn over,
and enhanced digestive and enzymatic activity of the
remnant bowel. The adaptive response begins with an
increase in the crypt cell proliferation rate, which
results in an increased villus height and an overall
increase in the functioning surface area for nutrient
absorption.²⁰ In some situations, the actual length of
the residual bowel increases; in almost all instances
the diameter increases significantly.\textsuperscript{20} If the resection or the loss is extensive or the adaptive response insufficient then lifelong dependence on TPN with its risk for associated complications is to be anticipated.

The remaining intestine lengthens to a greater degree after a resection of the proximal small bowel when compared with that after resection of the distal portion.\textsuperscript{21} Ileum is more adept to adaptation than jejunum.\textsuperscript{22} After resection of the jejunum, residual ileum adopts many of the morphologic features of the jejunum.\textsuperscript{23} The age at the time of small bowel loss also influences the adaptation - neonates have greater chances of having a successful adaptation as remnant intestine of neonates can increase in length substantially.\textsuperscript{24} The length of the residual bowel is the prime determinant of the adaptive response. The adaptive process is effective enough to allow full enteral nutrition even after 70 - 80\% of the small bowel mass has been removed.\textsuperscript{25} The best results occur when the ileocecal valve remains intact as it helps to prolong the intestinal transit, thereby promoting absorption. Loss of ileocecal valve almost doubles the minimum length of residual bowel required for successful adaptation. Minimum length required for eventual successful adaptation has been reported to be 40 cm without an intact ileocecal valve and 25 cm in the presence of an intact ileocecal valve.\textsuperscript{25} But the minimum length required depends on the age, status of the residual bowel and type of residual bowel as seen above. If the underlying disease is necrotising enterocolitis, then SBS can occur even with adequate bowel length as the residual bowel may also have widespread mucosal damage.\textsuperscript{26}

Mechanisms and Mediators that Propagate the Adaptive Response

1. Intraluminal nutrients: The reversal of gut mucosal atrophy associated with prolonged TPN and starvation has been observed with initiation of enteral feeds.\textsuperscript{27} Thus enteral nutrients act as stimulators of intestinal mucosal maintenance. Apart from the direct trophic effects, multiple factors such as hormones, secretions, peristalsis increased mucosal blood flow contribute to the indirect effect of enteral feeds in adaptive response. Complex nutrients that need more metabolic energy to absorb and digest trigger a better adaptive response, the so-called functional workload hypothesis.\textsuperscript{28} Long chain and unsaturated fatty acids are specially trophic to intestinal mucosa.\textsuperscript{29} Glutamine has been reported as vital for the proliferative effects of endogenous growth factors like epidermal growth factor and insulin like growth factor.\textsuperscript{30}

2. Gastrointestinal secretions: Endogenous pancreaticobiliary secretions have been found to be trophic to gut mucosa. Transposition of ampulla of vater to distal ileum leads to villous hyperplasia beyond the ampulla. Bile alone has been shown to stimulate RNA and DNA synthesis in bowel mucosa, an effect that is potentiated in conjunction with pancreatic secretions. Somatostatin sometimes used to decrease the fecal volume loss in SBS, acts by diminishing the output of pancreatic secretions, also blunts the adaptive response and this effect is reversible with growth factor administration in vivo.\textsuperscript{31}

3. Humoral factors: Many hormones have been implicated to participate in the adaptive response. The role of hormonal component has been shown by crossed circulation or vascular parabiosis experiments in animals. Enteroglucagon blood levels increase after intestinal resection and remain elevated and have been proposed to foster an adaptive response.\textsuperscript{32} Peptide YY has been shown to slow intestinal motility (acts as an ileal brake) and increase the time of contact between enteral nutrients and mucosa thereby helping in adaptation.\textsuperscript{33} Most convincing evidence has been gathered so far for epidermal growth factor and its receptor.\textsuperscript{34} Increased expression of EGF mRNA and protein, ileal EGF receptor during adaptation and blunted adaptation following decrease in endogenous EGF production and its restoration by exogenous EGF administration are the evidences for its role in adaptation.\textsuperscript{30} Other factors implicated in mediating adaptation include glucagon like peptide-2 and hepatocyte growth factor.

MANAGEMENT

Over the last few decades, survival of these children has dramatically improved largely attributable to early diagnosis and more facilities for imparting proper care.
The development and refinement of TPN has revolutionized the management of these cases. The management may be medical or surgical.

**MEDICAL MANAGEMENT**

With appropriate medical management a large fraction of children with SBS may adapt progressively to a full enteral feeding regimen.

The medical management comprises of the following:
1. Acute phase management
2. Nutritional support
3. Control of diarrhea

**Acute Phase Management**

In the acute phase, the treatment focuses on the replacement of fluid and electrolytes as the patient is at risk for dehydration, sodium imbalance and metabolic acidosis. Fluid losses are monitored and replaced adequately, electrolytes are monitored frequently and a constant vigil is kept for any abnormalities. Ringer’s lactate solution is preferred because of its lower chloride content and given the propensity of these children to develop acidosis.

**Nutritional Support**

This should begin promptly, either by the parenteral route or the enteral route. Central venous lines are placed after sepsis is cleared. If there is evidence of infection, peripheral parenteral nutritional support is established. Ongoing fluid losses are calculated and can be either added in TPN solution or given by a second line so that the TPN formulation is stable and does not require daily adjustment. After a stable state is reached, TPN is cycled so that the patient has significant periods of each day off the line. This allows for mobility and appears to reduce the incidence and severity of TPN associated cholestasis. Adequate quantities of micronutrients and fat soluble vitamins should be added to the daily TPN solution.

Enteral feeds should be started as soon as the bowel function returns. This also depends on the etiology of SBS, as patients with necrotising enterocolitis may take up to 3 weeks to resume normal bowel function. Enteral nutrition stimulates the adaptation and decreases the incidence of cholestasis associated with TPN. Gradual introduction of the enteral feeds is done as rapid introduction may exacerbate the secretory diarrhea with its attendant fluid losses. Elemental formulas are used initially to facilitate digestion and absorption and also to decrease the incidence of allergic reactions. Many such hypoallergenic formulas are available such as the protein hydrolysate formulas (pregestimil, vivonex) and even amino acid formulas (neocate). The proteins in these formulas are hydrolysed extensively through an enzymatic process and have very low antigenicity. Consequently, they are well tolerated by most children with SBS. In contrast to adults, tolerance of small infants to fat based formulas is more and they do not do well on calorically dense high carbohydrate formulas. So pediatric formulas generally have 40-50% of calories as fats. The composition of long chain and medium chain fatty acids varies in different formulas. Long chain fats have a higher calorie density and are better stimulators of adaptation but medium chain fats are more easily absorbed in a patient with SBS.

The carbohydrates present in enteral formulas are generally well absorbed except for lactose. Ratio of carbohydrates to fats ultimately determines the osmotic load presented to the intestine. Carbohydrates are digested rapidly, producing a high osmotic load, so a formula with only a modest carbohydrate content is preferred. Small children have more difficulty with carbohydrate rich formulas as they have greater propensity for bacterial overgrowth when fed these formulas, while in older children excess carbohydrates are converted to short chain fatty acids in colon, which are then absorbed, thus providing additional calories.

Proteins in the formulas are better provided in hydrolysed partially digested forms. But even complex proteins may be well absorbed and protein absorption is rarely a problem in SBS.

Feeds are initiated as a dilute infusion in a continuous tube feeding pattern. Initially, concentration is advanced at low volume rates reaching to a full concentration of 0.67 cal/ml for small children and 1 cal/ml for bigger children. Once the final concentration is reached in low volumes, enteral feeding rates are advanced, and parenteral rates are decreased isocalorically every 1-3 days as tolerated. Tolerance to enteral feeds is determined by testing for reducing substances in stools and monitoring volume and
consistency of stools. As fat malabsorption is not osmotically significant and protein malabsorption rarely seen, advancement of feeding is based on above criteria which monitor carbohydrate malabsorption only. Deficiency of fat soluble vitamins A, D, E and K, heavy metal deficiency such as of zinc, calcium, magnesium should be looked for and adequate replacement should be done.

Appropriate enteral feeding devices are selected based upon the duration of expected adaptation interval, etiology of SBS and motility of the residual bowel. Nasogastric tube feeding is indicated when the expected duration of tube feeds will be less than 3-4 months, when the child does not require continuous enteral feeds or when the child may be able to place his or her own nasogastric tube. Gastrostomy feedings are usually ideal for the long-term feeds and for continuous drip in feeds. These can be placed surgically or percutaneously with endoscopic guidance, with proper care and new generation of gastrostomy devices, the peristomal and other complications are minimal. Jejunostomy tubes are indicated in children with poor GI motility or those who do not tolerate gastrostomy feeds. Bolus feeds cannot be given and blockage with administration of complex formulas are the common problems. Given the advantages of continuous feeds in SBS patients, availability of new generation of infusion pumps have facilitated the administration of continuous feeds even in home settings. After the patient is stabilized and the acute phase is over, therapies targeted at promoting adaptation may be started. Most important is the early initiation of enteral feedings. Potential candidates are epidermal growth factor, insulin growth factor-1, glucagon like peptide -2 and hepatocyte growth factor.

**Control of Diarrhea**

Diarrhea in a patient with SBS results from multiple causes, the causative factor should be identified and therapy instituted accordingly. Early secretory diarrhea is controlled with careful dietary modifications guided by pH, volume and consistency of stools. Gastric hypersecretion complicates the acute phase of adaptation by augmenting diarrhea. Histamine-2 receptor blockers are useful in reducing water and sodium losses related to hypergastrinemia. If a more potent agent is required, proton pump inhibitors can be utilized such as omeprazole. Medications to slow peristalsis are used to prolong the intestinal transit time thereby allowing a longer contact time for absorption. Loperamide hydrochloride is a synthetic opioid derivative that inhibits motility in small bowel and colon. It is frequently used to slow the intestinal transit in the SBS, dose is 1 - 2 mg three times daily. If a second agent is required specially as the feedings are gradually advanced, then codeine in a dose of 0.5-1 mg/kg/dose 3-4 times a day is added. Use of antimitility agents, especially in children without an ileocecal valve, increases the risk of bacterial overgrowth. Bacterial overgrowth causes pain, fever, sudden increase in diarrhea with foul smelling stools and can retard the process of adaptation. When suspected, a specimen of stools and a gastric aspirate is taken for culture sensitivity, oral feeds are discontinued, antimitility agents are stopped, oral antibiotics usually metronidazole and intravenous fluids are instituted. Cholestyramine exchanges chloride ions and bind bile salts forming nonabsorbable complexes. The dose is 100-250 mg/kg/day in 3 divided doses. Use of cholestyramine may exacerbate fat malabsorption by diminishing bile acid pool leading to steatorrhea, hence it is not recommended for long-term use. Somatostatin and its synthetic analogues have been used in SBS. They act by reducing gastric acid secretion, gallbladder contraction, pancreatic exocrine output, bowel motility and small intestinal secretions. Increasing intestinal transit time and reducing secretions can result in improved fluid, electrolyte and substrate absorption, and is thought to be the mechanism by which somatostatin is beneficial. The net effect of somatostatin analogues on the process of intestinal adaptation is not clear yet. Other issues regarding their use is the side effect profile - abdominal pain, nausea, increased incidence of gallstones, facial flushing and headache.

Addition of 2% pectin to the diet improves the consistency of the stools and prolongs the intestinal transit and thus helps in adaptation. Management of diarrhea entails the prevention and treatment of troublesome perineal rash that develops in these children. Emollient oils such as coconut oil and zinc oxide paste can be used in early stage while 10% mixture of cholestyramine powder in a suspension of aquaphor base helps bind the excess bile acids which
potentiate the rash. Vagotomy has been reported as a possible procedure for the treatment of diarrhea, although this occurrence has no clear explanation.41

Management of Complications

Most devastating and frequent complication is the sepsis that is associated with central venous lines. The catheter related sepsis is more common in children with SBS as compared to other conditions requiring prolonged CVP lines placement. The incidence of enteric organisms causing CVP line sepsis is more in SBS patients.42

For these reasons, care of the central catheters should be meticulous. Regular dressings in proper aseptic manner, frequent cultures, flushings with urokinase and antibiotic installation (the so called antibiotic lock technique) can all be helpful in preventing CVP line related sepsis.

Bacterial overgrowth predisposes to episodes of gram-negative sepsis. Management includes stopping oral feeds, oral and/or intravenous antibiotics, assessment of motility and finding out dilated, dysmotile segments. Contrast radiographs with 24 hour and 48 hour films help in delineating problematic loops. Small dysmotile and dilated segments should be excised and longer ones can be tapered or used for intestinal lengthening procedures. Selective enteric decontamination with nonabsorbable oral antibiotics can also be helpful in reducing attacks of sepsis. Malabsorption results in deficiency of fat soluble vitamins and trace metal deficiencies. Adequate supplement doses of vitamin A, D and E should be added to diet. Vitamin K should be administered intravenously every week. Vitamin B_{12} supplementation may be required after ileal resections as ileum is the sole site for its absorption. Vitamin B_{12} can be administered parenterally or intranasally every one to 3 months. Zinc and calcium can be replaced orally while magnesium may be required to be administered parenterally as oral magnesium salts incite osmotic diarrhea. Cholelithiasis is seen in almost 10% of children with SBS. Cholecystectomy is recommended if gallstones are identified at any time. Some authors even recommend prophylactic cholecystectomy after major ileal resections.43 Oxalate renal stones are best prevented. Avoidance of steatorrhea, selective use of cholestyramine and frequent lookout for this problem are the currently recommended strategies.

D lactic–acidosis occurs due to enteric overgrowth with lactobacilli. Acute management consists of intravenous fluids, bicarbonate replacement and appropriate antibiotic therapy. Ultimately, therapy consists of decreasing carbohydrate intake, preventing bacterial overgrowth and treatment of GI tract with antibiotics to eliminate lactobacilli.

TPN associated cholestasis is one of the major complication leading to morbidity and mortality in the setting of SBS. Preventive strategies include early initiation of enteral feeds, prevention of sepsis, preventing overfeeding (hepatic steatosis), early cycling of TPN, removal or reduction of copper and manganese in TPN solutions and use of taurine supplemented PN.19 Use of ursodeoxycholic acid and cholecystokinin has shown some promise in the management of TPN associated cholestasis. Administration of oral antibiotics may cause of reduction of the intraluminal bacteria and this decrease the incidence of translocation and indirectly decrease the incidence of cholestasis.19

Surgical Therapy

Failing medical management, a trial of surgical intervention may be justified in some cases. undertaken. Surgical management may be done to achieve:

1. Institution of enteral tube feeding
2. Restoration of gastrointestinal continuity
3. Correction of obstruction
4. Resection of stagnant segments
5. Prolonging intestinal transit
6. Small bowel lengthening procedures
7. Intestinal transplantation.

Institution of Enteral Tube Feeding

Children with short bowel syndrome and concomitant intestinal failure have insufficient functional capacity to absorb sufficient nutrients, electrolytes, and/or fluid to sustain independent life. Although parenteral nutrition is often necessary, at least initially, the therapeutic goal should be to enhance intestinal adaption and enteral nutrient assimilation, and thereby reduce parenteral nutrition requirements. 

mebooksfree.com
induction of hyperphagia is critical. Enteral intake can be enhanced through enteric tube feeding like gastrostomy or jejunostomy that may be done by open surgery or percutaneous endoscopically.  

**Restoration of Gastrointestinal Continuity**

The foremost goal of surgical therapy in these cases is to restore the gastrointestinal continuity. Intestinal adaptation is facilitated after restoration of continuity like after closing on ileostomy or colostomy. The distal ileum, ileocecal valve and colon slow intestinal transit and add absorptive mucosa.

**Correction of Obstruction**

Any stricture and adhesive obstructions in the bowel should be treated early as these delay the process of adaptation.

**Resection of Stagnant Segments**

Dilated segments of bowel resulting from adaptation or ischemia lead to dysmotility, bacterial overgrowth, bacterial translocation, enteritis and malabsorption should be resected if the remaining bowel is of adequate length and the dilated segment is short. Other options include tapering, plication and intestinal lengthening procedures. Tapering removes valuable mucosal surface area so should not be performed in patients with already borderline short small intestine. Intestinal plication, which uses an inversion of the bowel wall, salvages absorptive mucosa and at the same time narrows the dysfunctional lumen. Plication may cause obstruction and dysmotility, also breakdown of plication can occur leading to recurrence of symptoms. Patients with critical small bowel length associated with dilated segments are best treated by performing a lengthening procedure.

**Prolonging Intestinal Transit**

Many procedures to prolong intestinal transit time have been tried in the past like pacing, denervation, recirculating bowel loops and vagotomy and gastric resection. However, only construction of intestinal valves and interposition of bowel segments have been found to be clinically useful.

**Intestinal Valves**

The purpose of creating intestinal valves surgically is to simulate ileocecal valve function, to slow intestinal transit and to prevent bacterial back wash into proximal bowel. Intestinal valves cause dilatation and hypertrophy of the proximal intestine and this may serve as the first step to subsequent bowel lengthening procedures.  

Intussuscepted nipple valves are the most commonly used valves. The valve is constructed like a Brooke ileostomy and preferably at the ileocolonic junction with about 8 cm of intestine (Fig. 55.1).

A prosthetic valve made of polytetrafluoroethylene requires only 3 cm of native intestine for its construction. It is made by placing a prosthetic band 1 cm wide around the intestine and then intussuscepting the intestine retrogradely over the band (Figs 55.2A to C).
Construction of the appropriate diameter and length of the valve is difficult as these vary with patient age, growth rate, diameter of the intestine and motility. The results of these valves have been variable. Potential complications include obstruction due to construction of too tight a valve, no benefit due to too loose a valve, erosion of the prosthetic into the lumen of small intestine and obstruction due to dislodgment and tissue reaction. Other valves like mucosal flap valve and ileocolonic valves have also been described but are not in much clinical use.

**Interposition of Bowel Segments**

This has been done by placing reversed intestinal segments or using colonic segments for interposition. Reversed intestinal segments induce retrograde peristalsis and slow the intestinal transit (Fig. 55.3). In addition, disruption of the nerve plexuses slows the myoelectrical activity. An alteration of the hormonal milieu has also been reported. Clinical improvement has been noted in up to 80% of the patients in whom an antiperistaltic segment has been used. The complications noted are transient obstructive symptoms and anastomotic leakage. There is a doubt about the long-term efficacy also. Optimal length for antiperistaltic segment is almost 10 cm in adults and 3-4 cm in children. In children, the interposed segment grows along with the rest of the intestine, so consistent results cannot be achieved.

Interposing a colonic segment in the remnant small intestine in either an isoperistaltic or antiperistaltic fashion will retard intestinal motility due to inherent slow peristaltic activity of the large bowel. By interposing a slower isoperistaltic segment proximally, the rate at which nutrients are delivered to the small intestine is slowed. The antiperistaltic segments of colon are placed in a more distal location like small intestinal segments. Interposed colonic segments absorb water, electrolytes and nutrients in addition to increasing the transit time. The effects are inconsistent but many patients have been reported to have a successful outcome. Stasis is a necessary side effect of these procedures that leads to bacterial overgrowth. Eosinophilic colitis presenting with bleeding can occur in interposed colonic segments. It may even necessitate excision of the interposed segment.

**Small Bowel Lengthening Procedures**

**Longitudinal Intestinal Lengthening Procedure (Bianchi Procedure)**

The procedure is based on the anatomical observation of peculiar blood supply of small intestine. The intestinal vasculature divides within the two mesenteric leaves into end arteries which alternate to each side of intestine. By dividing the bowel longitudinally between the two mesenteric leaves at a relatively avascular plane midway between the mesenteric vessels passing to each hemisegment, two parallel vascularized loops of half the diameter as the original one can be obtained (Fig. 55.4). The hemi-segments are rolled into tubes either by manual suturing or by stapler and are Anastomosed isoperistaltically to each other. In effect, a vascularized
loop of half the diameter and double the length is produced without loss of any valuable mucosa. The reduction in bowel diameter removes the problems of ineffective peristalsis and stasis (atrophy and bacterial translocation) while an increased bowel length prolongs transit and mucosal contact time. Disruption of peristalsis due to the division of circular muscle also helps by prolonging the transit time specially in the early postoperative period.48

This procedure is recommended in refractory short bowel syndrome with dilated small bowel loops. However, this procedure may not prolong survival in the setting of liver dysfunction.48 Thus the trial of medical management should not be too prolonged. Children with an obviously short length who may not adapt on medical management should be offered longitudinal intestinal lengthening procedure early when liver dysfunction has not yet set in. This procedure is not recommended in conditions like inflammatory bowel disease, chronic vascular occlusions and chronic infections, as all these conditions lead to an abnormal and unreliable vascularity. Similarly, segments like duodenum having essentially no mesentery are not suitable for longitudinal lengthening.

Successful adaptation to full enteral feeds has been reported in 45-70% of the children who underwent this procedure for refractory SBS.49,50 Factors associated with better outcome were more than 40 cm of residual small intestine, presence of ileocecal valve, presence of colon and treatable liver dysfunction.

Complications include leakage, fistula formation, stenosis due to inadequate vascularity. Loss of hemi-loop due to vascular insult has also been seen but all these complications have been infrequent.48 Most of the mortality and morbidity was due to liver dysfunction (Figs 55.5A to F).49

**Transverse Bowel Lengthening (Kimura’s Procedure)**

This technique consists of creation of an alternative blood supply on the antimesenteric surface of the small intestine and then dividing intestine into two parallel loops in the transverse place, isolating one loop on the new blood supply.51,52 The procedure is performed in 2 stages. In first stage a strip of serosa is removed from the antimesenteric bowel wall and this loop is anastomosed to a portion of the abdominal wall or liver that has been stripped off its peritoneal covering. With time collaterals develop and at 8-12 weeks the bowel is transversely divided into 2 loops. This technique may be used in circumstances where conventional LILT can’t be done like in duodenum.48 Random nature of the blood supply from vascular adhesions portends an increased risk of ischemic bowel loss in this surgical procedure. Further intra-abdominal surgery is very difficult after this procedure, so this procedure is generally recommended as the final lengthening option and cholecystectomy may be added at the same time given the propensity of the patients with SBS for developing gallstones (Fig. 55.6).45

**Sequential Intestinal Lengthening**

A combination of transverse and longitudinal bowel lengthening has been proposed to achieve increased bowel length. Initially a nipple valve was used to dilate the bowel, then dilated loop was divided horizontally and vertically at the same time into 3 segments which were rolled into tubes. The nipple valve was resected and isoperistaltic anastomosis was done.53

**Serial Transverse Enteroplasty Procedure (STEP)**

The serial transverse enteroplasty procedure (STEP) procedure is a successful and safe approach to lengthen small bowel in patients with short bowel syndrome.54 However, postlengthening dilatation may occur, which can lead to bacterial overgrowth and malabsorption. Some authors have reported success with a 2 STEP procedure to address this problem.55 Reapplication of the procedure requires careful stapling and a removal of small blind-ending segments to avoid further stasis.55

**Intestinal Transplantation**

Due to high incidence of associated complications this is usually the last option. Results are not as good as solid organ transplantation. Vascular anastomoses should be performed according to the state of graft and the recipient. The portal route is the first choice when possible. A two-stage gut reconstruction could decrease the incidence of complications, and offer a useful method in living-related small bowel transplantation.56 Generally, a cadaveric graft is used
Figs 55.5A to F: Steps of Bianchi's procedure
after ABO matching and a screening for cytomegalovirus. In the face of associated end stage liver disease, combined liver and small bowel transplant can be attempted but survival rates are less. Postoperative immunosuppression is mainly based on tacrolimus (FK506) and steroids, while azathioprine, cyclophosphamide and mycophenolate mofetil are useful in episodes of rejection. The lack of biochemical markers (like creatinine in renal transplant, bilirubin in liver transplant) makes it difficult to assess the post-transplant function. Assessment is based on clinical findings of stool frequency, volume, consistency and repeated endoscopies and mucosal biopsies. Rejection is very common due to abundance of gut associated lymphoid tissue. Sepsis, dysmotility, and post-operative gastrointestinal lymphoproliferative disease are the other commonly seen complications.

**MORBIDITY AND MORTALITY**

The overall morbidity and mortality is extremely high. Several complications have been encountered, the most common ones being sepsis, hydroelectrolyte imbalances secondary to loose stools; thrombosis or infection of the catheter; TPN-related cholestasis, and malabsorption syndromes. Sepsis is related to central venous line and episodes of bacterial overgrowth. An early consideration for bowel lengthening procedures and intestinal transplantation in a child whom a trial of medical management is not successful, should be given. Waiting till the liver disease is clearly end stage gives poor results with intestinal transplantation which must be then combined with liver transplant.

Stomas constructed in most congenital malformations that lead to the short bowel syndrome like state or are a result of it have their own inherent complications. Patients with ileostomies are at risk for severe metabolic disturbances. The small intestine essentially manages the balance of water and electrolytes and the absorption of nutrition. In short-bowel syndrome, dangerous consequences like kidney disorders may arise. In general the mortality rate for SBS has remained stable after a substantial decrease was seen with the introduction of TPN in early 80’s. Mortality rates range from 17-22% and the most common causes are sepsis and hepatic failure.

**LONG-TERM OUTCOME**

Majority of the children with SBS do well from a cognitive and development point of view. 10-15% of patients have some developmental delay. Most of the patients grow well, although they may remain small than their peers. The presence or absence of ileocecal valve affects the stool consistency and frequency. Surgical lengthening with both Bianchi and STEP procedures results in improvement in enteral nutrition, reverses complications of TPN and avoids intestinal transplantation in the majority with
few surgical complications. Intestinal transplantation can salvage most patients who later develop life-threatening complications or fail to wean TPN. Children with SBS are still at risk for different nutrient malabsorption even after weaning off TPN for a long time. Therefore, they need long-term, regular monitoring and intensive nutritional care to prevent various nutrient deficiencies. Bowel growth after massive small bowel resection provides an objective parameter of adaptation and a means of predicting ability to be weaned from TPN. Aggressive nutritional support makes even patients whose disease was previously considered hopeless, likely candidates to achieve freedom from TPN. The treatment is very expensive, more for developing countries where there is very little support from the government. The shorter the segment of the retained bowel and the longer the survival, the higher the cost.

**RECENT ADVANCES**

**Multidisciplinary Pediatric Intestinal Rehabilitation Programs**

A multidisciplinary approach to intestinal rehabilitation allows for fully integrated care of inpatients and outpatients with SBS by fostering coordination of surgical, medical and nutritional management. A multidisciplinary intestinal rehabilitation team has been found to decrease the liver failure related mortality due to early referral and increased survival to transplant. Analysis of the preliminary outcomes of the Group for the Improvement of Intestinal Function and Treatment [GIFT] program suggests that the natural history of neonatal short bowel syndrome remains unaltered to date despite a coordinated approach to care. However, improved communication and integration with the transplant service have resulted in earlier assessment, increased rates of transplantation, and decreased mortality from liver failure. Another multidisciplinary approach team has been reported to be associated with improved survival.

**New Developments**

Medicine is an ever changing field with research going on to develop better agents. Research is on for inducing neomucosal growth and further refinement of composite bowel tubes aimed at increasing actual enterocyte mass. Recently growth hormone and omega 3 fatty acid infusion has been tried in these patients.

**REFERENCES**

Intestinal obstruction is defined as an interference with the normal aboral transit of intestinal contents. It is probably the most common reason for emergency surgery in infants and children. Depending on the degree of obstruction to the flow of intestinal contents, intestinal obstruction may be defined as partial or complete. This distinction is important, since the prognosis and treatment are different. Intestinal obstruction may be further characterized as simple or strangulated, depending on the integrity of the blood supply to the involved bowel. Strangulation obstruction is an important, but also, one of the most difficult acute abdominal conditions to recognize, and may be life-threatening if the diagnosis is delayed.

HISTORICAL ASPECTS

The first recorded surgical procedure for an intestinal obstruction was performed by Praxagoras in 350 BC when he created an enterocutaneous fistula to relieve an obstruction. Non-operative management was the general rule until the nineteenth century, when surgical procedures became more frequent for intestinal obstruction. Most significant advances occurred in the early twentieth century when parenteral administration of saline solution was observed to be important in the management of intestinal obstruction and the radiographic techniques for its diagnosis were developed. Intestinal decompression by tubes in 1930s and the use of antibiotics in 1940s and 1950s were further important additions to the management of bowel obstruction.

ETIOLOGY

Intestinal obstruction may either be due to an actual physical barrier known as mechanical or dynamic obstruction, or due to a functional failure of progressive intestinal transit called paralytic ileus or adynamic obstruction. Mechanical obstructions may have congenital or acquired causes. Congenital causes may present in the neonatal period, as in intestinal atresia, or later, as in malrotation, duodenal web, or Hirschsprung’s disease. The various causes of pediatric intestinal obstruction have been classified in Table 56.1.

Pediatric Surgery—Diagnosis and Management

Paralytic Ileus

It is characterized clinically by the failure of aboral passage of intestinal contents in the absence of a mechanical obstruction. In ileus, the normal peristaltic motor function of the small intestine fails to occur. It is seen in most patients undergoing abdominal operations and is caused by several neural, humoral and metabolic factors. It may be caused by local factors such as peritonitis, ischemia or surgical manipulation of the bowel, retroperitoneal hemorrhage, operation or inflammation. Neuromuscular inhibition of intestinal motility also occurs due to prolonged intestinal distension, distension of other organs like the ureter, fractures of the spine or ribs, basal pneumonia or occult/systemic sepsis, uremia, diabetic ketoacidosis, and myxedema. Electrolyte imbalance, particularly hypokalemia, hyponatremia and hypomagnesemia, contribute to ileus. Drugs such as narcotics, antacids, anticoagulants, phenothiazines and ganglion-blocking agents, are other important causes of ileus. It is an acute, usually self-limiting condition.

Idiopathic Intestinal Pseudo-obstruction

It is characterized by symptomatic recurrent intestinal obstruction, like cramping abdominal pain, vomiting, distension and diarrhea or steatorrhea, without demonstrable radiographic findings of mechanical obstruction. The pathophysiologic effects are similar to those of mechanical obstruction, except that strangulation is rare. Heredity plays a role in this disorder. The main feature of chronic idiopathic intestinal pseudo-obstruction (CIIP) in older children is a hypotonic duodenum. It is suggested that this condition may result from ischemic injury to the peristaltic control mechanism.

PATHOPHYSIOLOGY OF INTESTINAL OBSTRUCTION

Simple Mechanical Intestinal Obstruction

In simple mechanical obstruction, the blood supply of the gut is intact. An obstructed gut dilates proximal to the obstruction due to accumulation of large volumes of fluid and gas, and this presents with abdominal distension. Initially, the peristaltic activity of the dilating gut increases to overcome the obstruction, causing rushes of hyperperistaltic bowel sounds, or high pitched tinkling sounds, or both. Later, as ileus develops, the obstructed gut becomes silent. Intestinal distension causes reflex vomiting. Water and electrolyte absorption is impaired and intestinal secretion is increased in the obstructed bowel. Inadequate fluid intake combined with the loss of fluid, by repeated vomiting and into the lumen of the obstructed gut, depletes the extracellular fluid, so that the child becomes dehydrated, hypovolemic, acidotic and may go into shock. Metabolic effects of fluid loss in simple mechanical obstruction depend on the site and duration of the obstruction. Proximal obstruction, causing relatively greater vomiting and less intestinal distension, results in the losses of water, Na⁺, Cl⁻, H⁺ and K⁺, producing dehydration with hypochloremia, hypokalemia and metabolic alkalosis. In distal obstruction with relatively greater intestinal distension, the serum electrolyte abnormalities are usually less dramatic. Intestinal distension also leads to increased intra-abdominal pressure, decreased venous return from the lower limbs and splinting of the diaphragm with impairment of ventilation.

During intestinal obstruction, whatever the cause, there is stasis and rapid proliferation of intestinal bacteria, which leads to the small intestinal contents becoming feculent. Bacterial translocation in the distended, obstructed intestine may be responsible for the systemic infections and septic consequences associated with intestinal obstruction.

Strangulation Obstruction

This occurs when the blood supply to the obstructed gut becomes impaired, which may be due to significantly increased intraluminal pressure, or due to a closed loop obstruction. A closed loop obstruction refers to a mechanical obstruction in which both the afferent and the efferent segments of the involved bowel are occluded, and hence, children with this condition are at high risk of developing strangulation, necrosis, and perforation. Pressure necrosis can develop if unyielding adhesive bands or hernial rings hold the obstructed distending gut. The deformity or twisting of the mesentery, as in volvulus or intussusception, can cause mesenteric vascular occlusion, which is a very dangerous condition and demands early treatment before gangrene of the bowel arises. Mesenteric vascular occlusion alone may give
rise to gangrene without mechanical obstruction. In addition to the effects of strangulation, the child has all the ill effects of simple obstruction. The loss of blood and plasma in strangulation obstruction is greater in predominant venous vascular obstruction than in predominant arterial vascular obstruction, and it can lead to shock in an already dehydrated child. Besides the loss of blood and plasma, another important factor in strangulation obstruction is the toxic material in the lumen of the strangulated bowel, which is formed due to the presence of bacteria and necrotic tissue. The ischemic gut mucosa readily permits the transudation of bacteria and toxins prior to perforation, producing systemic effects. As the strangulated gut becomes gangrenous, it may perforate into the peritoneal cavity, causing generalized peritonitis and septic shock. If it perforates into a hernial sac, the transudate containing lethal toxins and bacteria is more localized.

**Colonic Obstruction**

It generally follows a slower course producing less fluid and electrolyte disturbances than small bowel obstruction. There being more gut to dilate, the resulting abdominal distension may be so severe as to interfere with the child’s respiration by pushing up the diaphragm. Initially, only the colon dilates, but in the presence of incompetent ileocecal valves (seen more commonly), the dilatation progresses proximally involving the small bowel. The symptoms of dehydration are less severe as the colon can still absorb fluid above the obstruction. When the ileocecal valve is competent (which is uncommon), the obstructed colon behaves like a closed loop and the massively distended colon may perforate; the cecum being a likely site of perforation. Some of the common causes of colonic obstruction in children are acquired colonic stricture or stenosis following necrotizing enterocolitis, and Hirschsprung’s disease.

**DIAGNOSIS OF INTESTINAL OBSTRUCTION**

Intestinal obstruction should be suspected in any child presenting with abdominal pain of acute onset, vomiting, absolute constipation (ostipation) and abdominal distension with or without abdominal tenderness.

Abdominal pain is typically crampy, occurring in paroxysms at 4-5 minute intervals in proximal obstruction and less frequently in distal obstruction. As the bowel distends, its motility is inhibited and the crampy pain may subside. When crampy abdominal pain is replaced by continuous severe abdominal pain, strangulation or peritonitis should be suspected. Closed loop obstructions are associated with sudden onset of severe unremitting abdominal pain, out of proportion to the physical findings.

In high intestinal obstructions like those in the duodenum or upper jejunum, the vomiting appears almost simultaneously with pain, even before the onset of any significant distension and it may be constant, frequent and profuse. In contrast, in low small bowel obstructions, vomiting occurs a few hours after the onset of pain by which time there is significant abdominal distension with or without visible peristalsis. In distal intestinal obstruction, the vomiting is less frequent, but it is feculent because of the large bacterial population of intestinal contents. Vomiting is effortless in paralytic ileus. Obstipation indicates complete intestinal obstruction, after the bowel distal to the obstruction has emptied. In partial intestinal obstruction, the child may continue to pass loose stools, but abdominal distension and vomiting may still be present.

Physical examination should confirm the diagnosis, determine the level and degree of obstruction, exclude peritonitis, and estimate physiologic compromise and the influence of intercurrent illness. The most common systemic manifestations of intestinal obstruction are related to hypovolemia (e.g. tachycardia, tachypnea, altered mental status, oliguria, and hypotension). The presence of features of hypovolemia unresponsive to volume repletion, along with fever and leukocytosis, suggests the presence of strangulated bowel.

The abdomen is usually distended and hyper-resonant and visible peristalsis may be present. The distension is central in small bowel obstruction and peripheral in large bowel obstruction, but this classic distribution of distension may not be so evident in infants and children. Peristaltic activity is more likely to be seen in children with chronic subacute intestinal obstruction as in tubercular involvement, or Hirschsprung’s disease. Presence of a visible hernia or a previous laparotomy scar should be noted.
Abdominal tenderness is unusual in uncomplicated obstruction. However, localized tenderness, rebound tenderness and guarding suggest peritonitis and strangulation. Palpation may reveal distended loops of bowel, a hernia, or a mass (intussusception, feces, or tumor being the most common). The classic sausage shaped lump, hardening under the palpating finger synchronously with the bout of pain, is that of an intussusception. A “doughy” feel of the abdomen on palpation may suggest that the obstruction is probably due to abdominal tuberculosis.

On auscultation, the bowel sounds in intestinal obstruction are usually frequent, high-pitched, tinkling or musical, but in prolonged obstruction the bowel sounds disappear as intestinal motility decreases. In contrast, the abdomen is silent in diffuse peritonitis or in obstruction due to paralytic ileus. A rectal examination should never be omitted as it may reveal impacted stool, occult or frank blood, or an intraluminal mass such as a polyp or intussusceptum. During rectal examination, the presence of mucus and blood (red “currant jelly”) with absence of stool on the finger stall, suggests intussusception, whereas, a tense tender fluctuant mass in the pouch of Douglas indicates a pelvic abscess.

INVESTIGATIONS

Investigations are usually done to confirm the clinical suspicion and assess the general condition of the child. The results of the investigations do help in establishing the diagnosis but cannot and should not replace clinical judgement.

Laboratory Evaluation

The laboratory tests include hemoglobin estimation with a complete blood count; serum sodium, chloride, potassium, bicarbonate and creatinine; blood urea and urinalysis. These tests do not verify the presence of intestinal obstruction; rather, they give some evidence of the severity of the physiologic derangement or indicate the presence of ischemic bowel. The white blood cell count may be normal or mildly elevated in simple mechanical obstruction; but higher white blood cell counts arouse the suspicion of ischemic bowel. An elevated hematocrit and blood urea nitrogen reflect the degree of third space fluid losses and dehydration. Serum electrolytes are generally normal in distal obstruction; however, a pattern of metabolic alkalosis with hypokalemia and hypochloremia is seen in proximal bowel obstruction.

Radiologic Investigations

Radiographs usually confirm the clinical diagnosis and define more accurately the site of obstruction. Four X-ray views of the abdomen, including an upright chest, upright abdomen, supine abdomen and a left lateral decubitus view, are advisable in all patients with intestinal obstruction. The abdominal X-rays may reveal abnormally large quantities of gas in the bowel. In supine views, the distended small bowel is identified by the presence of valvulae conniventes (Fig. 56.1), whereas, the presence of haustral markings indicate colonic distension. The pattern of air-fluid levels in the upright views, in conjunction with the clinical history can help differentiate between a proximal small bowel or a distal intestinal obstruction. In complete mechanical small bowel obstruction, there is usually no gas visible distal to the level of the obstruction or in the pelvis, a “cut-off” sign which is almost pathognomonic of the condition (Fig. 56.2). The presence of significant amounts of colonic gas should raise the suspicion of a large bowel rather than a small bowel obstruction. Plain films may fail to distinguish
Intestinal Obstruction

paralytic ileus from mechanical obstruction, as gas-fluid levels are seen in both the conditions. In ileus however, the uniform presence of gas throughout the gastrointestinal (GI) tract including the stomach, small intestine and colon is more common (Fig. 56.3). When clinical symptoms indicate intestinal obstruction, the clinical findings supersede X-rays, as such films may appear normal despite the presence of strangulation obstruction.6

In newborns, thumb-sized intestinal loops (rule of thumb) and air-fluid levels are highly suggestive of neonatal intestinal obstruction.7 The more distal the level of intestinal atresia, the greater the number of distended intestinal loops and air-fluid levels observed on the abdominal radiographs. The site of atresia may appear as a larger loop with a significant air-fluid level7 (Fig. 56.4).

It is essential to realize however, that in newborns and small infants, it is very difficult to differentiate between dilated loops of small and large intestine on a plain abdominal skiagram as the colonic haustral markings are usually lacking.7,8 Therefore, differentiation between distal small bowel and colonic obstruction may be very difficult. Often however, despite the absence of haustral markings, neonatal colonic obstruction may be suggested by the presence of a large dilated loop or air-fluid level at the periphery of the abdominal field (Figs 56.5A and B). A grossly increased transverse diameter of the abdomen may be apparent on the abdominal radiograph in such patients (Figs 56.5A and B). It has also been suggested that a barium enema is essential in newborns with suspected low intestinal obstruction to differentiate between colonic obstruction (colonic atresia, neonatal Hirschsprung’s disease, meconium plug syndrome,
small left colon syndrome), and low ileal obstruction (distal ileal atresia, meconium ileus, total colonic aganglionosis). In the case of small bowel obstruction, a “microcolon” is characteristically seen on the barium enema (Fig. 56.6). Omission of a barium enema may also result in failure to identify an associated colonic or rectal atresia in patients with a more proximal bowel atresia. The contrast enema may also locate the position of the cecum in regard to intestinal rotation and fixation. A gastrografin enema may be both diagnostic and therapeutic in cases of meconium ileus and meconium plug syndrome.

Barium studies of the upper gastrointestinal (GI) tract are also often required for the diagnosis of malrotation and associated conditions.

The role of radiologic contrast studies in suspected intestinal obstruction in older children is more controversial. Although contraindicated in high grade or complete obstruction, contrast examinations may still be helpful in selected cases, for example in suspected cases of intussusception or Hirschsprung’s disease. Barium enema is both diagnostic and therapeutic in intussusception where hydrostatic reduction is a well-established procedure for management. The characteristic “beak” of volvulus at the cecum or terminal ileum and medial deviation of the cecum on contrast enema examination, suggests the persistence of an omphalomesenteric duct remnant as the etiology of obstruction. Upper GI and follow-through contrast studies are not routinely advised in suspected intestinal obstruction, especially in children, and may provide misleading information. However, for upper GI contrast studies, metrizamide is highly useful because it is nearly isotonic, is not absorbed or
Intestinal Obstruction

639
diluted significantly in the gut, is not toxic, and is quickly absorbed if it escapes into the peritoneum through a perforation. In difficult diagnostic cases of partial or intermittent small bowel obstruction, small intestinal transit with radiopaque, non-digestible markers, has also been done to challenge and localize the site of obstruction.18

Abdominal ultrasonography has been shown to be useful in the diagnosis of small bowel and colonic obstruction and can help in determining the location and cause of obstruction.19,20 It is the most useful investigation in defining the character of an abdominal mass, the only limitation being the presence of excessive bowel gas. It can delineate the mass of an intussusception, which is characteristically seen as a "target lesion" (Fig. 56.7). An ultrasound is the investigation of choice for pelvic pathology especially in adolescent girls. Roundworm infestation, which is a relatively common cause of intestinal obstruction in children in developing countries, has been shown to have a typical ultrasonographic appearance. In longitudinal section, the ascaris worm presented as a linear intraluminal mass with 3 or 4 linear echogenic interfaces; in the cross-section, it is round, sometimes appearing as a target sign; and some worms also showed serpentine movement.21 Abdominal sonography has been suggested as a successful basic diagnostic technique in early postoperative intestinal obstruction when it can separate mechanical causes, such as intussusception, from paralytic ileus.22 Okada et al have analyzed hemodynamics in the superior mesenteric artery using pulsed Doppler sonography (PDS) and have found it useful in differentiating strangulating obstruction from simple obstruction.23

Contrast enhanced CT scans or MRI may occasionally be needed to assist in the diagnosis of intestinal obstruction. CT is sensitive for diagnosing complete obstruction of the small bowel and for determining the location and cause of obstruction.24 On CT, the criteria for small bowel obstruction included a discrepancy in caliber between the proximal dilated and the more distal collapsed small bowel loops, or generalized small-bowel dilatation (> 2.5 cm) in the presence of a collapsed colon.25

**TREATMENT OF INTESTINAL OBSTRUCTION**

The overlapping sequence of events in the management of children with intestinal obstruction should be investigation, resuscitation and operation. Active preoperative management is needed to stabilize the child hemodynamically so as to minimize the intraoperative morbidity and mortality. This involves establishing an intravenous line and replacing fluid and electrolyte deficits and continuing losses; ensuring adequate urine output; and typing and cross-matching blood, if surgery is anticipated. In addition to the fluid therapy, withholding of all oral intake and intestinal decompression are other important supportive measures in these patients. A good caliber nasogastric tube should be placed and hourly aspiration is done along with continuous drainage. There is no advantage in the use of long intestinal tubes over the standard nasogastric tube.26 The use of antibiotics in simple mechanical intestinal obstruction, during the period of non-operative management, is controversial. Since the non-ischemic but distended small intestine may allow the passage of bacteria and toxins into the portal circulation and peritoneal cavity, broad-spectrum antibiotics that include coverage of gram-negative aerobes and anaerobes, should be administered during resuscitation, particularly if strangulation is suspected.

Surgery is usually necessary in most patients with suspected complete small bowel obstruction. The presence of fever, tachycardia, localized tenderness and leukocytosis indicates that surgery is mandatory in these patients, including those with no history of previous abdominal surgery and those with
incarcerated external hernias.\textsuperscript{27,28} Conservative or non-operative therapy can be attempted for 6-12 hours in early simple mechanical obstructions, especially partial or early postoperative obstructions (within 3 weeks of a previous laparotomy), and in children with recurrent small bowel obstructions. Most of the patients successfully treated non-operatively will show definite clinical improvement within 24 hours, and nearly all will improve by 48 hours, and so this is the maximum period of observation prior to proceeding for surgery.\textsuperscript{26} The consequences of delay include necrosis and perforation and may necessitate a massive bowel resection and lead to local or systemic sepsis.

The decision to operate is based on clinical judgement. The timing of surgery depends on three factors: Duration of obstruction, reflected in the severity of fluid, electrolyte and acid-base abnormalities; the opportunity to improve vital organ function; and consideration of the risk of strangulation.\textsuperscript{3} Except in very exceptional cases, surgical intervention should only be undertaken when the child is adequately hydrated and has an adequate urine output and normal serum electrolytes, and this should be achieved as soon as possible, preferably within 6-8 hours of presentation and admission.

**Operative Treatment**

All children with intestinal obstruction undergo surgery under general anesthesia, administered with an endotracheal tube in place. Vomiting and tracheobronchial aspiration of the feculent vomitus is a serious risk during induction in these children.

In general, the nature of the problem determines the approach to the operative management in these children. Surgery involves relieving the obstruction with, if present, resection of gangrenous bowel. In incarcerated inguinal hernia, operative reduction and herniotomy is usually sufficient. Lysis of adhesions or division of band(s) relieves obstruction due to adhesions or bands. Excision of a lesion with restoration of intestinal continuity is a frequently used approach, as in non-reducible intussusception, intestinal duplications or strictures and stenosis. The placement of a cutaneous fistula, such as a colostomy, proximal to the obstruction is also a recommended surgical alternative. Laparotomy, enterotomy and removal of foreign body, bezoar and roundworms, is the treatment in obturation obstruction of small bowel due to these causes. If technically possible, the distended bowel should be emptied of its luminal contents, so as to improve the blood supply of the bowel and facilitate abdominal closure.\textsuperscript{29} Creating an intestinal bypass is rarely done in pediatric patients.

The determination of bowel viability may sometimes be extremely difficult. The color of bowel, presence of motility and arterial pulsations are reassuring indicators of viable bowel. If intestinal viability is questionable, it should be placed in warm packs for 15-20 minutes and then re-examined. If there is still a reasonable doubt regarding its viability, the bowel should be resected.

**Intestinal Obstruction in Childhood—Experience at Kalawati Saran Children’s Hospital (KSCH)**

At Kalawati Saran Children’s Hospital, New Delhi, in the two-year period from February 1999-March 2001, there were a total of 279 admissions in the Pediatric Surgery department with the diagnosis of intestinal obstruction. Of these, 108 (39%) were newborns, while 171 patients (61%) were infants and children more than 1 month of age. The various causes of neonatal intestinal obstruction are shown in Table 56.2, while the etiology of intestinal obstruction in children more than 1 month of age is depicted in Table 56.3. The topic of neonatal intestinal obstruction is discussed in detail elsewhere and will not be covered in this chapter.

In our series, the common causes of intestinal obstruction were intussusception, postoperative obstruction due to adhesions, Hirschsprung’s disease, obstruction due to roundworms, tuberculous intestinal obstruction, and non-specific acute jejunoileitis (Table 56.3).

The majority (28/33) of patients presenting with obstruction due to intussusception were infants between 3 months to one year, and all underwent either operative reduction (14/33) or resection of non-viable segment of the intestine and primary anastomosis (19/33). All those who presented with incarcerated inguinal (n = 5) or umbilical (n = 2) hernia were also infants less than 6 months age and all underwent operative reduction.

The infrequent causes of intestinal obstruction in our series were congenital or inflammatory bands (n = 5); non-specific intestinal strictures (n = 3); paralytic ileus (n = 3); intraperitoneal abscesses with adhesive obstruction, duplication cyst and chylolymphatic mesenteric cyst in two cases each; and a bezoar and intestinal lymphoma in one case each.

The common causes of pediatric intestinal obstruction in our series were congenital or inflammatory bands (n = 5); non-specific intestinal strictures (n = 3); paralytic ileus (n = 3); intraperitoneal abscesses with adhesive obstruction, duplication cyst and chylolymphatic mesenteric cyst in two cases each; and a bezoar and intestinal lymphoma in one case each.

The common causes of pediatric intestinal obstruction such as congenital atresia or stenosis, intussusception, anomalies of rotation and necrotizing enterocolitis have been discussed in detail elsewhere in this book. Some of the remaining causes will be discussed here especially those disease entities which are commonly seen in developing countries like India.

**PARALYTIC ILEUS**

Usually resolves spontaneously on conservative therapy, which includes nasogastric decompression, administration of intravenous fluids for the maintenance of intravascular volume, and correction of electrolyte imbalance, especially hypokalemia. When ileus persists or occurs without an obvious etiology, a laparotomy may sometimes be necessary to confidently rule out mechanical obstruction or intra-abdominal sepsis.

Mortality from obstruction with intestinal gangrene ranges from 4.5-31%, whereas with simple mechanical obstruction relieved within 24 hours, the mortality is about 1%. Because no test reliably detects strangulation preoperatively, operation should be performed as soon as is reasonable.

**ACUTE JEJUNOILEITIS**

Acute necrotizing inflammation of the small intestine or acute necrotizing jejunoileitis has been frequently reported from South Asian countries. The etiology of the condition is still obscure. In children, this condition has been described in only a few reports, although Parvathy and Varma found it to be a common disorder in children. In a detailed study, Chandrasekhar et al reported 18 patients in whom the diagnosis was confirmed at laparotomy, and found that abdominal pain, fever and blood in stools were the most frequent presenting features. X-rays features and other investigations including bacteriological studies were non-specific. All patients presented in the period from May to October. Other authors have also reported similar findings. In 12 of the 18 patients reported by Chandrasekhar et al, bowel resection was performed, and in those patients in whom complete resection of the involved bowel was possible, the postoperative course was very smooth. An interesting finding noted by the authors was the presence of extensive neovascularization in the resected bowel with evidence of Type I and Type III hypersensitivity reactions in 4 patients. An immune mediated etiology was suggested.

In our series of 14 patients, the age ranged from 3 months to 12 years, although the majority of patients were 6 years to 12 years old at presentation. Somewhat similar to the findings of Chandrasekhar et al, 12 of the 15 patients presented between May and October. The common presenting symptoms included abdominal pain, fever, abdominal distention and obstruction. Three patients had a history of diarrhea preceding the presentation with features of jejunoileitis. Abdominal distension and tenderness,
visible bowel loops and features of toxemia were commonly seen. Blood in the stools was reported by only 4 patients (29%). We found that abdominal X-rays were quite helpful in diagnosing this condition. Characteristic findings included dilated jejunal and proximal ileal loops, thickened bowel wall, and paucity of gas in the distal bowel (Fig. 56.8). In 3 patients, ultrasonography (US) showed the presence of free fluid in the abdomen. Four patients were managed conservatively with nasogastric suction, intravenous fluids and observation. Significantly, in these 4 patients, clinical improvement was very gradual, occurring over a period of 5-12 days. One of these patients was readmitted 12 days after discharge with recurrence of symptoms and signs and underwent laparotomy. A total of 11 patients underwent laparotomy. Laparotomy showed congestion, inflammation, and varying degrees of necrosis of the small intestine, usually extending from the mid-jejunum to proximal or mid-ileum. Flimsy bowel adhesions were seen frequently, and in 3 patients, inflamed omentum with hemorrhagic areas was seen adherent to the bowel loops. Enlarged mesenteric lymph nodes were common. In 10 patients, the surgical procedure consisted of proximal decompression of the bowel, adhesiolysis, and peritoneal lavage as the condition of the bowel was not severe enough to warrant bowel resection. Postoperatively, the time-interval before resolution of signs and symptoms varied from 5-14 days. One boy, aged 4 ½ months had extensive jejunal and ileal necrosis and underwent resection of two long segments of intestine with anastomosis of viable bowel. This child died in the early postoperative period as a consequence of sepsis and multi-organ failure. It is noticeable, that as compared to other reports, bowel resection was performed in only one patient, reflecting perhaps that most of our patients presented with disease at an early stage. In addition, probably because in 10 out of the 11 patients who underwent laparotomy, diseased bowel was not removed, the postoperative course was usually stormy and prolonged. Histopathological examination of resected bowel and omentum showed evidence of non-specific hemorrhagic necrotizing inflammation.

**OBSTRUCTION DUE TO ROUNDWORM INFESTATION**

Roundworm (Ascaris lumbricoides) infestation, usually of the ileum, is common in children in tropical and sub-tropical countries like India. It is a frequent cause of abdominal pain and partial small intestinal obstruction in children. In our experience, roundworm boluses were the fourth most common cause of intestinal obstruction and all these children were more than 2 years of age. Those children presenting with subacute obstruction are initially managed conservatively with intravenous fluids, nasogastric suction, antispasmodics and anthelminthics. In our series of 19 children presenting with roundworm obstruction over a period of two years, two-thirds (13/19; 68%) were managed conservatively. In the remaining 6 children presenting with acute intestinal obstruction, surgical exploration was done. There were no deaths in our series, although postoperative morbidity and mortality in these children is not uncommon. Surgery is reserved for those presenting with acute intestinal obstruction and those who fail to improve on conservative treatment. Factors such as bands or adhesions contribute to failure of medical therapy. Early recognition of the condition would avoid serious complications and morbidity.
ADHESIVE INTESTINAL OBSTRUCTION

Intraperitoneal adhesions are a common cause of postoperative and recurrent obstruction in infants and children. The incidence of obstruction caused by postoperative adhesions in children, has been reported as 2.2-8%. In children, adhesions ranked seventh as the cause of intestinal obstruction in the series of Janik et al, but if neonatal intestinal obstruction and pyloric stenosis were to be excluded, then adhesions would be the fourth commonest cause in this series. In our experience, adhesions were the second most common cause of intestinal obstruction in infants and children (excluding neonatal causes and pyloric stenosis). Intra-abdominal adhesions form after almost any laparotomy, especially for inflammatory conditions, intussusception, Meckel’s diverticulum, malrotation, congenital diaphragmatic hernia and gastrochisis. Majority of adhesive obstruction, 80-90%, occurs within the initial two years of the previous laparotomy. Adhesions occur in the areas of ischemia or serosal damage. Rough tissue handling, presence of foreign material such as glove powder, excessively long suture ends, residual blood in the peritoneal cavity, mass ligatures of omentum or mesentery, and excessive use of dry pads or sponges, are some of the factors that significantly increase the likelihood of adhesion formation.

Sudden onset of crampy abdominal pain followed by loss of appetite, nausea and bilious vomiting in a child with history of abdominal surgery should suggest the diagnosis of adhesive intestinal obstruction. The clinical manifestations vary with the site (proximal or distal) and the stage of obstruction at the time of presentation and have been detailed earlier in this chapter. Mostly, the diagnosis of adhesive intestinal obstruction is clinical, but it needs to be confirmed by plain supine and erect abdominal radiographs. Rarely, contrast studies may be required in selected cases.

The initial treatment of adhesive intestinal obstruction is resuscitation as outlined above, and administration of broad-spectrum antibiotics to suppress bacterial translocation and help prolong the viability of ischemic intestine.

In the management of adhesive intestinal obstruction, the most difficult part is to decide if and when the child is to undergo surgery. When incomplete obstruction is suggested on clinical and radiographic findings, the child may be kept on conservative trial. In the series of Akgur et al, by conservative approach in selected patients with adhesive intestinal obstruction, overall 40% were spared operation, without any adverse occurrence. It must be kept in mind that bowel perforation can occur even with incomplete intestinal obstruction and hence, surgery should be considered if the child does not improve significantly in 6-12 hours of conservative trial. As a general rule, the presence of fever, tachycardia, leucocytosis, and/or abdominal tenderness, or complete obstruction, warrants immediate surgical exploration. At the time of surgery, it is advisable to enter the peritoneal cavity through a new incision or a fresh extension of the previous one, as the bowel may be adhered to the old scar and thereby be at risk of injury during laparotomy. The operations performed are adhesiolysis alone or combined with decompressive enterotomy, resection-anastomosis of bowel of doubtful viability, or repair of intestinal perforation(s). It should be kept in mind that during the first six weeks after an initial surgery, if the child presents with adhesive obstruction and undergoes surgical exploration, the risk for iatrogenic injury to the bowel is greatest, because the adhesions are highly vascular and heavily collagenized during this interval. Therefore, careful sharp dissection of adhesions with gentle handling of the intestine is a must in these patients. Janik et al have reported that delaying adhesiotomy and entering the gastrointestinal tract during adhesiotomy are associated with significantly increased morbidity. In their experience, the rate of wound infection in these children ranged from 4-50%, being lowest for those children who had lysis of adhesions only, and highest for those who had lysis and decompressive enterotomy or perforation repair.

POSTOPERATIVE INTUSSUSCEPTION

Postoperative small bowel intussusception occurs spontaneously and is an uncommon cause of intestinal obstruction. It usually involves the small bowel alone and occurs within two weeks of a previous laparotomy. It has been seen in the upper jejunum after routine herniotomy (without opening the sac) in an infant, and in the midileum after endorectal pull-through surgery for Hirschsprung’s disease. Typically, the child does well for several days and may
even resume oral intake. Thereafter, the child may present with abdominal cramps, anorexia, bilious vomiting, abdominal distension, and irritability, suggesting a mechanical obstruction. The diagnosis of this condition is difficult, as it needs to be differentiated from the postoperative paralytic ileus. Abdominal radiographs show an obstructive pattern. A barium enema is usually not helpful, because most of these lesions are located in the ileum or jejunum. Abdominal ultrasonography may help in the diagnosis of postoperative intussusception. However, the best diagnostic procedure is an upper GI contrast examination. In general, most postoperative small bowel intussusceptions require surgery for correction. In most cases, the intussusception can be reduced manually and strangulation is uncommon.

REFERENCES

Abdominal tuberculosis is still a common disease in developing countries. Abdominal tuberculosis is defined as infection of the peritoneum, hollow or solid abdominal organs with Mycobacterium tuberculosis.

It can involve any part of the gastrointestinal tract; peritoneum, lymph nodes, and solid viscera like liver, spleen and pancreas.[1] Its clinical presentation is protean thus causing a diagnostic dilemma, frequently mimicking other diseases. The accurate diagnosis of abdominal tuberculosis requires a high index of suspicion, as most of the investigations are non-specific and less sensitive. Abdominal tuberculosis is predominantly a disease of adolescence and young adults. The incidence and severity of abdominal tuberculosis are expected to increase with increasing incidence of HIV infection. Though potentially curable, it is a major cause of morbidity and mortality in developing countries.[2]

INCIDENCE

Some of the largest series of abdominal tuberculosis in the world have been reported from developing countries.[3] The incidence is rising in Western countries due to immigration from Third World countries and rising trend of human immunodeficiency virus infection.[4]

In a series from India, Abdominal tuberculosis accounts for 0.8% of all hospital admissions, 15% of all intestinal obstructions and 5-7% of all gastrointestinal (GI) perforations (excluding appendicular).[5] It is, however, commoner in children, affecting those above 5 years of age and particularly those residing in rural areas.[2] In a study from Madras in India, 3.6% of 1028 hospitalized children had abdominal tuberculosis.[6] Involvement of the chest, meninges or lymph nodes is more common, the overall incidence of tuberculosis being as high as 0.7-2 per 1000 children.[6]

The disease is predominant in females.

The incidence of abdominal involvement in cases with pulmonary Kochs was much higher before the era of antitubercular drugs.[7,8] Extra-pulmonary tuberculosis accounts for 10-15 percent of all cases of tuberculosis and may represent up to 50 percent of patients with AIDS. Other sites of extra-pulmonary tuberculosis more frequent than abdominal Kochs in decreasing order of frequency include lymphatic, genitourinary, bone and joint, miliary and meningeal tuberculosis. Tuberculosis (TB) of the gastrointestinal tract (GIT), is thus the sixth most frequent form of extra-pulmonary site.[9] Abdominal tuberculosis denotes involvement of gastrointestinal tract, peritoneum, lymph nodes, and solid organs, i.e. liver, spleen, and pancreas. Each is further classified into primary (no evidence of past/present pulmonary tuberculosis) or secondary (complicating pulmonary TB, usually from swallowing of infected sputum, sometimes from hematogenous spread). Additionally, the peritoneum may also be infected by reactivation of latent focus, rupture of mesenteric lymph nodes and from tubercular salpingitis. Hepatosplenic tuberculosis is common as a part of disseminated and military tuberculosis.

Nearly all cases of abdominal TB are due to the human strain of Mycobacterium tuberculosis, although few reports implicate atypical mycobacteria in some cases. Infection due to the bovis species is rare, largely due to the practice of boiling milk. In India, the organism isolated from all intestinal lesions has been Mycobacterium tuberculosis and not M. bovis.[10]
PATHOGENESIS

The peritoneum and the ileocecal region are the most likely sites of infection. The involvement of the gastrointestinal tract is seen in 65-78% of patients of abdominal tuberculosis.2

The postulated routes of infection into the gastrointestinal tract include hematogenous spread from reactivation of old primary lung focus, ingestion of infected sputum from active pulmonary focus, contiguous spread from adjacent organs and through lymph channels from infected nodes.

The most common site in the intestine is the terminal ileum and ileocecal region due to increased physiological stasis, increased fluid and electrolyte absorption, minimal digestive activity and an abundance of lymphoid tissue at this site. It has been shown that the M cells associated with Peyer’s patches can phagocytose BCG bacilli. The frequency of bowel involvement declines as one proceeds both proximally and distally from the ileocecal region. The other sites in order of frequency include colon and jejunum. The perianal region is a relatively uncommon site. Tuberculosis may also present as a nonhealing fistula in ano with undermined edges. Rarely, tuberculosis may involve unusual sites like esophagus, stomach, duodenum and appendix.

PATHOLOGY

Tuberculosis is a chronic inflammatory lesion with formation of characteristic tuberculous granulomas of variable size in the mucosa or the Peyer’s patches. They are often seen just beneath the ulcer bed, mainly in the submucosal layer. Microscopically, the submucosa is primarily involved with chronic inflammatory cells, epitheloid cell granulomas and Langerhans giant cells (with nuclei at the periphery). Submucosal edema or widening is inconspicuous. These granulomas characteristically tend to be confluent, in contrast to those in Crohn’s disease. Caseation necrosis is the absolute differentiating feature from Crohn’s disease. Acid fast bacilli (AFB) are found in only 4.6% of cases.11

Tubercular ulcers are relatively superficial and usually do not penetrate beyond the muscularis.12 They may be single or multiple, and the intervening mucosa is usually uninvolved. These ulcers are usually transversely oriented in contrast to Typhoid or Crohn’s disease where the ulcers are longitudinal or serpiginous.13 Cicatrical healing of these circumferential ulcers results in strictures. Occlusive arterial changes may produce ischemia and contribute to the development of strictures.14 Endarteritis also accounts for the rarity of massive bleeding in cases of intestinal tuberculosis.15 Angiograms of superior mesenteric arteries have been shown to be abnormal with arterial encasement, stretching and crowding of vessels, and hypervascularity.15 Patients with strictures had occlusion of the vasa recta, while ulcerated lesions had hypervascularity.

In chronic lesions there may be variable degree of fibrosis of the bowel wall which extends from submucosa into the muscularis. Mesenteric lymph nodes may be enlarged, matted and may caseate. Characteristic granulomas may be seen only in the mesenteric lymph nodes specially after antitubercular treatment has been started.

The initial stage seen in the authors experience is a stage of acute inflammation characterized by neovascularization, congestion and edema formation noticed over the serosal surface of the intestine, gonads, uterus. These types of lesions are most commonly seen in the upper jejunum and mid-ileum. The symptoms produced include recurrent acute pain abdomen specially after food intake. Other symptoms are usually missing. There is no fever and no loss of appetite. Hematological tests are normal and so is the serology for tuberculosis. The diagnosis can however, be made on laparoscopy or diagnostic laparotomy.

The chronic intestinal lesions produced by tuberculosis are of three types—ulcerative, hypertrophic, and stricturous. These lesions may occur in combinations, i.e. ulcerohypertrophic or ulcerohypertrophic.

The ulcerative form is more often seen in malnourished patients, while hypertrophic form is classically found in relatively well nourished patients. The bowel wall is thickened and the serosal surface is studded with nodules of variable size. These ulcerative and stricturous lesions are usually seen in the small intestine. Colonic and ileocecal lesions are ulcerohypertrophic. The patient often presents with a right iliac fossa lump constituted by the ileocecal region, mesenteric fat and lymph nodes. The ileocecal angle is distorted and often obtuse. Both sides of the ileocecal valve are usually involved leading to
incompetence of the valve, in distinction to Crohn’s disease. In tuberculous peritonitis, the peritoneum is studded with multiple whitish or yellow-white tubercles. It is thick and hyperemic with a loss of its shiny luster. The omentum is also thickened, vascular and inflammed.\(^{16}\)

The gross pathology is characterized by transverse ulcers, fibrosis, thickening and stricturing of the bowel wall, enlarged and matted mesenteric lymph nodes, omental thickening, and peritoneal tubercles. In children, however, involvement of the peritoneum and lymph nodes are more common than GI tuberculosis.

**Peritoneal Tuberculosis Occurs in Four forms\(^{1}\)**

1. Wet type with generalized ascitis
2. Encysted (loculated) type with a localized abdominal swelling;
3. Dry type with adhesions and
4. Fibrotic type with abdominal masses composed of mesenteric and omental thickening, with matted bowel loops felt as lump(s) in the abdomen.

It is common to find a combination of these types.
