The nodal involvement due to tuberculosis is commonly mesenteric or retroperitoneal. The lymph nodes may show evidence of caseation or calcification. Intestinal, peritoneal, and nodal tuberculosis may occur together in varying combinations. The abdominal solid organs may also be affected with tuberculosis namely liver, spleen and pancreas. However, primary tuberculosis of solid organs remains very rare and requires confirmation beyond doubts.

**CLINICAL PRESENTATION**

The disease is more rampant in malnourished children hailing from rural or lower socioeconomic backgrounds, but it not uncommon to see the disease in higher societies living in an endemic area. It is more commonly seen in adolescent girls. Fifteen percent of the affected children have active pulmonary tuberculosis, and a further 15-20\% have an evidence of past tuberculosis.\(^{17}\) Abdominal tuberculosis in older children may present with varied presentations like Granulomatous hepatitis, Terminal ileitis, mesenteric lymphadenitis, ascites, gastrointestinal symptoms and may mimic Crohn’s.\(^{7,8}\)

The clinical presentation is diverse and a high degree of suspicion is important to guide the array of investigations in the proper direction. The delay in presentation can vary between 1 and 14 months.\(^{18}\) The clinical presentation of abdominal tuberculosis can be acute, chronic or acute on chronic.\(^{19,20}\) One-third of patients with abdominal tuberculosis have constitutional symptoms of low- high grade fever (40-70\%), weight loss (40-90\%), night sweats, anorexia and malaise.\(^{1}\)

The characteristic abdominal symptom described is alternating constipation and diarrhea. Other symptoms include diarrhea, constipation and pain which can be either colicky due to luminal compromise, or dull and continuous when the mesenteric lymph nodes are involved. On physical examination, the characteristic nodes may be felt on palpation. There may be features of ascites, lump abdomen, or visible peristalsis with dilated bowel loops. The authors have managed an unusual case of tuberculous sigmoid stricture presenting with features suggestive of Hirschsprung’s disease. The diagnosis could be established only during laparotomy. Thus, in cases with doubt, a trial of antitubercular treatment or an exploratory laparotomy may be justified depending upon the clinical presentation.

The tubercular peritonitis and nodal forms are more commonly seen in children and adolescents as compared to gastrointestinal form.

**Peritoneal Tuberculosis**

1. **Wet type peritonitis with generalized ascitis.** The abdomen is grossly distended and stands out prominently in a malnourished child, with little muscle mass and subcutaneous fat.
2. **Encysted (loculated) ascitis type:** The child may be asymptomatic or present with systemic symptoms. The physical examination may reveal a localized abdominal lump, which may be due to loculated ascites, enlarged lymph node or matted omentum and intestines.
3. **Dry type with adhesions:** This is the usual type seen in a child with relatively good immunity. The child presents with subacute abdominal obstruction or a history of feeling of a moving ball of wind. A high index of suspicion is essential to start a trial of
antitubercular treatment that provides early relief in these cases.

4. Classic “Plastic” form: This is the fibrotic type with abdominal masses composed of mesenteric and omental thickening, with matted bowel loops felt as lump(s) in the abdomen. The child has gastrointestinal symptoms along with a doughy feel of the abdomen. The latter is due to diffuse peritonitis with thickening and adhesions of omentum, mesentery and peritoneum. The symptoms include diarrhea (attributed to malabsorption, which itself is due to reduced absorptive surface, obstruction of lymphatics or blind loops due to stenosis/adhesions) or alternating diarrhea and constipation. The classic presentation is, however, with attacks of subacute intestinal obstruction, most of which resolve on conservative management. A lump is found in 25-33% of cases, most often in the right iliac fossa, in the ileocecal and small bowel tuberculosis.

Mesenteric Lymphadenitis

Nodal involvement can present as a lump abdomen or intestinal obstruction due to kinks and adhesions. Obstruction of bile duct, pancreatic duct, duodenum, inferior vena cava and ureter by a lymph node have all been reported, but are rare.

Gastrointestinal Involvement

Acute Inflammatory Stage

In the inflammatory stage, the child may present with nonspecific symptoms of vague abdominal pain, mild discomfort, anorexia, malaise and fever. After a relay of investigations, if no cause is identified, an exploratory laparotomy is done in view of the persisting symptoms. On laparotomy, only congestion and neovascularization may be appreciated. A serosal biopsy may be done though without any significance as most of the time it is not positive for evidence of tuberculosis. The histopathological report is often nonspecific tuberculosis. It has often been seen that the symptoms subside on starting antitubercular treatment. The ESR if high initially is a good measure to follow the response to therapy.

Esophagogastrroduodenal Tuberculosis

The involvement of esophagus is extremely rare. Clinical presentation includes dysphagia, odynophagia and a midesophageal ulcer due to esophageal tuberculosis.

Stomach and duodenal tuberculosis each constitute around 1 percent of cases of abdominal tuberculosis. Gastroduodenal tuberculosis may present with dyspepsia and gastric outlet obstruction. Most patients (73%) in a series of 30 cases of duodenal tuberculosis reported from India had symptoms of duodenal obstruction mostly due to extrinsic compression by tuberculous lymph nodes. Complications include hematemesis, perforation, fistulae (pyeloduodenal, duodenocutaneous, blind), excavating ulcers extending into pancreas and obstructive jaundice by compression of the common bile duct. There was no associated pulmonary lesion found in more than 80 percent cases. Segmental narrowing may be seen on barium studies. Duodenal strictures are usually short. CT scan may reveal thickening of the wall and/or lymphadenopathy. Endoscopy findings are nonspecific, and demonstration of granulomas or acid fast bacilli on endoscopic biopsy material is unusual. Surgical bypass has been required in the majority of cases to relieve obstruction but successful endoscopic balloon dilatation (TTS balloon, Microvasive) of duodenal strictures has also been reported.

Jejunooileal Tuberculosis

Though not so common, tubercular involvement of the jejunum and ileum may present with malabsorption and subacute intestinal obstruction. On exploration, there is jejuno-ileitis with nonspecific inflammatory changes on biopsy.

Terminal Ileal and Ileocecal Tuberculosis

Small bowel or ileocecal tuberculosis most commonly presents with obstructive symptoms due to narrowing of the lumen by hyperplastic cecal tuberculosis, strictures of the small intestine or due to adhesions. Adjacent lymph nodal involvement can lead to traction, narrowing and fixity of bowel loops. In India, around 3-20 percent of all cases of bowel obstruction are due to tuberculosis.

Stricturous type of intestinal tuberculosis presents with features of recurrent subacute intestinal obstruction in the form of obstipation, vomiting, abdominal distension, and colicky abdominal pain. This may be associated with gurgling, feeling of ball
of wind moving in the abdomen, and visible intestinal loops.

Intestinal perforations due to tubercular etiology are usually single and proximal to a stricture. Tuberculosis accounts for 5-9 percent of all small intestinal perforations in India, and is the second commonest cause after typhoid fever.25,26

Ulcerative type of intestinal tuberculosis can present with chronic diarrhea and features suggestive of malabsorption. Malabsorption is a common complication and tuberculosis should be ruled out in every case of malabsorption in India.2 The cause of malabsorption in intestinal tuberculosis is postulated to be bacterial overgrowth in a stagnant loop, bile salt deconjugation, diminished absorptive surface due to ulceration, and involvement of lymphatics and lymph nodes.

**Segmental Colonic Tuberculosis**

Segmental colonic tuberculosis refers to involvement of the colon without ileocecal region, and constitutes 9.2 percent of all cases of abdominal tuberculosis. It commonly involves the sigmoid, ascending and transverse colon. Multifocal involvement is seen in one third of patients with colonic tuberculosis.27 The median duration of symptoms at presentation is less than 1 yr. Lower abdominal pain is the predominant symptom and hematochezia occurs in less than one-third.27 There may be chronic constipation. Other manifestations of colonic tuberculosis include fever, anorexia, weight loss and change in bowel habits. The diagnosis is suggested by barium enema or colonoscopy. Colonic tuberculosis may simulate late presentation of Hirschsprung’s disease, Crohn’s disease, ameboma or malignancy.

**Rectal and Anal Tuberculosis**

Involvement of the rectum with tuberculosis is rare and may present with hematochezia, constitutional symptoms and constipation.28 The rectal bleeding may be caused by mucosal trauma caused by hard stool traversing the strictured segment. Digital examination may reveal an annular stricture. The stricture is usually tight and of variable length with focal areas of deep ulceration. Anal tuberculosis is not uncommon and may also be seen in pediatric patients.29 The usual presentation is with anal discharge and multiple fistulae with ragged margins. Perianal swelling may be seen in one-third cases.

**Acute Abdomen**

Abdominal tuberculosis may rarely present with an ‘acute abdomen (14%) which may be due to rupture of a caseous lymph node, intestinal perforation, tuberculous peritonitis or ruptured mesenteric abscess.19 The patient may present with complications like acute obstruction or perforation especially in the presence of stricture. Involvement of the appendix is usually a part of ileocecal involvement. However, unusual cases of isolated acute appendicitis or tubercles seen in an incidental case of appendectomy have been reported.20

**Varied Presentation**

Abdominal tuberculosis may also present with pyrexia of unknown origin. The involvement of the liver presenting as hepatomegaly may be diagnosed on liver biopsy and abnormal liver function tests like reversed AG ratio and disproportionate elevation of ALP.30 The miliary and local forms of hepatic tuberculosis have quite similar clinical presentations and pathological features. Hepatosplenic tuberculosis is common as a part of disseminated and military tuberculosis. In neglected cases, the child may develop military tuberculosis and appear cachexic.

Children may also present with urinary symptoms in cases of genitourinary tuberculosis. It is not unusual to find children with renal tuberculosis presenting as a nonfunctioning kidney, pyonephrosis or discharging sinus in the lumbar region. Female patients of abdominal tuberculosis may present with menstrual disorders or later with infertility as a result of involvement of the uterus or fallopian tubes.

Tubercular psoas abscess is also common in children presenting with malaise, distension of the abdomen in the lumbar region and altered gait. The diagnosis may be suspected on eliciting the restricted extension movement of ipsilateral hip joint and confirmed on ultrasonography. A cold abscess is sterile on culture.
INVESTIGATIONS

Diagnosis is usually made through a combination of radiologic, endoscopic, microbiologic, histologic and molecular techniques.

Hematological Tests

It is usual to find anemia and hypoalbuminemia. Total leucocyte count is raised in 50% cases. There may be associated lymphocytosis.

Erythrocyte Segmentation Rate (ESR)

A raised ESR, though nonspecific, is a very supportive finding and supplements the clinical finding. Other factors contributing to a raised ESR should be taken into account. It is a good marker to assess the response to treatment.

Mantoux Test

An induration of less than 6 mm diameter indicates either-(a) an uninfected patient, (b) recent infection, (c) anergy due to malnutrition or disease states like measles, or (d) overwhelming tuberculosis infection (50% of autopsy proved cases of severe tuberculosis had been Mantoux negative). Induration in the range of 6-9 mm indicates either past infection or BCG vaccination. It may also be found in some cases of active infection particularly where atypical mycobacteria are involved. Induration of 10-14 mm in a child less than 5 years of age, strongly indicates active infection. Patients with more than 14 mm are four times more likely to have active disease than those with a Mantoux test in the range of 10-14 mm. If the patient has been vaccinated with BCG before, then an induration of more than 15 mm at 1 year, or 12 mm at 2 years after vaccination is considered positive.

Serologic Tests

Soluble antigen fluorescent antibody (SAFA) and ELISA tests have a limited role because of their inability to distinguish between past and present infections.

A positivity rate of 92 for ELISA with 12 percent false positives and a positivity rate of 83 percent with 8 percent false positives for SAFA, has been reported. Using competitive ELISA with monoclonal antibody against 38 kd protein, a sensitivity of 81 percent, specificity of 88 percent and diagnostic accuracy of 84 percent has been reported. However, ELISA remains positive even after therapy, the response to mycobacteria is variable and its reproducibility is poor. Hence the immunological tests can only suggest a probable diagnosis and should not be relied on completely.

Radiology

Chest Skiagram

Evidence of tuberculosis in a chest skiagram supports the diagnosis but a normal chest skiagram does not rule it out. It may show signs of active tuberculosis in 15% of patients. The findings can be—(a) miliary tuberculosis in a sick child without eosinophilia, (b) atelectasis, emphysema, bronchiectasis, parenchymal opacity—any of these when present with pleural effusion or hilar lymphadenopathy, indicates active disease, (c) patchy consolidation or infiltration can be non-specific, but when associated with a positive Mantoux test and cavitation in the apex, it indicates activity. Signs of ‘old’ tuberculosis are present in 20% of patients, like obliterated costophrenic angle, calcified hilar lymph nodes or a fibrocalcific lesion.

Plain Skiagram Abdomen

Plain skiagram abdomen may show enteroliths proximal to the site of obstruction. A mottled calcification in the mesenteric lymph nodes and any evidence of ascitis may be seen on the plain film. An erect skiagram is also invaluable at the time of abdominal pain in demonstrating dilated jejunal and ileal loops with multiple air fluid levels, with an absence of gas in the colon and fixed bowel loop in cases of obstruction, pneumoperitoneum in cases of perforation and any intussusception. It may be helpful to demonstrate hepatosplenomegaly.

Contrast Studies

The combined modalities of barium meal and enema together are positive in 80-85% cases of gastrointestinal tuberculosis. The former is considered superior in picking up ileocecal involvement, the commonest site.
in GI tuberculosis while the latter is more sensitive for colonic involvement (Fig. 57.1). Small bowel lesions are sometimes missed due to overlapping loops.

**Barium Meal Follow Through**

The radiologic findings that may be seen on small bowel barium meal study are:

1. mucosal irregularity and rapid emptying (ulcerative)
2. flocculation and fragmentation of barium (malabsorption)
3. stiffened and thickened folds
4. luminal stenosis with smooth but stiff contours (“hour glass stenosis“)
5. dilated loops and strictures
6. displaced loops (enlarged lymph nodes), and
7. adherent fixed and matted loops (adhesive peritoneal disease).

The mucosal details possible with double contrast barium examination allows visualization of the ulceration in the early stages of the disease. These ulcers are shallow with characteristic elevated margins. With progression, the ulcers may become confluent. Other features include bowel wall thickening, and extrinsic compression by lymph nodes.

**Barium Enema**

The following characteristics may be seen on a barium enema:

1. Early involvement of the ileocecal region manifests as spasm and edema of the ileocecal valve. Thickening of the ileocecal valve lips and/or wide gaping of the valve with narrowing of the terminal ileum (“Fleischner” or “inverted umbrella sign”) are characteristic.
2. “Conical cecum”, deformed (irregular, shortened, narrowed) cecum and pulled up due to contraction and fibrosis. The hepatic flexure may also be pulled down due to a shortened ascending colon
3. Increased (obtuse) ileocecal angle and dilated terminal ileum, appearing suspended from a retracted, fibrosed cecum (“goose neck deformity”).
4. Deformed and incompetent ileocecal valve
5. “Purse string stenosis”– localized stenosis opposite the ileocecal valve with a rounded off smooth cecum and a dilated terminal ileum.
6. “Stierlin’s sign” characterized by lack of barium retention in the inflammed segments of the ileum, cecum and variable length of the ascending colon, with a normal configured column of barium on either side. It appears as a narrowing of the terminal ileum with rapid emptying into a shortened, rigid or obliterated cecum.
7. “String sign” – narrow stream of barium indicating stenosis.

Both stierlin and string signs can also be seen in Crohn’s disease and hence are not specific for tuberculosis.

Enteroclysis followed by a barium enema may be the best protocol for evaluation of intestinal tuberculosis.

**Ultrasonography**

Ultrasonographic examination of the abdomen is helpful in peritoneal and nodal tuberculosis. It may also identify thickened and dilated bowel loops. The findings are however operator dependent. The following features may be seen on ultrasonography.

1. Free or loculated ascitis. Fluid collections in the pelvis may have strands, debris and thin septae. These fine mobile strands or septae may be due to high fibrin content of the exudative ascitic fluid.

![Fig. 57.1: Barium meal follow through in a case of abdominal tuberculosis depicting matted bowel loops displaced on the left side of the abdomen](image)
2. “Club sandwich” or “sliced bread” sign is due to localized fluid between radially oriented bowel loops, due to local exudation from the inflamed bowel (interloop ascitis).

3. Lymphadenopathy may be discrete or conglomerated (matted). The echotexture is mixed heterogenous, in contrast to the homogenously hypoechoic nodes of lymphoma. Small discrete anechoic areas representing zones of caseation may be seen within the nodes. Calcification in healing lesions is seen as discrete reflective lines. Both caseation and calcification are highly suggestive of a tubercular etiology, neither being common in malignancy related lymphadenopathy.

4. Bowel wall thickening is best appreciated in the ileocecal region. The thickening is uniform and concentric as opposed to the eccentric thickening at the mesenteric border found in Crohn’s disease and the variegated appearance of malignancy. Diseased intestine is recognised as non-specific bowel wall thickening showing as a hypoechoic halo measuring more than 5 mm. Dilated small bowel loops and occasionally, ulceration may be visible.

5. A thickening of the small bowel mesentery of 15 mm or more and an increase in mesenteric echogenicity combined with mesenteric lymphadenopathy may be seen in early abdominal tuberculosis. Pathologically, this mesenteric thickening results from lymphadenopathy, fat deposition, and edema due to lymphatic obstruction which makes it more echogenic.

6. Pseudo-kidney sign – involvement of the ileocecal region which is pulled up to a subhepatic position.

Ultrasonography may also be useful for guiding procedures like ascitic tap and fine needle aspiration cytology or biopsy from the lymph nodes or hypertrophic lesions. US-guided fine-needle aspiration biopsy (FNAB) has been used successfully in the diagnosis of abdominal tuberculosis. CT scan can also pick up ulceration or nodularity within the terminal ileum, along with narrowing and proximal dilatation. Involvement around the hepatic flexure of colon is common. Complications of perforation, abscess, and obstruction are also seen. Tuberculous ascitic fluid is of high attenuation value (25-45 HU) due to its high protein content. Thickened peritoneum and enhancing peritoneal nodules may be seen. A smooth peritoneum with minimal thickening and marked enhancement after contrast suggests tuberculous peritonitis whereas nodular and irregular peritoneal thickening suggests the presence of peritoneal carcinomatosis. Omental thickening is well seen often as an omental cake appearance.

Lymph nodes may be interspersed. The contrast enhancement of tuberculous lymph nodes on contrast-enhanced CT (CECT) have been described as (four patterns) – peripheral rim enhancement, non-homogenous enhancement, homogenous enhancement and homogenous non-enhancement, in order of frequency. Different patterns of contrast enhancement could be seen within the same nodal group, possibly related to the different stages of the pathological process. Caseating lymph nodes are seen as having hypodense centers and peripheral rim enhancement. The presence of nodal calcification in the absence of a known primary tumor in patients from endemic areas suggests a tubercular etiology. CT findings can help differentiate it from other inflammatory and neoplastic diseases, particularly lymphoma and Crohn’s disease. In tuberculosis the mesenteric, mesenteric root, celiac, porta hepatitis and peripancreatic nodes are characteristically involved, reflecting the lymphatic drainage of the small bowel. The retroperitoneal nodes (i.e., the periaortic and pericaval) are relatively spared, and are almost never seen in isolation, unlike lymphoma.

The tuberculous involvement of the pancreas may show as well defined hypoechoic areas on ultrasonography and as hypodense necrotic regions within the enlarged pancreas. CT was more accurate than ultrasound in detecting abnormalities like portal and peripancreatic lymph nodes, and bowel wall thickening. However, bowel wall dilatation was better appreciated on ultrasound than CT scan.

**Computed Tomographic (CT) Scan**

Ileocecal tuberculosis is usually hyperplastic and well evaluated on CT scan. Circumferential thickening of cecum and terminal ileum, adherent loops, large regional nodes and mesenteric thickening can together form a mass centered around the ileocecal junction. CT scan can also pick up ulceration or nodularity within the terminal ileum, along with narrowing and proximal dilatation. Involvement around the hepatic flexure of colon is common. Complications of perforation, abscess, and obstruction are also seen. Tuberculous ascitic fluid is of high attenuation value (25-45 HU) due to its high protein content. Thickened peritoneum and enhancing peritoneal nodules may be seen. A smooth peritoneum with minimal thickening and marked enhancement after contrast suggests tuberculous peritonitis whereas nodular and irregular peritoneal thickening suggests the presence of peritoneal carcinomatosis. Omental thickening is well seen often as an omental cake appearance. Lymph nodes may be interspersed. The contrast enhancement of tuberculous lymph nodes on contrast-enhanced CT (CECT) have been described as (four patterns) – peripheral rim enhancement, non-homogenous enhancement, homogenous enhancement and homogenous non-enhancement, in order of frequency. Different patterns of contrast enhancement could be seen within the same nodal group, possibly related to the different stages of the pathological process. Caseating lymph nodes are seen as having hypodense centers and peripheral rim enhancement. The presence of nodal calcification in the absence of a known primary tumor in patients from endemic areas suggests a tubercular etiology. CT findings can help differentiate it from other inflammatory and neoplastic diseases, particularly lymphoma and Crohn’s disease. In tuberculosis the mesenteric, mesenteric root, celiac, porta hepatitis and peripancreatic nodes are characteristically involved, reflecting the lymphatic drainage of the small bowel. The retroperitoneal nodes (i.e., the periaortic and pericaval) are relatively spared, and are almost never seen in isolation, unlike lymphoma.

The tuberculous involvement of the pancreas may show as well defined hypoechoic areas on ultrasonography and as hypodense necrotic regions within the enlarged pancreas. CT was more accurate than ultrasound in detecting abnormalities like portal and peripancreatic lymph nodes, and bowel wall thickening. However, bowel wall dilatation was better appreciated on ultrasound than CT scan.

**Magnetic Resonance Imaging** when compared to CT added no additional information.
Cytology and Biochemistry of Ascitic Fluid

In presence of ascites, the diagnosis can be established with Cytology and Biochemistry. The ascitic fluid in abdominal tuberculosis is clear or straw colored, with glucose concentration less than 30 mg/dl, high protein content greater than 3g/dl, with a total cell count of 150-4000/cu mm, usually more than 1,000/cu mm (consisting predominantly of lymphocytes (>70%). The ascites to blood glucose ratio is less than 0.96. Adenosine deaminase is increased in tuberculous ascitic fluid due to the stimulation of T-cells by mycobacterial antigens. In coinfection with HIV the ADA values can be normal or low. High interferon-?? levels in tubercular ascitis have been reported to be useful diagnostically. Combining both ADA and interferon estimations may further increase sensitivity and specificity. AFB smear and culture are positive in only 10-15% cases but the yield rises dramatically by culturing a litre of fluid concentrated by centrifugation. Fluorescent staining with auramine-O is superior to Ziehl-Neelsen staining with regard to positivity and ease of detection. In children, AFB may be recovered from stomach wash, keeping in mind that scant saprophytic mycobacteria may also be present as normal flora.

Polymerase chain reaction (PCR) conducted with ascites fluid has produced DNA sequences compatible with tuberculosis. PCR can be a rapid and reliable method for identification of peritoneal tuberculosis; acceleration of the diagnostic decision-making process prevents exposure to unnecessary surgery and allows early initiation of anti-tuberculosis treatment.

Percutaneous Peritoneal Biopsy

It is recommended only if there is ascites, and may be positive in 64% cases. An open biopsy or a laparoscopy aided biopsy directed at suspicious looking areas gives better results. Image-guided percutaneous peritoneal biopsy seems to be a sufficient, safe and inexpensive method for diagnosis of peritoneal tuberculosis.

Imaging Bacterial Infection with (99mTc) Tc-ciprofloxacin (Infecton)

A new radioimaging agent, Tc-99m ciprofloxacin (Infecton) has been used to detect deep seated bacterial infections, such as intra-abdominal abscesses. Patients with suspected bacterial infection have been subjected to Infecton imaging and microbiological evaluation reporting an overall sensitivity of 85.4% and a specificity of 81.7% for detecting infective foci. Sensitivity was higher (87.6%) in microbially confirmed infections. Infecton may aid in the earlier detection and treatment of deep seated infections and serial imaging with infecton might be useful in monitoring clinical response and optimizing the duration of antimicrobial treatment.

Colonoscopy

Colonoscopy has been used for the diagnosis of colonic or ileocecal tuberculosis. The appearance is nonspecific. Most commonly ulcers, strictures, or edematous and polyloid mucosal folds are seen. Mucosal pinkish nonfriable nodules of variable sizes with ulcerations in between the nodules in a discrete segment of colon most often in the cecum, are pathognomic. Areas of strictures, pseudopolyloid edematous folds, and a deformed and edematous ileocecal valve may be seen.

Multiple biopsies should be taken from the edge of the ulcers. The tissue should also be examined for AFB smear and culture as the histology may not be characteristic.

Endoscopic biopsy specimens may be subjected to polymerase chain reaction for detection of AFB. Granulomas have been reported in 8-48 percent of patients and caseation in a third of positive cases. The limitations of colonoscopic biopsy are that previous antitubercular therapy can alter the histology, and the fact that granulomas are often found in the submucosa. Of 82 patients of GI tuberculosis, colonoscopy was diagnostic in 47 patients only.

Laparoscopy

It is a very useful investigation in doubtful cases. Visual appearances have been found to be more helpful (95% accurate) than either histology, culture or guinea pig inoculation (82.3 and 37.5% sensitivity respectively). The laparoscopic findings in peritoneal tuberculosis can be grouped into 3 categories:

1. Thickened peritoneum with tubercles: Multiple, yellowish white, uniform sized tubercles (about 4-5 mm), diffusely distributed on the parietal peritoneum. The peritoneum is thickened,
hyperemic and lacks its usual shiny luster. The omentum, liver and spleen can also be studded with tubercles.

2. Thickened peritoneum without tubercles.

3. Fibroadhesive peritonitis with markedly thickened peritoneum and multiple thick adhesions fixing the viscera.

**Markers for Treatment Response**

**ESR**

The most common marker used to assess response to antitubercular treatment is ESR that tends to fall with a positive response to antitubercular treatment.

**Acute Phase Proteins**

Acute phase proteins may be measured in tuberculous patients to form a baseline to measure the response to treatment. A significant decrease in the concentrations of C-reactive protein, ceruloplasmin, haptoglobin and alpha-1-acid glycoprotein has been seen with antitubercular treatment. The proportions of patients with abnormal values on admission and at the end of treatment were 62 and 14% for C-reactive protein, 78% and 50% for ceruloplasmin, 86% and 26% for haptoglobin and 92% and 6% for alpha 1-acid glycoprotein, respectively.

**Cancer Antigen–125 Levels (CA–125)**

Cancer antigen–125 levels have been measured to be high in cases of abdominal tuberculosis. CA – 125 may thus serve as a potential follow-up marker of disease activity and treatment response in tuberculous peritonitis.

**DIFFERENTIAL DIAGNOSIS**

In the hypertrophic form of intestinal tuberculosis, the clinical picture may mimic malignant neoplasms such as lymphoma or carcinoma. In the ulcero-hypertrophic form, it may mimic inflammatory bowel disease. The nodal form of abdominal tuberculosis may closely mimic lymphomas. Ascitic form can be difficult to distinguish from malignant peritoneal disease and sometimes ascites due to chronic liver disease. In cases of hepato-splenomegaly, all other causes need to be excluded before considering a tubercular etiology.

Sometimes, when all investigations are negative and TB is strongly suspected, then a laparotomy (or a mini-lap) may be indicated for inspection of peritoneal cavity, taking a biopsy of a lymph node or omental nodule or correction of a stenotic bowel lesion can also be done simultaneously, if found.

**TREATMENT**

**Laparotomy**

In circumstances where the clinical suspicion of intra-abdominal disease is strong, but results of investigations are equivocal, a diagnostic laparotomy may be a safer option. Where clinical suspicion is strong and imaging features are suggestive, a therapeutic trial of ATT may be justified. However, laparotomy is definitely indicated where malignancy cannot be ruled out with certainty. In many patients, it may not be possible to rule out malignancy even at laparotomy. A frozen section examination may help in such cases. A mesenteric lymph node should always be removed in such cases as caseation and granulomas are much more likely to be present in lymph nodes than intestinal lesions. An omental nodule may also be taken for biopsy. The correction of a stenotic bowel lesion may be done if found. Rarely cases may present with acute intestinal obstruction and need urgent laparotomy (Figs 57.2A and B).

**Medical Treatment**

Antimicrobial treatment is the same as for pulmonary tuberculosis. Medical treatment with standard full course of Anti Tubercular Treatment (ATT) is indicated in all patients with abdominal tuberculosis. In peritoneal tuberculosis, only medical treatment is required. Intestinal tuberculosis is a systemic disease. In GI tuberculosis, surgery may be required and preferably should be done 6-8 weeks after starting the antitubercular therapy. Though the use of short course regimens for 6-9 months have been found to be equally effective by few studies, many physicians still extend the treatment duration to 12-18 months according to the conventional regimens in cases of abdominal tuberculosis. This is justified in view of the unpredictable absorption due to the diseased gut and associated symptoms like vomiting and malabsorption.

The main drugs used are Isoniazide, rifampicin, ethambutol, pyrazinamide (PZA) and streptomycin (SM). Thiacetazone and PAS are not recommended for
use for abdominal tuberculosis. In a study of 350 patients with extrapulmonary tuberculosis (including 47 children), a 9 months regime using only INH and rifampicin was successful in 95% cases with 0.7% cases relapsing in a follow-up of 9 years. Patients with peritoneal, nodal, or ulcerative intestinal disease are usually treated with drugs (ATT). Some authors have recommended the addition of corticosteroids in patients with peritoneal disease in order to reduce subsequent complications of adhesions. No controlled studies have been performed to show their benefit. Patients with intestinal obstruction due to strictures and hypertrophic lesions require surgical treatment. However, some reports have shown successful treatment of obstructing intestinal lesions with ATT alone.

Though patients usually report improvement in systemic symptoms in few weeks, relief of intestinal symptoms may require a much longer duration. Routine LFT estimations are not necessary, unless the patient has suspected icterus or malaise, anorexia or abdominal pain. INH, rifampicin and pyrazinamide should be discontinued in the presence of icterus or a three-fold rise in transaminases. As the antitubercular therapy causes healing with fibrosis, this may result in further narrowing and intestinal stricture. Therapy can also alter the histopathological picture and may even increase the perforation rate.

Surgery

In extra-GI tuberculosis, surgery is not required in all cases, the major role of surgery being biopsy. The abdomen should be closed without drainage even in the presence of ascites or peritonitis. In GI tuberculosis, if symptoms recur after starting drugs, then elective surgery is planned. Emergency surgery may be required in 25-30% cases of abdominal tuberculosis particularly those who present with perforation, acute intestinal obstruction not responding to conservative measures, acute peritonitis and rarely significant hematochezia. Bypassing the stenosed segment was practiced when effective antitubercular drugs were unavailable, as any resectional surgery was considered hazardous in the presence of active disease. This practice however, produced blind loop syndrome, fistulae and recurrent obstruction in the remaining segments. With the advent of antituberculous drugs, more radical procedures became popular in an attempt to eradicate the disease locally. These procedures were often not tolerated well by the malnourished patient. Moreover, the lesions are often widely spaced and not suitable for resection.

The recommended surgical procedures today are conservative. A period of preoperative drug therapy is controversial. Strictures which reduce the lumen by half or more and which cause proximal hypertrophy or dilation are treated by strictureplasty. This involves a 5-6 cm long incision along the antimesenteric side which is closed transversely in two layers. A segment of bowel bearing multiple strictures or a single long tubular stricture may merit resection. Resection is segmental with a 5 cm margin. Tubercular perforations are usually ileal and are associated with distal strictures. Resection and anastomosis is
preferred as simple closure of the lesions is associated with a high incidence of leak and fistula formation and thus higher mortality.\(^5\) For ileocecal tuberculosis, limited resection of the ileocecal area rather than formal right hemicolecction, involves lesser dissection and thus less chances of injury to the duodenum or ureter. For colonic lesions, resection is advocated.

Some obstructing intestinal lesions may also relieve with antitubercular drugs alone without surgery.\(^7\) The mean time required for the relief of obstructive symptoms was 6 months.

Emergency surgery for intestinal obstruction is best avoided as it carries 18-24% mortality.\(^2\) Thus, every patient who presents with intestinal obstruction should initially be managed conservatively. Tubercular perforations carry a high mortality despite surgery. In contrast, elective surgery for GI tuberculosis carries only 0.5-2% mortality. Despite the advent of newer antitubercular drugs, abdominal tuberculosis carries a mortality of 4-12% which is largely due to associated problems of malnutrition, anemia, and hypoalbuminemia and due to acute complications.

REFERENCES

Congenital alimentary tract anomalies are rare developmental errors that have historically been known by a number of different names, including enterocystomas, enterogenous cysts, supernumerary accessory organs, ileum duplex, giant diverticula, and unusual Meckel’s diverticulum. The term duplication in relation to the intestinal tract was first used by Fitz in 1884. In 1937, Ladd suggested that such anomalies be collectively designated as alimentary tract duplications. In the 1950s, Gross further defined the clinical and pathologic features of these anomalies and recommended that the term duplication be used to describe all such lesions in diverse locations from the mouth to the anus. As proposed by Gross, current nomenclature reflects the anatomic location of the duplication rather than the histologic features of its mucosal lining.

Duplication anomalies are found throughout the alimentary tract. Approximately 80% are located within the abdominal cavity, while the remaining are intrathoracic or cervical (Fig. 58.1). These anomalies vary widely in size and are either spherical or tubular. Seventy-five percent are considered cystic, with no communication to adjacent intestine; 25% are cylindrical structures that may or may not have one or more direct communications across a common septum. All intestinal duplications have a well-developed layer of smooth muscle and are lined with various types of gastrointestinal mucosa; multiple mucosal types are frequently found in the same lesion. Most intestinal duplications share a common wall with a segment of normal intestine. Thoracic duplications may or may not share a muscular wall with the esophagus, whereas duplications in the abdomen generally share a muscular wall and lie in the mesentery of the gastrointestinal (GI) tract. Because multiple duplications are found in 10-20% of cases, the diagnosis of one duplication mandates the search for another duplication elsewhere in the GI tract.

One-third of intestinal duplications typically present within the newborn period, approximately two thirds present within the first two years of life, and others present later in childhood or in adulthood. Some duplications (e.g. esophageal, colonic and rectal) are often associated with other congenital anomalies. Although duplication anomalies are sometimes diagnosed incidentally, most patients present with pain and/or obstructive symptoms resulting from the
effects of distention of the duplication or compression of adjacent organs. Additionally, abrupt hemorrhage with hemodynamic instability can occur if a cyst lined with gastric mucosa ulcerates and later erodes into adjacent organs and/or vessels. Preoperative diagnosis can be difficult because symptoms are often confused with other more common surgical diagnoses.

Although duplications in the pediatric population are benign, duplications that remain undiagnosed into adulthood may present as malignancies later in life. Although rare, malignant tumors can occur in various gastrointestinal sites. Resection or other surgical procedures are thus required to eliminate symptoms and prevent recurrence. For the most part, the choice of operative approach is determined by the anatomy of the duplication and the extent to which it integrates with normal anatomic structures. Attention to vital structures and vessels is of paramount importance in preserving function without significant compromise.

In this chapter, I will expand the general information presented in my overview by briefly discussing various embryological theories and by focusing on relevant anatomy, clinical presentation, diagnostic guidelines, and diverse surgical approaches for the wide spectrum of alimentary tract duplication anomalies.

EMBRYOLOGY

Since the early 1900s, a number of different theories attempting to explain the embryologic events that culminate in intestinal duplication have been proposed, but no single theory adequately explains duplications in all alimentary tract locations. It is thus likely that some combination of theories is correct or that these anomalies occur through some as yet undefined mechanism.

The split notochord theory relates alimentary tract duplications to the neurenteric canal, and provides an explanation for the 15% of enteric duplications associated with vertebral defects. Before the formation of the mesoderm, the embryo consists of two layers (endoderm and ectoderm) that are in direct contact. These layers remain in contact for a short while at the primitive pit until mesoderm forms between them. A transient opening (the neurenteric canal) develops, connecting the neural ectoderm with the gastrointestinal endoderm. The notochord forms in the mesoderm, just caudal to the neurenteric canal. In the pathologic state, the migrating notochord is split by the persistent neurenteric canal, resulting in the development of vertebral anomalies. Enteric duplications are among the possible abnormalities related to failure of regression of the neurenteric canal. The diverticular theory suggests that there is a failure of the normal regression of embryonic diverticula, which are common in the developing human GI tract. Their presence at numerous sites around the gut wall offers an explanation for small cystic duplications in the intestinal wall and for enteric cysts located in the presacral space. This theory does not explain the preponderance of enteric cysts in the bowel mesentery, or the finding of multiple types of mucosa lining the wall of these duplications. Another theory postulates that errors of epithelial recanalization result in formation of cysts located intramurally. This could explain the presence of small submucosal duplications. For the interested reader, in-depth information pertaining to the embryogenesis of duplications can be found in a comprehensive embryology text for surgeons edited by Skandalakis and Gray.

ORAL AND LINGUAL DUPLICATIONS

Oral and lingual duplications are extremely rare. They may affect the lips, tongue and the pharynx and may present as small asymptomatic lesions or as complete and obvious duplications of the mouth and tongue, sometimes containing ectopic gastric mucosa. Treatment consists of excision or repair with closure of the remaining mucosa.

CERVICAL AND THORACIC DUPLICATIONS

Though relatively uncommon, esophageal duplications are a well-recognized entity in pediatric surgery, and meta-analysis of reported findings indicates that they comprise approximately 20% of alimentary tract duplications. They are part of the spectrum of pulmonary foregut anomalies that includes neurenteric and bronchogenic cysts, esophageal atresia, and tracheoesophageal fistula. These anomalies originate from the primitive foregut prior to its separation into the trachea and esophagus. Early in embryogenesis, there is a single primitive foregut tube. During the first three to four weeks of
development, a ridge divides this tube into two lumina. Abnormal budding or division can leave rests of cells that form cysts anywhere along the tracheobronchial tree or esophagus. The fact that some cysts are remote from the source of origin implies their migration during embryogenesis. Because the foregut has cells that have both gastrointestinal and respiratory potential, embryologically derived cysts can have either or both types of epithelial lining.

Esophageal duplications are primarily cystic, but can be tubular, and 10% of tubular duplications connect to the esophageal lumen (Figs 58.2A to F). Most cystic duplications are simple and unilocular and contain thick, mucinous material, however, complex multiloculated cysts also occur. Multiple cystic duplications occur as either separate intrathoracic cysts or multiple intramural esophageal cysts. The mucosal lining of esophageal duplications contains gastric mucosa in up to 40% of cases, but may contain pseudostratified columnar, small intestinal, or large intestinal mucosa.10

Duplications can occur anywhere along the esophagus and two thirds of duplications occur on the right side of the esophagus. Distal esophageal

Figs 58.2A to F: A. Schematic of normal esophagus, stomach and duodeum, B. Esophageal cystic duplication, C. Esophageal duplication (intramural cystic), D. Tubular esophageal duplication, E. Tubular esophageal duplication emptying into the duodenum, F. Tubular esophageal duplication emptying into the posterior gastric region
duplications are the most common, occurring in 60% of cases; 23% of cases occur in the upper esophagus, and 17% in the middle portion. Patients with distal duplications are often asymptomatic, but those that are symptomatic may present with dysphagia (Fig. 58.3). Cervical esophageal duplications are generally diagnosed in children due to the presence of a neck mass or symptoms of upper airway obstruction. They can be confused with cystic hygromas, thyroglossal duct cysts, branchial cleft cysts, or other solid tumors such as teratomas. Duplications of the middle esophageal portion usually present with compression of the trachea at a young age, and can also be confused with bronchogenic cysts (Fig. 58.4).

Esophageal duplications can traverse the diaphragm and communicate with the stomach, duodenum, or jejunum (Fig. 58.5). As well, separate intestinal duplications may coexist with a thoracic duplication. In rare cases, three or more duplication anomalies may coexist. Approximately 50% of posterior mediastinal duplications are associated with vertebral anomalies, primarily of the lower cervical and upper thoracic vertebrae. These duplications, as well as neurenteric cysts (discussed below) can be explained by the previously cited split notochord theory.

Foregut duplications that communicate with the spinal canal are called neurenteric cysts. These duplications are most often found adjacent to lower cervical or upper thoracic vertebral anomalies; they are only rarely located intracranially or in the lumbosacral position. About half of patients with neurenteric cysts also suffer from malformations of the spinal cord and column such as spina bifida, hemivertebrae, butterfly vertebrae spondylolisthesis, and Klippel-Feil deformity. Communication with the spinal canal may exist through a fistula or a fibrous tract. It is not unusual to find coexisting intraspinal and mediastinal lesions, and they reportedly occur in 25-75% of cases; coexisting intestinal duplications have
also been reported. Additionally, there have been reports of other coexisting esophageal anomalies, such as esophageal web and esophageal atresia, both pure and with a tracheoesophageal fistula. Though coexisting pulmonary abnormalities such as bronchiectasis, intrapulmonary bronchogenic cysts, bronchial atresia, and extralobar sequestration have been reported, they are rare. Such reports nevertheless reflect the wide spectrum of embryology-related abnormalities that can occur.

Prenatal ultrasound may suggest the presence of a thoracic duplication, but it generally cannot differentiate various types of echogenic masses. A plain chest radiograph may reveal a posterior mediastinal mass and related vertebral anomalies. A barium esophagogram can be helpful by revealing extrinsic compression of the esophagus by the duplication, but it rarely shows a connection between the esophagus and duplication, and does not distinguish an esophageal duplication from a bronchogenic cyst. When tubular duplications communicate with the esophageal lumen, they can be revealed on a barium esophagogram (Fig. 58.6). While many vascular rings show esophageal distortion, they too are usually recognizable; tracheoscopy and esophagoscopy can, however, be useful in differentiating them from duplications. A computed tomography (CT) scan is extremely helpful in providing information that differentiates a cystic mass from solid neurogenic tumors and vascular structures, thus providing specific anatomic details of the relationship of the lesion to other thoracic and mediastinal structures; it does not differentiate between epithelial and nonepithelial lined cysts (Fig. 58.4). Technetium-99m pertechnetate scintigraphy is used to determine if there is secreting gastric mucosa.

Virtually all recognized esophageal duplications should be excised. The surgical approach depends on the location and extent of the duplication(s) as well as adjacent structures involved. Simple cystic duplications adjacent to the normal esophagus can be readily excised. Intramural esophageal duplications that share a common muscular wall are best removed by excising the mucosa of the duplication and preserving the lumenal integrity of the normal esophagus. In some patients, especially those with distal esophageal duplications, esophageal motility may remain abnormal post-resection. Thoracoabdominal incisions may be required to remove large tubular duplications that traverse the diaphragm and communicate with the gastric or intestinal lumen. These lesions are particularly notorious for causing peptic ulceration and gastrointestinal hemorrhage. Once resected the long-term prognosis is generally excellent.

**GASTRIC DUPLICATIONS**

Duplications of the stomach are the least common of the abdominal duplications. Nearly twice as many females as males are affected. Most cases are identified in the first year of life, but many are not diagnosed until maturity. Gastric duplications vary in size, ranging from small asymptomatic lesions to very large palpable cystic masses that displace adjacent structures. These lesions are generally located on the greater curve or posterior wall of the stomach, but can be located on the lesser curve, the anterior wall, or in the pylorus (Figs 58.7A and B). Pyloric duplications are quite rare, and imitate pyloric stenosis by compressing the lumen of the pylorus, causing projectile vomiting with accompanying electrolyte disturbances and malnutrition. Only rarely are gastric duplications completely separate from the stomach and located in the retroperitoneum. Although case reports of imperforate anus and vertebral anomalies do appear in the literature, specific anomalies are not typically associated with gastric duplications.
These duplications are cystic and generally do not communicate with the lumen of the stomach. Penetrating ulcerations of the cyst wall and erosion into the stomach, pancreas or colon or through the abdominal wall have, however, been reported. Gastric duplications are commonly present in infants with abdominal distention and non-bilious vomiting; weight loss is frequently present as a result of volume depletion and malnutrition from protracted vomiting. Gastrointestinal hemorrhage is also frequently seen, either as melena or hematemesis. Pain is secondary to distention of the cyst or peptic ulceration.

Complications associated with gastric duplications occur frequently, with gastrointestinal bleeding and perforation with peritonitis being the most common.

Prenatal ultrasound may suggest the diagnosis, but an upper GI series or postnatal ultrasound is generally required to confirm it. CT delineates the dimensions and anatomic boundaries of the lesion. Contrast in the GI tract helps determine whether a connection to the stomach is present. Because pancreatic pseudocysts are the most common cysts in the lesser sac, mistaking a gastric duplication for a pancreatic pseudocyst is a common error.

Although removal of the entire duplication is the ideal treatment, the presence of a common muscular wall between the diverticulum and the normal stomach may render this impossible. If so, surgeons must be familiar with alternatives. When the area of common gastric wall is small, the entire duplication, together with a portion of normal gastric wall, may be removed. When the defect is large, a partial gastrectomy or stripping of the mucosa as described by White may be indicated. With this procedure, the duplication is first aspirated to prevent spillage and is then opened along its entire length, creating two flaps that have their base on the common wall. Each of these flaps is resected back to the common wall, with the surgeon taking care to protect the gastroepiploic vessels. The small remaining mucosal strip at the base is then removed. Although White’s technique originally entailed suturing the transverse colon to the bed of the cyst, Lembert’s sutures may be used to invert the raw area if it is not too large. A third option is removing the entire common wall between the duplication and the normal stomach and reconstructing the stomach. These latter two options are best for lesions that are difficult to separate from the stomach.

As cited earlier, pyloric duplications are rare. The surgical treatment of choice is complete extramucosal excision of the duplication. More complicated procedures such as gastrojejunostomy and mucosal stripping have been done, but these are rarely indicated.

DUODENAL DUPLICATIONS

Duplications of the duodenum are also rare, comprising about 6% of enteric cysts of the alimentary tract. At least half present in the first few months of
life and most usually present before age 10, but some patients are not diagnosed until later in life. Duodenal duplications vary in size and are commonly cystic. These lesions are usually lined with duodenal mucosa, but ectopic gastric mucosa is sometimes (15-20%) present.\textsuperscript{17,18} Duodenal duplications occur in the first and second portions of the duodenum and usually (75%) do not connect to the duodenum. They are most often located posteromedially, sharing a common wall with the true duodenum and often partially embedded in the head of the pancreas (Fig. 58.8). Duodenal duplications generally occur singly, but they have been reported to occur in association with Meckel’s diverticulum and other duodenal, gastric, thoracic, and ileal duplications.

Obstruction of the duodenum is the usual clinical presentation. Other presenting symptoms include vomiting, gastrointestinal bleeding and perforation from ectopic gastric mucosa, and jaundice or pancreatitis from ampullary obstruction. A palpable mass is also sometimes noted. In many patients, however, symptoms may be vague and difficult to localize, making duplications quite difficult to diagnose and prolonging the course of illness.

Diagnosis is generally made after an upper GI series. These studies demonstrate complete obstruction or narrowing of the duodenal lumen, a widened C-loop, or an intraluminal-filling defect of the duodenum. Ultrasound and CT are also valuable in that they define the anatomy of the duplication in relation to surrounding organs and vascular structures. The presence of a cyst with motility in its wall, as revealed by ultrasound, is highly suggestive of a duplication. Since some lesions connect to the pancreatic duct, an endoscopic retrograde cholangiopancreatography (ERCP) may be helpful. Additionally, a technetium-99m iminodiacetic acid scan can rule out a choledochal cyst.

Treatment options include resection of the cyst with or without a segment of the duodenum, or partial excision of the cyst and total mucosal excision. These options are particularly attractive for those patients who have ectopic gastric mucosa within the cyst; leaving this mucosa increases the risk of postoperative peptic complications.

**Duplications Associated with Pancreatitis**

Some duodenal duplications appear to connect to a pancreatic duct.\textsuperscript{19} These anomalies largely occur in the head of the pancreas and may be associated with nausea, vomiting, weight loss and abdominal pain. Most patients experience multiple episodes of pancreatitis and have a history of multiple hospitalizations with undiagnosed abdominal pain. Diagnosis is extremely difficult, but ERCP is particularly helpful in delineating the anatomy of the duplication and its connection to the pancreas. In addition to resection, some patients may require a Whipple procedure or a Roux-en-Y jejunal drainage of the cyst. Since the best procedure for any one lesion is dependent upon the anatomy of the cyst and its connection to the pancreatic duct, operations for this problem must be individualized.

**ILEAL AND JEJUNAL DUPLICATIONS**

The small intestine is the most common location of enteric duplications, accounting for about half of all lesions in large published series. Of these, two thirds are located in the ileum and one third is located in the jejunum. These duplications are present in both cystic and tubular forms. Noncommunicating spherical cystic lesions of varying sizes are the most common. They are frequently located at the ileocecal junction and share a common blood supply and wall with the

---

**Fig. 58.8:** Cystic duplication of the duodenum
ileum (Fig. 58.9). Tubular duplications may be separate from the bowel, have a separate but attached wall, or may share a common wall. They are typically found within the mesentery and generally share a common blood supply and a common muscular wall with the adjacent bowel. Communication with the normal intestine is uncommon, but when present, it may lie at one or several points along the common wall. If the communication is located distally, the lesion may drain into the small bowel and remain asymptomatic. If, however, the lesion is proximal, the distal end of the duplication dilates, causing obstruction, perforation or volvulus. Gastric mucosa occurs in 33% of ileal and 50% of jejunal duplications, and is more likely to occur in tubular duplications (80%) than in cystic duplications (20%). This point is important to keep in mind because tubular duplications are more difficult to resect and if the ectopic gastric mucosa is not removed, complications are likely to occur.

Fifty percent of small bowel duplications present during the neonatal period and 50% present between 1 month and 2 years of age; seventy five percent present by age 2. These duplications are mobile and thus are often difficult to palpate. Because of the high incidence of gastric mucosa in jejunal duplications, peptic ulceration with hemorrhage occurs frequently, and complications from ulceration (e.g. melena and perforation) are more commonly seen with these duplications than with those in any other part of the GI tract. Other complications include intestinal obstruction and volvulus. In children older than 2 years of age, rectal bleeding and intussusception are common presentations. Small bowel duplications tend to occur either as an acute event in the perinatal period, or with a puzzling clinical picture after a long asymptomatic period. Ileal duplications are frequently diagnosed as appendicitis, Hirschsprung’s disease, or intussusception; jejunal duplications are sometimes confused with Meckel’s diverticulum, peptic ulcer disease, malrotation, or atresia when presentation occurs in the newborn period. Ultrasound can be helpful in revealing cystic duplications and a Meckel scan performed for bleeding occasionally reveals ectopic mucosa (Fig. 58.10). Generally, however, diagnosis is made at laparotomy for intestinal obstruction rather than preoperatively.

Operative approach varies, depending upon the anatomy of the duplication and its adjacent intestine, which may share a common blood supply. Cystic duplications and short tubular duplications are most easily treated with resection of the duplication alone or resection of the duplication and the involved wall (Fig. 58.11A). The latter procedure requires intestinal reconstruction with an end-to-end anastomosis (Fig. 58.11B). By contrast, long tubular duplications are far more difficult to treat and present the surgeon with a clinical challenge. When resection of the intestine is not an option because of the length of normal bowel that would have to be sacrificed, other approaches must be used. Long tubular duplications that are not amenable to complete resection may
require stripping the mucosa of the duplication as described by Wrenn (Fig. 58.12).\textsuperscript{20} Ischemia of the adjacent small intestine after this operation has, however, been reported. A unique method of treatment that is worthy of consideration is gastroduplication. Described by Jewett and colleagues in 1958, this procedure involved connecting the distal end of the lumen of the duplication to the gastric lumen. The treatment included resection of the connection between the ileum and the duplication with reconstruction of the normal ileum by end-to-end anastomosis. The distal end of the long duplication was then anastomosed to the stomach, leaving the long duplication draining into it (Figs 58.13A and B). A 25-year follow-up of the patient on whom this procedure was performed revealed no complications.\textsuperscript{21}

**COLONIC Duplications**

Review of available cases suggests that there are three types of enteric duplications associated with the hindgut.\textsuperscript{22,23} These include midline duplications, cystic remnants of the tailgut, and bilateral duplications of the colon and rectum (Fig. 58.14). Midline duplications are almost always cystic and as such, have the characteristics of other cystic enteric duplications. They lie posterior to the rectum and usually share a common wall with it. Signs of bowel obstruction are
frequently present, but volvulus, urinary retention, and colonic perforation are also seen. Treatment generally entails colonic reconstruction and anastomosis.

Cystic tailgut duplications are more common in females. They are located between the anus and the sacrum. In contrast to midline duplications, they have no common wall and are thus easily excised without sacrificing the rectum wall. The cystic structure is considered to be a remnant of the opening between the ectoderm and endoderm at the posterior end of the neural tube, and hence represents the persistence of a normal embryonic structure. Gastric mucosa is present in about 10% of these duplications. Presenting signs and symptoms include an asymptomatic mass, rectal bleeding, rectal prolapse and constipation caused by rectal recompression; some children also present as fistula in ano. Twenty percent to 45% of these duplications have a fistula to the rectum or the skin. Ultrasound, CT scan, and barium enema are thus useful in evaluating these anomalies. CT or MRI is used to rule out anterior meningomyelocele. Treatment consists of resection of the entire duplication or its mucosa, using a transanal or posterior sagittal approach. In light of reports of adenocarcinoma in untreated rectal duplications, at least a mucosal resection should be performed.

In contrast to midline and tailgut duplications, bilateral duplications are primarily tubular, and exist as a side-by-side rather than an over-and-under doubling. Such pairing often is accompanied by pairing of other midline structures of the posterior part of the body, but most cases show less than complete doubling. Review of reported cases of bilateral duplications reveals a wide spectrum of anorectal duplication anomalies, including double rectum that may empty into the genitourinary tract, vagina, or perineum (Figs 58.15A to C). Patients with colorectal duplications also have a high incidence of complete duplications of the bladder, ureter, and external genitalia (bifid penis and scrotum). Patients with hindgut duplications have a high incidence of skeletal abnormalities, which may manifest in vertebral, pelvic and sacral anomalies — an example being a patient with a hindgut duplication and cloacal exstrophy. The mucosal lining of these duplication anomalies is usually normal colonic mucosa.

As revealed in a review of 57 patients with tubular colonic duplications (1876-1981) conducted by Yousefzadeh and colleagues, associated anomalies are common. Gastrointestinal anomalies were seen in 49% of patients, and included double appendix, double ileum, omphalocele, Meckel’s diverticulum, and malrotation. Eighty percent of patients had anomalies involving at least one system other than the GI tract, and 55% of patients had anomalies involving at least three systems; urologic, genital, and spinal anomalies were common.

Tubular colonic duplications are often observed at birth together with duplications of the genitals or bladder. Patients also may present with acute or chronic lower intestinal obstruction, rectovaginal fistula, rectal prolapse, and urinary tract infections. Diagnosis is generally made by urinary tract evaluation, perineal inspection, and contrast studies of the colons. Due to the high incidence of coexisting anomalies, meticulous clinical and diagnostic evaluation of patients is essential.

Symptoms are caused when the distal obstructed pouch of the duplication that usually connects to the normal colon proximally fills with feces, thereby causing compression of the normal colon (Figs 58.16A and B). Although each case must be individualized, treatment generally involves either of two surgical approaches. In the first approach, the distal part of the duplicated colon is connected to the normal colon with a linear stapler, the connection being distal enough to ensure that the duplication does not fill with
feces. In cases where the normal rectum and the duplication are separated, the distal part of the duplication can alternatively be resected (Figs 58.17A and B). When the duplicated colon connects to the urinary tract or vagina, the second surgical approach is generally used. With this approach, the duplication is divided and an endorectal mucosectomy of the distal duplication is performed. The muscular cuff is then closed and an end-to-side anastomosis connecting the remaining distal end of the duplication to the normal colon is performed. Since tubular duplications do not usually have ectopic gastric mucosa, resection of the duplicated segment is rarely necessary. Although malignancy has been reported in untreated cases of colonic duplication, these reports do not exist in cases treated with distal diversion.

**SUMMARY**

Duplications of the alimentary tract comprise a rare, but interesting constellation of anomalies. The clinical presentation and symptoms of patients are variable,
often making an accurate diagnosis quite difficult and prolonging the course of illness. Both diagnosis and treatment require a methodical, individualized approach.

REFERENCES

Bezoars, today, known as an uncommon cause for gastrointestinal symptoms, have been mysteries since ancient times and are known to propound diagnostic and therapeutic challenges. The incidence has decreased dramatically in the recent times, and most of the residents now see it as a museum specimen. The diagnosis depends on a high index of suspicion. The most common type is Trichobezoar (hair) that is usually found in adolescent psychiatric females. Some patients have bezoars that fill their entire stomach, while others are able to loosen them with ingestion of cellulase enzyme especially in cases of phytobezoars (vegetable matter). Treatment of the causative factor is essential to prevent recurrence.

TERMINOLOGY

The word “bezoar” has been derived from the arabic word “bazahr”, Persian word ‘Padzahr’ or Turkish word ‘Panzehir’, all meaning antidote or counter-poison. Animal bezoars were widely used in medicine until the 18th century. Bezoars are concretions of foreign materials that are created in the intestinal tract of various animals and humans. Bezoars have built up a reputation as being talismans of luck, power, or health, to ward off the evil spirits for the last couple of thousand years. Bezoars have been said to cure animals and people of rabies by attaching the bezoar to the wound to suck out the poison. Bezoars were used as antidotes to some poisons and were considered so precious that a gold-framed bezoar was included in the inventory of Queen Elizabeth’s crown jewels in 1662. The term trichobezoar was first described by Baudemant in 1779 while the term phytobezoar is attributed to Quain since 1854.

DEFINITION

Bezoars are masses of solidified concretions of organic or non-biological foreign material commonly found in the stomach or small bowel. A bezoar is a concretion (tightly packed collection) of a partially digested or undigested foreign substance in the stomach or intestine. It has a tendency to remain there indefinitely unless removed.

CLASSIFICATION

1. Trichobezoars: An agglomeration of hair. Trichobezoars take the shape of the stomach, its surface is slimy and it has a foul odour due to putrefaction of food. These are the most common types of bezoars encountered.
2. Phytobezoars: These consist of partially digested agglomeration of vegetable matter such as leaves or undigested foods. Phytobezoar is made of fibrous food stuff, most commonly due to unripened persimmons. A persimmon bezoar is also known as diospyrobezoar. The phytobezoar is a compact mass of fibers, skins, seeds, leaves, roots, or stems of plants.
3. Lactobezoars: These are milk coagulums seen in small babies who are artificially fed. It is grayish white in color, shaped like the stomach and has slimy surface. The presence of casein as the predominant protein is necessary for the development of a lactobezoar. It has even been reported in an eight year old girl.
4. Pharmacobezoars: These are concretions of medication (sucralfate, aluminum hydroxide gel), shellac.
5. **Iniobezoars (coirbezoars):** Concretions due to coconut cover fibers or rope.9
6. **Pseudobezoars:** These include loose aggregation of pits, seeds, citrus pith, or even bubblegum may mimic true bezoars. Jungle banana seeds and sunflower seeds have also been implicated.10,11
7. **Rare forms:** These include cloth ingestion, Paper ingestion, plastic ingestion, Vinyl glove ingestion, Sponge bezoar and Polystyrene bezoar.12-16 Children have been reported to swallow plastic toys.17 Combination forms like trichophytobezoars may also be found.

**ETIOLOGY**

**Neuropsychiatric Disorders**

This is the most common cause in children with bezoar formation. These are usually adolescent females who in a rage of temper or unsound mind pluck their long hair and swallow it.4,5 Huge trichobezoars have been reported in these patients. In a series of 24 children with trichotillomania attending psychiatry outpatient department, the majority were females (66.7%).18 Most belonged to age group 6-10 years (54.2%) and nuclear family (68.5%). Nail-biting (25.0%) was the commonest associated neurotic trait, followed by enuresis (20.9%) and temper-tantrum (12.5%).18 A past history of hysterical fits and neurotic depression was found in 3 cases (12.5%) and 2 cases (8.3%) respectively. Family history of neurosis was seen in mothers and fathers of 20.9% and 12.5% cases respectively. Trichobezoars and trichophytobezoars were found in 6 cases (25.0%) and 3 cases (12.5%) respectively. Upto 22.2% cases of trichobezoar were asymptomatic and detected only on screening psychiatric patients.18

The other types of bezoars reported in mentally retarded patients include, “polystyrenomania” from ingestion of styrofoam cups and vinyl glove bezoar.15,16 A girl with icardi syndrome has been reported to lose 10 pounds weight due to the development of a lactobezoar.8

**Associated Partial Congenital Obstructions**

Associated partial congenital obstructions like duodenal web, operated case of ileal atresia, serious digestive antecedents, corrosive esophagogastitis and follow up case of esophageal atresia.2

**Intraluminal Obstruction**

Phytobezoars as a cause of small bowel obstruction has been associated with a carcinoid tumor of the ileocecal area.19

**Postpartial Gastrectomy**

Phytobezoars may occur in patients after partial gastrectomy, especially when accompanied by vagotomy. Hypochlorhydria, diminished antral motility, and incomplete mastication are the main predisposing factors. Unpeeled persimmon, orange or grapefruit pulp are the usual offenders, thus postgastrectomy patient must be warned of ingesting citrus fruits as a prophylactic measure.20

**Postgastroplasty**

The vertical banded gastroplasty used in the treatment of morbid obesity has been associated with gastric bezoars. This may be a predisposing factor in obese older children.

**Diabetic Gastroparesis**

Causes a loss of normal pyloric function and decreased gastric acidity, thus predisposing to formation of phytobezoars.21

**Uremia**

Uremic patients frequently present predisposing conditions such as autonomic neuropathy, diabetes mellitus and delayed gastric emptying.22 Gastric bezoars cause anorexia. Thus the possibility of a gastric bezoar should be considered during evaluation of anorexic uremic patients.

**Trichotillomania and Trichophagia**

Some people may have a bad habit of plucking their hair (trichotillomania) and chewing it constantly. It also has been reported in adolescent girls with a normal frame of mind.23 Such patients are cured after surgical removal of the bezoars and not prone to recurrence.

**PATHOGENESIS**

Phytobezoars are concretions of hair casts in the stomach. The hair strands get retained in the folds of
Bezoars in Children

673

the gastric mucosa because the friction surface is insufficient for peristalsis propulsion. In about 5% of patients there are separate hair masses in the stomach.5,24

The phytobezoar is a compact mass of plant products that collects in the stomach or small intestine. Other food particles, such as fats, crystals, granules, fibers, and residues of salts, are incorporated into the mass and contribute to the growth of the bezoar.25

Persimmon is a fruit grown mainly in Japan and Asia that contains large amount of ‘shibuol’ a phlobatranin, that is coagulated by gastric acid into a compound that efficiently bonds vegetable fibers, seeds, and pieces of skin together.1 Ingestion of unripe persimmons, especially on an empty stomach with or no food matter to interfere with the contact and aggregation of the seeds and fragments of skin, predisposes to development of this type of bezoar. Patients that have undergone surgical procedures for peptic ulcer disease or any procedure on the stomach or who for other reasons, such as diabetic gastroparesis, have a loss of normal pyloric function and decreased gastric acidity are prone to form phytobezoars. Persimmon peels or pits, orange or grapefruit pulp are the usual offenders.

Non-persimmon phytobezoars have tannin monomers, which are polymerized in the stomach to form the necessary glue for bonding the vegetables. Another factor may be mechanical and dependent on the insoluble and indigestible fibre content. Although firm and compact when freshly removed phytobezoars tend to be friable and crumble early after drying. On section they are found to be composed of an amorphous gummy material interspersed with cellulose fibers and occasionally seeds and skin.

SITES

The most common site for bezoar formation is the stomach followed by the small intestine. Rarely, esophageal bezoars have also been reported.26

The trichobezoars may extend from the stomach to the small intestine or even the colon in continuity, this entity is known as Rapunzel syndrome.27 The name is driven from the name of a princess in a fairy tale who had very long hair, thus the trichobezoar with a tail extending into the intestinal lumen simulate very long hair. Recently, synchronous bezoars have also been reported in the stomach and the small intestine, one in stomach and the other either in jejunum or ileum.28,29

CLINICAL PRESENTATION

Trichobezoar are classically seen in an adolescent female with mental retardation who presents with alopecia and an upper abdominal mass which on moving can cause intermittent gastric outlet obstruction.45 In a comprehensive review of 303 cases up to 1938, about 80% of the cases were less than 30 years and more than 90% were females.30

The history of ingestion of hair or any material like plants, seeds or even plastic is important.

Most bezoars are generally asymptomatic but may present with bloating, vague upper gastrointestinal discomfort, malabsorption, and postprandial fullness. There may be appreciable loss of appetite, weight-loss, vomiting, loose stools, pancreatitis, pain abdomen, jaundice, anemia and hypoalbuminemia.5,31

When the size increases, symptoms due to mass effect like abdominal pain, compression or intestinal obstruction are produced. It often occurs in adolescent girls with psychiatric disorders.32 The patient may present with only a short history of mild abdominal pain despite having a trichobezoar weighting 700 g and measuring 24 × 16 × 10 cm.33 Complicated cases may present with Gastroenteritis, GI bleeding, intestinal obstruction, peritonitis or perforation chronic irritation of the gastric antral mucosa may also lead to formation of hyperplastic polyps.17,27

Early diagnosis and treatment is important to avoid later fatal complications such as gastric perforation and intestinal necrosis.34,35

A firm, nontender, freely mobile epigastric mass may be seen and palpated in uncomplicated cases. One may appreciate the crepitus on palpation. A rare case of sunflower-seed bezoar impacted at the anal verge has also been reported.11 It is not unusual for children to have rectal impactions with seeds of some fruits in some parts of the world. A per rectal palpation is essential to rule out this cause in children presenting with constipation.

INVESTIGATIONS

A plain abdominal skiagram may pick up a bezoar as a space occupying lesion. In cases presenting with small bowel obstruction, the erect abdominal film may
show multiple air-fluid levels. A barium swallow may delineate a filling defect in the stomach of the same shape, with partial penetration of the barium into the mass causing an irregular outline. Renal excretion of oral gastrografin has been seen on an abdominal film in a patient with incomplete intestinal obstruction due to multiple bezoars. Ultrasonography may depict an intraluminal mass presenting as an arc-like surface echo casting clear posterior acoustic shadow within the lumen of the dilated small bowel. Compression of the mass with a transducer may induce fluid shift around the mass. Ultrasound might thus suggest the diagnosis, though not confirm it.

CT scan of a trichobezoar occupying the entire lumen of the stomach may appear as a concentric inhomogeneous mass with entrapped air, surrounded by contrast material. A mottled appearance with variable proximal dilatation of the small bowel may be seen in cases with the bezoar confined to the small intestine. Beside conventional radiology and sonography, the diagnostic procedure of choice is endoscopy. On endoscopy, bezoars have an unmistakable irregular surface and may range in color from yellow-green to gray-black. An endoscopic biopsy that yields hair or plant material is diagnostic.

NON OPERATIVE TREATMENT

With-holding Feeding

Treatment of lactobezoars has been done by with-holding feeding for 24 hours. There was no recurrence of symptoms following resumption of feeding.

Dissolution with Enzymatic Digestion

Dissolution of the undigested bolus by ingestion of cellulase and proteolytic enzymes such as papain have been proved effective in the management of phytobezoars. 1.2 L of dissolved cellulase (0.5 g/dL water) can be given orally over 24 hours for 2 days. Parenteral Metoclopramide for several days may increase peristalsis by accelerating gastric emptying.

Complete dissolution of the gastric phytobezoar with cellulase was achieved in all 7 patients in a series with no side effects or recurrences during follow-up.

In a series of 36 patients with phytobezoars, Papain was successful in treating 87% (13 of 15) and cellulase in 100% (19 of 19) of the patients. Adverse effects reported in the papain group were gastric ulcer, esophageal perforation, and hypernatremia; the cellulase group did not report any adverse effects. Enzymatic dissolution is ineffective for large bezoars.

Suction and Lavage

A food bolus requires no treatment. A liquid diet, gastric suction and lavage may be beneficial. Gastric lavage with 1% sodium bicarbonate has also been reported.

Solution following partial gastroscopic bezoar crumbling.

The dissolution of large gastric phytobezoars with cola nasogastric lavage has been reported to be effective following failed attempt at endoscopic fragmentation and removal. Patients were treated with 3 liters of Cocacola nasogastric lavage over 12 hour period. Nasogastric lavage was very well tolerated and complete phytobezoar dissolution was achieved all cases without any procedure-related complications. With this safe, rapid and effective method, patients may be treated in the medical ward, avoiding therapeutic endoscopy or surgery. Serial water-soluble contrast enemas have been used in the treatment of sodium poly styrene sulfonate bezoars.

Endoscopic Retrieval

After the first gastroscopic removal of a bezoar by McKechnie in 1972, different endoscopic methods have been reported including a water jet, forceps, snare, and basket.

Saeed banding device has been used to remove food impaction in patients with eosinophilic esophagitis.

Mechanical endoscopic fragmentation of the bezoar followed by removal of residual bezoar in one or more sittings has been done. In a series using a modified needle-knife (bezotome) and a modified mechanical lithotriptor (bezotriptor), 18 bezoars up to 10 × 8 × 8 cm in size, were successfully fragmented and complete clearance was achieved with no complications. The disadvantages of gastroscopic removal include failure in huge and solid bezoars and risks of perforation and intestinal obstruction.
**Gastroscopy with Laparoscopically Assisted Fragmentation**

A two channel method using gastroscopy with laparoscopically assisted fragmentation for retrieval of large gastric bezoar has been reported.48

**ESWL Fragmentation**

Fragmentation with extracorporeal shock wave lithotripsy has also been described.49

**OPERATIVE REMOVAL**

**Gastrotomy**

Gastrotomy is the treatment of choice for trichobezoars. Endoscopic removal of trichobezoar usually fails and open surgery is required.4,5 The rocklike concretions usually require only surgical removal. Gastrotomy is done and all the contents are evacuated. The bezoar has the shape of the stomach, is foul smelling and has slimy surface. Trichobezoars have an unmistakable irregular surface and may range in color from yellow-green to gray-black and is coated with food particles. Phytobezoar is greenish brown in colour and lactobezoar is grayish white.

Vinyl glove bezoars require surgical removal as endoscopic removal is impossible because the gloves become hardened and matted.15 Surgical removal has also been required for polystyrene bezoar.16 Pathological and biochemical examination reveals the composition of the mass.

**Rapunzel Syndrome**

The diagnosis of Rapunzel syndrome is usually made during laparotomy when during extraction of the bezoar, the tail keeps coming from the pyloric end and may even be as long as 100 meters long. Surgical extraction is the therapy of choice in Rapunzel syndrome. It has been seen that endoscopic removal fails due to the large extension in these cases.

**Milking of Bezoars into Caecum**

Ileum is the most commonly reported site of obstruction in persimmon phytobezoars. At laparotomy, milking of the bezoars into caecum is successful in most of the cases.6

This treatment has also been recommended for total jungle banana obstruction.10 As recurrence and presentation at multiple sites are possible, all of the gastrointestinal tract should be thoroughly examined intraoperatively.10

**Enterotomy and Direct Extraction**

If milking of the contents beyond the ileocaecal junction in small bowel obstruction due to phytobezoars is not possible, enterotomy and direct extraction of the contents is done.6 Psychotherapy, behavior modification, and antipsychotic treatment are essential to prevent recurrence. Clomipramine may be of benefit in such cases.

**COMPLICATIONS**

Bezoars when present for a long time induce changes in the stomach and the intestine. In children, the most devastating effect is due to the space they occupy in the stomach. This causes malnutrition, repeated vomiting and bloating sensation. During childhood good nutrition is mandatory for health. Other common complications include ulceration, bleeding, obstruction, perforation, and so also the intussusception may also occur with small bezoars.4,20,50 Mortality rate may be as high as 30% in untreated cases, mainly due to gastrointestinal bleeding, obstruction or perforation.4 Multiple ulcers secondary to extensive pressure in the antrum were observed in a case with recurrent bezoar formation.32 A case intestinal obstruction associated with the superior mesenteric artery blocking the duodenum has also been reported.51

Fatal massive gastrointestinal bleeding from a large gastric ulcer caused by a vinyl glove bezoar while awaiting surgical consultation has been reported.15 The most common cause for mortality is gastric perforation. In cases with a history of trichophagia and signs of peritonitis, urgent surgical exploration is mandatory.

Complications can also occur during attempted removal. Copious pooling of fluid and solid food particulate was noted in the posterior oropharynx, interfering with immediate intubation and then bronchial aspiration have been reported in a boy during Endoscopic attempted removal of an esophageal bezoar.26
FOLLOW-UP

Treatment should also focus on prevention of recurrence, since elimination of the mass will not alter the conditions contributing to their formation.\(^5\)

Psychiatric follow-up is needed to prevent this complication in children with serious digestive antecedents and to reduce the risk of recurrences.\(^4\) A subsequent psychiatric consultation in a girl operated twice for trichobezoar at an interval of seven years revealed depressive personality disorder.\(^32\)

High-fiber diets are being recommended by government agencies, cancer institutes, and manufacturers of high-fiber foods. Patients who have undergone surgical procedures for peptic ulcer disease or stomach cancer or have a loss of normal pyloric function and decreased gastric acidity are prone to form phytobezoars. Such patients should avoid identified foods that lead to phytobezoar formation—oranges, persimmons, coconuts, berries, green beans, figs, apples, sauerkraut, brussels sprouts, and potato peel.\(^25\) The feeding habits of children should be supervised with adults and any abnormal feeding habit of swallowing non edible substances should be kept on a check.

REFERENCES

Helminthic infestation is widely prevalent in developing countries. Patients are usually malnourished, present with features of acute intestinal obstruction either due to massive infestation of the intestine by round worms or sometimes following inadequate anthelminthic therapy. These worms form a ball causing mechanical obstruction. Occasionally, this round worm mass could be palpated per abdomen. If it persists for a long period they can cause intestinal ischemia, perforation and peritonitis. Uncomplicated round worm obstruction can be treated conservatively, but if it becomes persistent or develops complication, a laparotomy is indicated.

**ETIOLOGY**

The infective stage of ascariasis lumbricoides is the mature larvae containing egg.\(^1\)\(^2\) It is broadly oval, has a thick shell with an outer mamillated covering, and measures approximately 40 × 60 mm eggs are passed in the faeces of infected individuals and mature in 5-10 days under favorable environmental conditions to become infective. Each female has a life span of 1-2 year and is capable of producing 200,000 eggs/24 hour.

**PATHOGENESIS**

After a human host ingests the eggs, larvae are released from the eggs and penetrate the intestinal wall before migrating to the lungs via the venous circulation. They then break through the pulmonary tissues into the alveolar spaces, ascend the bronchial tree and trachea, and are reswallowed. On their arrival in the small intestine, the larvae develop into mature adult worms. Males measure 15-25 cm × 3 mm, and females measure 25-35 cm × 4 mm.\(^2\) The pathogenesis of pulmonary ascariasis is not known, although a hypersensitivity phenomenon may be involved. Adult worms may cause gastrointestinal disease by obstructing the gut or biliary tree, or pancreatic duct or the appendix or goes to the peritoneum.

**CLINICAL MANIFESTATIONS**

No specific gastrointestinal symptoms occur in some patients, but the frequency is unknown. During the larval migratory phase, an acute transient pneumonitis (Loffler’s syndrome) associated with fever and marked eosinophilia may occur. Acute intestinal obstruction may develop in patients with heavy infections. Children are more prone to this complication because they have smaller diameters of the intestinal lumen and often have large numbers of worms. Worm migration can cause peritonitis, secondary to intestinal wall penetration, and common bile duct obstruction resulting in acute obstructive jaundice.\(^2\) The adult worms can be stimulated to migrate by stressful conditions (e.g. fever, illness, or anesthesia) and by some antihelminthic drugs. A. lumbricoides has been found in the appendiceal lumen in acute appendicitis, but a causal relationship is uncertain.

**Intestinal Ascariasis**

Ascaris induced intestinal obstruction is a frequent complication in children with heavy worm loads in endemic areas.\(^3\) It constitutes 5 to 35% of all cases of bowel obstruction in such regions. It is caused by an aggregated mass of worms blocking the bowel lumen especially in the terminal ileum. The obstruction is usually partial.
However, when prolonged, it can become complete. Prolonged obstruction may be complicated by intussusception, volvulus, hemorrhagic infarction of the bowel, and perforation.\(^1\)

The symptoms start with colicky abdominal pain, vomiting, and constipation. Vomiting of worms is a frequent occurrence and often gives a clue to the cause. Physical findings include abdominal distention, increased bowel sounds, and a characteristic lump, usually felt in the right lower quadrant.

Complicated obstruction is suspected when the child is febrile, is toxic, and has physical signs of peritonitis. Plain abdominal films reveal air-fluid levels and multiple linear images of ascaris in dilated bowel loops. Filling defects may be identified in contrast studies (Figs 60.1A and B). Ultrasonography of the abdomen can demonstrate dilated bowel with thickened wall and worm mass causing bowel obstruction. The worms are identified as curved echogenic structures, depicting active mobility on real-time scanner.\(^3\)

The echogenic structures may reveal central anchoic tube, representing digestive canal of the worm. Treatment is primarily conservative and includes adequate fluid and electrolyte replacement, nasogastric suction, specific antihelminitics therapy, and antibiotics. Gastrografin (Squibb; diatrizoate meglumine 66% and diatrizoatre sodium 10%) 15 to 30 ml introduced into the stomach through a nasogastric tube has been advocated for partial bowel obstruction.

Gastrografin is a hyperosmolar substance and causes excess fluid in the vicinity of and around the worm mass causing their separation. Laparotomy is indicated in the following situations: persistence of mass in the same site for more than 24 hours; persistent abdominal pain and tender mass; toxemia and rising pulse rate with disappearance of the mass.

The most common surgical procedure is to express and advance the parasite bundle manually toward the colon. If this maneuver is unsuccessful, worms can be delivered through enterotomy. Intestinal resection is warranted if the bowel shows evidence of gangrene or infarction (Figs 60.2A to D).

Prognosis is good if the patients present early or have partial bowel obstruction. However, often patients present late in their illness, with complicated obstruction and underlying malnutrition.

They tolerate surgical procedures poorly. Mortality rate is high in patients needing bowel resection for complicated obstruction.

**Appendicular Ascariasis**

In endemic areas with high parasite load, the moving adult worm may enter the appendicular lumen and reach its tip. As a result, acute appendicular colic and even gangrenous appendicitis may occur and the worms may reach the peritoneal cavity adjacent to the appendix. The diagnosis is usually made at laparotomy and management has been surgical.\(^4\) If the disease presents early, colonoscopic removal of the worms has also been described.

**Pancreatic Biliary Involvement**

Ascaris is an important cause of pancreatic biliary disease in countries with a high rate of infection. The magnitude of the problem can be judged by the fact that in endemic areas, ascariasis is equal to gallstones as a cause of biliary tract disease (37\% Vs 35\%). In another study, Ascaris was the cause of pancereatitis in 59 of 256 patients (23\%) compared with 112 subjects (44\%) with gallstone – induced pancreatitis.

Although diagnosed predominantly in tropical countries, roundworms are seen worldwide, including the United States. An increase awareness of pancreatic biliary Ascaris is important in view of the recent mass migration of people from endemic countries of the Far East and frequent travel to such countries. Despite the small lumen of the ampulla, roundworm invasion is not uncommon, perhaps because the duodenum and upper jejunum are the natural habitat of the parasite. From the ampulla, the worms migrate into the bile duct, gallbladder, and the intrahepatic biliary tree, resulting in biliary colic, pyogenic cholangitis, and hepatic abscess. Another mechanism of biliary obstruction is when fragments
of the adult worms serve as a nidus for gallstone formation. Ascaris-related biliary stones are usually of the pigment type, and are aided in their formation by factors such as bile stasis and ascending bacterial infection.

It is estimated that in endemic countries, ascaries ova or an immature worm is the cause of stone formation in 10 to 66% of patients. As in the biliary tree, presence of roundworms in the pancreatic ducts may cause acute pancreatitis or the calcified remnants of the worm may result in recurrent episodes of pancreatitis.

**Peritoneal Ascariasis**

Ascaris may enter the peritoneal cavity through a gangrenous bowel filled to the bursting point with ascarides or through a perforation caused by typhoid, amebic, or tubercular ulcer. In a small percentage, the worms may be seen wandering in the peritoneum with intact bowel. In either of these conditions, patients present with fatal peritonitis.

If patients survive, wandering peritoneal ascaris disintegrate, and a granulomatous reaction is elicited around the disintegrated worm and ascaris eggs. A chronic granulomatous peritonitis with adhesions simulating tubercular peritonitis occurs.3

**REFERENCES**

Hirschsprung’s disease has probably existed from antiquity. The earliest recognisable description was by Frederick Ruysch in 1691. He described a five year old child who had died and who had gross dilatation of the sigmoid colon at postmortem.

Other case reports of patients who had severe constipation and gross distension from the neonatal period were reported in the literature prior to Hirschsprung’s landmark description. In 1886, at a pediatric conference in Berlin, Hirschsprung describes the course of two male infants who had died aged 7 and 11 months of age respectively. Autopsies had shown marked dilatation and hypertrophy of the colon with no apparent obstruction distally.

Further reports followed and by 1908 Finney had collected 206 cases from the literature. At that stage the disease was known as Hirschsprung’s disease. Various theories regarding the aetiology were proposed but none found lasting acceptance. Most attention was paid to the megacolon which attained a size and thickness rarely seen by present day surgeons. A colonic diameter of greater than 15 cm with a wall thickness of 3 cm has been described. In the absence of a visible obstruction and given the normal appearance of the distal bowel, the physicians of the day were unable to explain the condition.

A disorder of neuromuscular function was considered a likely cause of the condition. In 1908, Finney was aware of suggestions that the intramural plexuses were absent in Hirschsprung’s disease. He was unable to find any literature on the subject. When such evidence did arrive in the form of two papers from Dalla Valle the surgical world seemed unaware.

Dalla Valle described the autopsy features of two brothers who had died of Hirschsprung’s disease. He documented the absence of ganglion cells in the distal normal calibre colon.

These findings were confirmed in a further two cases by Cameron in 1928. However, the cause of Hirschsprung’s disease remained controversial until 1948 when Whitehouse and Kernohan from the Mayo Clinic described aganglionosis in 11 patients with Hirschsprung’s disease. In the same year Zuelzer and Wilson reported similar findings in a further 11 patients. It is notable that, of these 22 patients, only three were alive at the time of writing.

In Zuelzer and Wilson’s paper there are a few other notable features. Five of their patients belonged to one family. In two children with colostomies, studies on the distal bowel showed an absence of peristalsis. Finally, one of their children became unwell, collapsed and died within an hour in a manner which might in retrospect be attributed to the enterocolitis of Hirschsprung’s disease.

Finally, in 1949, Bodian et al confirmed that the aganglionic segment extended to and included the rectum.

In the absence of a defined aetiology treatment was unsatisfactory. Nonoperative treatment was shown to be unsatisfactory. In Finney’s review he noted that two thirds of those treated with medication subsequently died. The comparable surgical mortality was 48%. Colostomy was often followed by return of normal health but symptoms returned with stoma closure. Excision of dilated bowel with anastomosis was followed by a return of symptoms.

Somewhat better results were achieved by colectomy and ileorectal anastomosis but there are no
follow up details. Similarly, sympathectomy was employed to produce colonic relaxation and some success was reported. No follow up is provided and the lack of subsequent reports suggests that failure was the rule.

All changed in 1948 when Swenson and Bill from the Children’s Hospital in Boston produced the first report of a successful treatment for Hirschsprung’s disease. In this report the authors undertook rectosigmoidectomy to remove the ‘spastic’ portion of the bowel in three patients and had good results. The second report noted that 23 patients had now undergone surgery. The extent of resection was determined by the appearance of the bowel on a barium enema. At this time the authors seemed unaware of the histological features of Hirschsprung’s disease.

The following year a further report from Dr Swenson noted the absence of peristalsis in the affected bowel and suggested that aganglionosis was responsible for the clinical features of Hirschsprung’s disease.

By 1955 the importance of rectal biopsy as an aid to diagnosis was understood. This last refinement ushered in the modern era of management of this disorder. All variations in biopsy technique, laboratory diagnosis and surgical management are based on the original descriptions of aganglionosis and rectosigmoidectomy.

ETIOLOGY AND PATHOGENESIS

The etiology of Hirschsprung’s disease is unknown. It is clear that enteric ganglion cells migrate from the neural crest, along the course of the vagus nerves, to the intestine. In the human fetus the rectum is innervated by the twelfth week of gestation. The passive migration and neuronal differentiation appears to depend on the intercellular matrix.

The conventional theory to explain the presence of an aganglionic segment in Hirschsprung’s disease is that migration was incomplete. Failure of ganglion cell precursors to differentiate and mature would result in similar findings. The distal aganglionic bowel remains tonically contracted and does not exhibit normal peristalsis. The reason for the increased muscle tone is not clear. Study of the aganglionic bowel shows abnormalities of neuropeptides and reduced levels of nitric oxide synthase in the enteric nervous system.

A number of the ganglion cells are part of an inhibitory system of neurones that facilitate intestinal relaxation. Their absence probably accounts for the tonic contraction that results.

MOLECULAR GENETICS

At present two genes have been implicated in strongly increasing the susceptibility to Hirschsprung’s disease, and doubtless others will come to light in the near future. Mutations of the RET proto-oncogene have been intensively studied. This gene has been located to the long arm of chromosome -10q11.2. The RET gene encodes a tyrosine kinase trans-membrane receptor whose ligand is a neurotrophic factor. The manner in which the gene abnormality contributes to aganglionosis is unclear. Mutations of the RET proto-oncogene have been found in 50% of those with familial Hirschsprung’s disease but were not related to the length of the aganglionic segment. In sporadic Hirschsprung’s disease mutations of this gene are found in 10-30% of patients.

The second gene which has been implicated is termed the endothelin-B receptor gene (EDNRB). This gene has been localised to chromosome 13q22. Mutations of this gene carry a risk of Hirschsprung’s disease in heterozygotes and homozygotes together with sex dependent variable penetrance. In homozygotes the risk of Hirschsprung’s disease was 74% compared to 21% in heterozygotes.

Apart from the genetic factors affecting the growth and development of the enteric nervous system, the role of the intercellular matrix has also received attention. Deficiency in the microenvironment may inhibit or prevent migration of neural cells in the distal intestine.

At present there is no unifying concept to explain how these factors interact to produce the clinical picture of Hirschsprung’s disease.

INCIDENCE

The incidence of Hirschsprung’s disease is 1 in 4,500 to 1 in 5,000. The male/female ratio is about 4 to 1 overall, but this disparity diminishes to 1.5 to 2:1 with total colonic disease.
The pattern of inheritance is unclear but with longer segment disease (beyond the sigmoid colon) inheritance is compatible with a dominant gene with incomplete penetrance. In studies of RET gene mutation, similar mutations showed greater penetrance in males than in females and resulted in differing lengths of aganglionic bowel within the same family. The risk to siblings also varies. For disease confined to the distal half of the large bowel the risk for a male sibling is 5%, regardless of the sex of the index case. The risk to a female sibling is 1% if the index case is male and 3% if the index case is female. For longer segment disease (proximal colon with or without small bowel) an affected male results in risks of 17 and 13% to future male and female siblings respectively. For longer segment disease, when the index case is female, the risk is 33% for a subsequent male sibling and 9% for a subsequent female sibling. Finally, in a single hospital review from Boston, a definite history of Hirschsprung’s disease was reported in 5% of patient’s families.

For offspring of affected patients the exact risk is not clear but is raised above that of the general population. Parker et al considered that those with short segment disease had perhaps a 2% risk of having affected children, with a higher risk for those with long segment disease.

ASSOCIATED ANOMALIES

The literature suggests that a substantial number of these children will have other abnormalities. In a birth cohort of about 700,000 infants in British Columbia, Spouge and Bard found other anomalies in almost 30% of infants with Hirschsprung’s disease. These included urological anomalies (2.2%), anorectal malformations and colonic atresia (4.5%), small bowel atresia (1%), deafness (2.2%) and cardiovascular anomalies (5.6%). Also included was Down’s syndrome (2.8%).

A more recent review from Denmark showed that 5% of patients with Hirschsprung’s disease had Down’s syndrome. The Boston review showed a higher proportion of patients with Down’s syndrome (8%) and an overall incidence of 22% for associated anomalies in these children. This figure is in keeping with other reports in the literature. It is clear therefore that a systematic effort should be undertaken to establish the presence or absence of other anomalies in these children.

The recognition of other GI anomalies such as pyloric stenosis and small bowel atresia (both about 1%) may be delayed by the presence of Hirschsprung’s disease. Similarly, the recognition of Hirschsprung’s disease may be delayed by prior treatment of these problems.

There is also an association with other disorders of the neural crest. These are sometimes referred to as neurocristopathies. These have received detailed attention because of the possible insight that might be provided into the molecular basis for Hirschsprung’s disease. Included in this group of conditions are Ondine’s Curse (congenital central hypoventilation syndrome), Waardenburgh’s syndrome (sensori neural deafness and disorders of pigmentation), multiple endocrine neoplasia (MEN2A) and familial medullary thyroid carcinoma. MEN2A includes medullary thyroid cancer, hyperparathyroidism and phaeochromocytoma. Association of all these conditions with Hirschsprung’s disease have been recorded. The association of Ondine’s Curse appears to be ominous in terms of survival.

The link with Waardenburgh’s syndrome has been clear for over 20 years and has recently been attributed to mutation in the gene encoding endothelin 3. Mutations in the RET proto-oncogene are known to account for all MEN2 variants and these mutations occur at sites known to be linked with Hirschsprung’s disease. A link with neuroblastoma and ganglio-neuroblastoma has also been established but the mechanism is not understood.

Patients with two or more neural crest abnormalities are rare. The author has not encountered Hirschsprung’s disease in over 200 children with neuroblastoma, nor indeed any of the other neurocristopathies in over 150 patients with Hirschsprung’s disease.

PATHOLOGY

An absence of ganglion cells in the intermuscular (Auerbach’s) and submucosal (Meissner’s) plexuses is
the hallmark of Hirschsprung’s disease. In association with this feature, thickened nerve trunks are seen in the intermuscular plane and in the submucosa.

The length of the aganglionic segment varies. Two large multicentre reviews from the United States and Japan show that disease confined to the rectum, with or without the sigmoid colon, constitutes 75-80% of the total.\textsuperscript{50,51} In a further 7-15% the left colon and splenic flexure are involved and about 8% have total colonic aganglionosis. A small number of this group of children have extensive or even total small bowel aganglionosis.

The standard histological technique for examining tissue is by hematoxylin and eosin staining of formalin fixed tissue. Reliable diagnoses can be produced by pathologists who have sufficient interest and experience. Diagnosis is reliable even on very small biopsy specimens. An added refinement is to have accurate intraoperative results based on frozen section histology. However, such expertise is not present in all hospitals and surgeons, of necessity, have to adapt their approach to make the best use of local facilities.

Acetylcholinesterase (AChE) staining is also popular but not universally available.\textsuperscript{52} Meier-Ruge considers this histochemical technique to be more reliable and easier to use in practice.\textsuperscript{53} This histochemical stain shows the absence of ganglion cells and heavy staining of coarse nerve fibres in the bowel wall, including the muscularis mucosae and lamina propria. The heaviest staining of nerve fibres is in the distal bowel, with fewer nerves being seen more proximally. Lake et al from Great Ormond Street reported no false positive or false negative diagnoses in dealing with 458 suction rectal biopsies.\textsuperscript{55} They considered that acetylcholinesterase histochemistry provided the most reliable means of diagnosing Hirschsprung’s disease.

Others have reported less encouraging results with a 29% false negative rate.\textsuperscript{56} For the present, in most centres, hematoxylin and eosin staining may be the most practical means of diagnosis.

The junction between ganglionic and aganglionic bowel is called the transition zone and usually corresponds to the area of tapering or coning between dilated and non-dilated bowel seen on X-ray or at laparotomy. With long segment disease however, false cones are known to occur so the gross appearance is not a reliable guide to the presence or absence of ganglion cells.

Histologically the transition zone is considered to show reduced numbers of ganglion cells and an increase in nerve fibres. The length of the transition zone varies from a few millimetres to many centimetres. The level at which ganglion cells terminate in Auerbach’s and Meissner’s plexuses are similar at each point in the circumference.\textsuperscript{57} Gross irregularities of the associated nerve fibres are also seen in the transitional zone with increasing abnormality and thickening of the extrinsic nerves towards the distal aganglionic bowel.\textsuperscript{58} It is also clear that the ganglion cells are not evenly distributed around the circumference of the bowel. At different points of the circumference the bowel may be ganglionic or aganglionic.\textsuperscript{57,59} At this hospital we have seen many children who have transitional zone changes extending over long lengths of colon.

**CLINICAL PRESENTATION**

About 94-98% of normal full term newborn infants will pass meconium within the first 24 hours of life.\textsuperscript{60,61} It is exceptional for a normal baby not to have opened its bowels by 48 hours. A history of delayed passing of meconium is considered a common feature of Hirschsprung’s disease. At least 40% of my own patients with Hirschsprung’s disease had passed meconium within the first 24 hours of life. A failure to pass meconium in this time is not a reliable indicator on its own.

The presence of abdominal distension is usual unless the baby has had a rectal examination or rectal washout. Bilious vomiting and poor feeding are also common.

The majority of infants who present within the neonatal period have signs of low intestinal obstruction—distension, bilious vomiting and little or no passage of stool.

Examination will reveal generalised distension, active bowel sounds and a narrow empty rectum on rectal examination. Withdrawal of the finger may be followed by passage of gas and meconium.

Plain abdominal X-ray will show many loops of distended gas filled bowel with typically, an absence of gas in the rectum (Fig. 61.1). The differential diagnosis will include causes of low intestinal obstruction in addition to Hirschsprung’s disease such as intestinal atresia, meconium ileus, small left colon and meconium plug syndromes.\textsuperscript{62,63}
The second type of acute presentation is with enterocolitis. Hirschsprung’s two index patients died after a diarrhoeal illness associated with mucosal ulceration. Bill and Chapman wrote the first clear description of Hirschsprung’s enterocolitis. They described a syndrome of fever, distension and explosive diarrhea, progressing rapidly in some patients to hypovolemia and death. The mortality at that time was 32%. They related the occurrence of enterocolitis to mechanical obstruction and recommended decompression. X-rays show gross distension with thickened bowel wall (Fig. 61.2).

There is now an extensive and contradictory literature on the subject. The etiology remains obscure. Some have noted a relationship to the presence of Clostridium difficile and its toxins in the stool to the development of enterocolitis. Others have not confirmed this. Our own figures suggest an increased risk with Down’s syndrome, female gender and a family history of Hirschsprung’s disease. Diagnosis within the first week of life appears to lessen the risk of enterocolitis. Bill and Chapman noted that enterocolitis tends to recur and this has been confirmed by Elhalaby et al, who noted a mean number of 2.2 episodes in those who developed this complication.

The third and least common acute mode of presentation is with intestinal perforation. The risk of perforation is higher with total colonic disease and in these children, the perforation is usually in the aganglionic bowel. With short segment disease, the perforation is proximal to the aganglionic zone.

In older infants and children the history is of long standing constipation and distension, sometimes associated with failure to thrive. The clinical picture of massive abdominal distension and marasmus that was frequently seen 60 years ago, is not often encountered today. These children would have been managed with a combination of laxatives, suppositories and enemas but with only partial success.

Thus far I have not personally encountered a child who was entirely asymptomatic for the first 12 months of life. Such patients have been described but this must be quite rare. I have encountered one patient with total colonic aganglionosis who was entirely asymptomatic for the first four months of life and this is the longest period of lack of symptoms I have encountered in a child with Hirschsprung’s disease. It is not clear why children with similar lengths of aganglionic bowel have such differing clinical presentations.

**INITIAL MANAGEMENT**

The management for those presenting with neonatal intestinal obstruction is the same as for any other form of obstruction—intravenous fluids, nasogastric
decompression and consideration of antibiotics. If rectal examination produces gas and meconium then causes of complete mechanical obstruction, such as atresia, have been out-ruled. If no gas or meconium are produced after rectal examination then a single rectal washout with saline is performed. The aim is to establish if there is gas in the distal intestine to narrow the range of differential diagnoses. If there is no gas after the washout, a contrast enema is performed. This will show the colonic anatomy, may demonstrate the presence of a meconium plug or a small left colon, and if the contrast reaches gas filled intestine then intestinal continuity is confirmed. It is usual for children with Hirschsprung’s disease to pass large amount of gas and meconium after a washout or a contrast enema and the infant’s clinical condition will then improve.

If the presentation is with enterocolitis then urgent decompression is necessary. A rectal examination and rectal washouts are employed and are usually successful. Failure to decompress under these circumstances will indicate a need for surgery. If decompression is successful then surgery should be deferred until a time of greater physiological stability. All these children should receive oral Vancomycin as well as broad spectrum intravenous cover.

For those infants and children presenting with a history of constipation, the need for urgent investigation is less pressing. Recourse to enemas and washouts will alter the appearance of the bowel on a contrast enema. This is perhaps less relevant a concern at the present time than was previously the case when diagnosis was predominantly based on the enema appearance.

**DIAGNOSIS**

There is no substitute for a tissue diagnosis. Reliance on contrast enemas or manometry is less secure and less accurate.

Rectal suction biopsy has been proved satisfactory and reliable in the hands of expert pathologists.\textsuperscript{70} All surgeons do not have access to such expertise and may need to provide larger or full thickness biopsies.\textsuperscript{16} Regardless of the method used, the biopsies should be taken from the posterior rectal wall, at least 25 mm above the dentate line. The bowel below this level is hypoganglionic and the failure to see ganglion cells may not be pathological.\textsuperscript{71}

Various methods of obtaining biopsies have been described. Suction biopsy instruments are widely used in young infants but we have found the use of punch biopsy forceps to be preferable in older children.\textsuperscript{72,73} Inevitably, rectal biopsy is followed by a small but inevitable number of complications which include bleeding, perforation and occasional fatality.\textsuperscript{74}

The use of anorectal manometry has largely been confined to specialist centres. This technique assesses the relaxation of the internal anal sphincter in response to rectal distension. A failure of the sphincter to relax, or indeed an increase in tone, is a feature of Hirschsprung’s disease.\textsuperscript{75} Although the instrumentation and technique are straightforward, the method has not found widespread use. In some centres manometry is used as a screening test to more clearly define those who need to undergo biopsy.

Contrast enemas are widely used, both to make the diagnosis and to establish the position of the transition zone. Not infrequently contrast enemas are requested in the presence of intestinal obstruction in newborns to more clearly define large bowel anatomy. Subsequent to the enema marked decompression may be achieved and the infant’s condition improved.

When specifically looking for Hirschsprung’s disease the recommendation is to use 50% dilute barium sulphate. The fluid is injected slowly and the least possible amount of contrast is used.\textsuperscript{40,76} The irregular contracted rectum and distal sigmoid colon with a transition cone into dilate proximal bowel will be seen. With standard length Hirschsprung’s disease the contrast enema appearance will usually correspond with the histological findings. With long segment or total colonic disease the appearance on the enema may not be reliable and false cones are known to occur.

A delayed X-ray film taken at 24-48 hours may demonstrate retention of contrast, lending support to a diagnosis of Hirschsprung’s disease (Fig. 61.3).\textsuperscript{76} Little has changed in the radiological diagnosis of Hirschsprung’s disease since Hope et al in 1965 suggested that the cardinal features included a transition cone, irregular bizarre contractions of the aganglionic zone and barium retention.\textsuperscript{76} However, the reliability of barium enema in this context is questionable. The experience of Smith and Cass is fairly typical—in a series of 24 infants, mostly neonates, the false negative rate for barium enema was 24%.\textsuperscript{76} In addition the error rate was 53% in judging
the position of the transition zone. Others have reported substantial - up to 43% - false positive rates of diagnosing Hirschsprung’s disease by barium enema in infancy.78,79

In this hospital we no longer utilise barium enema when Hirschsprung’s disease is suspected. The diagnosis is made only by rectal biopsy and the level of transition is made on the basis of operative frozen section biopsy.

**TREATMENT**

Once the diagnosis has been established there are many options for treatment. The first decision is whether or not to bring out a stoma. Many infants can be managed for a period of weeks or months by means of daily saline rectal washouts. However, a proportion of children will not achieve satisfactory decompression by this means. Some of these children will have extensive disease but in some with standard length Hirschsprung’s cannot be managed in this way. Equally, some families cannot tolerate this type of intervention. Whatever the circumstances, if washouts are unsatisfactory then a stoma will be necessary.

The next consideration is where to site the stoma. For many years in this hospital the approach to Hirschsprung’s disease was a three stage reconstruction—right transverse colostomy, pull-through at 6-9 months of age and colostomy closure some weeks later. Others have used a two stage procedure—fashioning the stoma above the transition zone and then using the stoma as the apex of the pull-through. It is clear however that in many, a single stage reconstruction is safe and effective.

A multiplicity of procedures is available, some of which may be performed laparoscopically. Regardless of the method used the aim is to relieve symptoms and achieve optimal bowel control with a minimum of complications.

The decision to perform a single or multi stage procedure should be based on local facilities and expertise. It will also depend on the characteristics of the patient population. If delayed presentation is a feature of the local population then primary pull-through of very dilated bowel may be inadvisable.

Single stage procedures can only be accomplished if reliable frozen section histology is available. Incorrect information from intraoperative frozen sections will result in abnormal bowel being pulled through or normal bowel being discarded. This concern is not purely theoretical and it seems likely that only laboratories dealing with large numbers of such biopsies will be able to produce acceptable results.80

In the absence of such expertise, biopsies taken at the time of stoma formation may be examined prior to the definitive procedure.

In attempting to define the length of the aganglionic bowel, biopsies may be sent from the apex of the sigmoid colon, distal descending colon, splenic or hepatic flexures and appendix of terminal ileum. Given the unpredictable anatomy of the transition zone it is unwise to take biopsies closer than at these intervals. In addition, each of these sites can be brought to the anus.

Three pull-through operations and their variants are in common use throughout the world and will be described here. These are the Swenson, Duhamel and Soave procedures.13,81-84 All are modified from the original descriptions but in each case the original concept is valid.

The Rehbein State and endorectal transanal pull-throughs are not described here.85-87 These operations have not gained widespread acceptance and, to this author at least, the concept in each case is unsound.

When performed by open operation the initial approach is similar for each operation. The patient is placed in semi-lithotomy position and a bladder

---

**Fig. 61.3:** Longitudinal section of rectum showing triangle of posterior rectal wall and opposing anterior wall of ileum to be excised with GIA stapler
catheter is inserted. Various incisions are used but it is essential to be in a position to dissect deep in the pelvis and this can only be achieved if the incision is close to the symphysis. A lower mid line incision is the most adaptable. The site chosen for the pull-through is chosen on the basis of histological evaluation either by frozen section or standard formalin-fixed tissue histology.

There are three phases to each of the operations—a colonic, rectal and anal phase. The colonic phase consists of mobilising the sigmoid and descending colon up to and including the splenic flexure. The meso-colic vessels are then divided in order to allow the site of the proposed pull-through to extend at least 7cm over the symphysis. Great care is necessary to achieve the required bowel length with an adequate blood supply. Once the proximal bowel has been prepared for the pull-through, attention is turned to the rectal phase of the operation.

In each case the use of a fixed table mounted retractor is of great value at this phase of the procedure. The Swenson operation entails dissection of the rectum from its attachments in a plane on the rectal muscle wall. Although many advocate commencing this phase with ligation of the inferior mesenteric vessels, this is unnecessary. The dissection may be commenced on the wall of the distal sigmoid or upper rectum. The use of fine right angled artery forceps and bipolar diathermy makes this a rapid and relatively trouble free dissection. It was an extremely tedious dissection when the vessels required individual ligation. Bipolar diathermy is satisfactory for all but larger adolescents.

The dissection advances distally, dissecting the full circumference of the rectum. Deep in the pelvis it is important to remain close to the rectum on its anterior aspect. When the dissection has reached to within 2 cm of the dentate line anteriorly and 1 cm posteriorly this phase is complete. The distal extent of the dissection is judged by inserting a finger in the anus. At this stage the bowel is divided at the level chosen for the pull-through and the two ends sutured closed.

The anal phase of the dissection then commences. The apex of the dissected rectum is drawn out through the anus, evertting the rectum. If the dissection has been adequate the anus may be partially everted. An incision is made from 9 to 3 o’clock anteriorly through the rectal wall, 1-2 cm above the dentate line. Only the bottom of the dentate line can be identified with any certainty and this is the point from where measurements are made.

Through this opening in the rectum the ganglionic colon is pull through with care to avoid torsion. The colon is opened at its apex and sutured full thickness to the cut edge of anorectum with interrupted absorbable 4/0 sutures.

The incision of the rectum is then completed in stages, as is the anastomosis.

Posteriorly in the 6 o’clock position the suture line should be about 1 cm from the dentate line. The rectum is now free and should be sent for histological examination.

The commencement of the Duhamel procedure is identical. The early phase of rectal dissection is also the same. The dissection proceeds circumperipherally until within 3-4 cm of the dentate line. This level is well below the pelvic peritoneum.

The anal phase then commences. It is best to partially evert the anus for this phase. This is easily accomplished by using tissue forceps at the 3 and 9 o’clock positions. An incision is then made along the dentate line from 4 to 8 o’clock and a retrorectal tunnel developed initially with scissors and then with a long clamp. This tunnel should quickly reach the level of the abdominal dissection. The tunnel is then widened to accommodate the pull-through bowel.

The previously divided and sutured bowel is then pulled through with care to avoid torsion. The open end is sutured to the anal incision with interrupted absorbable 4/0 sutures. Finally, the double wall between rectum and colon is stapled and divided with a linear stapler. Alternatively, a crushing clamp can be left attached.

Within the abdomen the rectum is transected a few millimetres beyond the apex of the staple line. The open end of rectum is then closed with a running extramucosal 4/0 suture. As this suturing takes place deep in the pelvis great care is necessary to ensure accurate placement of the sutures.

The early stages of an endorectal pull-through are as outlined above. There is no phase of perirectal dissection however. The tendency is to commence the endorectal resection as low as is convenient. This usually occurs close to the peritoneum of the pelvic floor. Infiltration of fluid into the submucosa is often mentioned as an aid to dissection. In practice it seems to obscure the anatomy and is probably rarely performed.
At the level chosen the muscle coat is divided with scissors circumferentially to enter the submucosal plane. This plane is then dissected with gauze pledgets or with artery forceps. The dissection is easier in young infants. The submucosal dissection progresses to a level about 1 cm above the dentate line and the mucosal tube is then everted.

Some surgeons opt to perform the distal part of the anorectal resection from below, but it may be difficult in practice to have the rectal and anal planes of dissection coincide.

Once the dissection has been completed the mucosal tube is divided 1-2 cm above the dentate line and the ganglionic bowel is pulled through and sutured at this level. There seems little reason to perform the original Soave operation which left the pull through bowel outside the anus and most now perform the Boley modification.88

The catheter is usually removed after 24 hours and enteral feeding resumed once intestinal function is established.

When these operations have been performed as single stage procedures, an EUA performed 2-3 weeks after operation is recommended. This allows assessment of healing and of any tendency to stenosis or septum formation.

In the presence of a defunctioning stoma a contrast study should be performed after two weeks. If the appearances are satisfactory the stoma may then be closed.

**Management of Patients with Total Colonic Aganglionosis**

Total colonic aganglionosis, with or without small bowel involvement is reported in 7-8% of children with Hirschsprung’s disease in large series.50,51 The author’s own incidence is 14%.89

Presentation is similar to other children with Hirschsprung’s disease but there is an impression that many infants with total colonic disease have delayed onset of symptoms. As noted above, one of my own patients was entirely symptom free for the first four months of life while being breast fed.

On occasion the clinical features may be indistinguishable from meconium ileus or necrotising enterocolitis.90,91 Perforation when it occurs in these infants is usually in the aganglionic bowel.69,89,91 Only an awareness of the possibility will lead to a timely diagnosis. The author’s experience suggests that recognition of total colonic disease is frequently delayed and several ineffective operations may be performed as a result. In common with others we have found that a short rectal pouch, as for recto sigmoid disease, is preferable to the long side to side Martin modification.89,92,93

Neither have we attempted single stage procedures in these children. They have very loose stools initially and are more easily managed with an ileostomy. Otherwise, severe and distressing perianal excoriation may result.

Mortality in this group of patients has diminished markedly. Between 1978 and 1982 the mortality in our patients was 30%. In the years 1980-1996 this figure had dropped to 6%.89,91 The improvement in survival is related to improved central venous catheters for intravenous feeding, the use of loperamide to prolong bowel transit and routine monitoring of urinary sodium. The last of these we have found to be of great benefit.91 On spot urines, the urinary sodium should be greater than 10 mmols/L. Twenty four hour collection of urine allows more accurate estimation of sodium balance but in practical terms repeated spot checks are entirely satisfactory.94

For infants with total or near total intestinal aganglionosis we are not clear that there is a surgical solution. Others have reported extended myotomy/myectomy under these circumstances combined with a stoma. Ziegler et al reported on a heterogenous group of 16 patients with very extensive disease.95 They were treated in eight different centres. Twelve had 10 cm or less of ganglionic intestine and the remainder had up to 40 cm of small bowel.

Of 10 survivors, two were on full enteral feeds, both of whom had less than 10 cm of ganglionic intestine. It was not clear whether a simple myotomy was more or less affective than a myectomy. The evidence therefore is that in desperate circumstances this may be an option worth trying. The variability of presentation with Hirschsprung’s disease and the unpredictable nature of severe short bowel make it difficult to make informed decisions under these circumstances. Nixon noted that he had one patient who had 19 cm of jejunum who had undergone a standard Duhamel procedure and who had survived into adult life prior to the advent of home intravenous feeding.96
EARLY COMPLICATIONS

Surgery for Hirschsprung’s disease is associated with all the usual complications that may follow major intestinal surgery. In a review of major series, Fonkalsrud suggested that postoperative bleeding is uncommon (less than 2%). Wound infection was reported in about 7% but this was probably an underestimate, as most infections present after discharge from hospital. Other wound complications such as dehiscence also occur but are relatively uncommon.

Procedure specific complications such as leakage have received considerable attention. If there are systemic signs of leakage after a single stage pull-through, a proximal defunctioning stoma should be fashioned and left in place for about three months. This is sufficient time for healing to occur. The incidence of leakage varies widely in different series. Swenson et al reviewing 483 patients, reported anastomotic leakage in 5%. Subsequently, 6.2% of patients had an anastomotic stricture. The early mortality was 3.3%.

Leakage after a Duhamel procedure is unusual. A radiological leak was seen in two of my own patients from the apex of the rectal pouch—a rate of 1.3%. Reviewing the experience in Indianapolis, Engum and Grosfeld reported one enterocutaneous fistula in 235 children after a Duhamel operation. Formation of a faecal bolus in the neorectum was reported in 11%. There were no operative deaths in this series.

Complications specific to the endorectal procedure and its modifications include cuff abscesses and anastomotic strictures. Cuff abscesses seem to be relatively uncommon. Polley et al reported a 2% incidence of cuff abscesses in their patients. Langer et al reported that almost 50% of their patients undergoing endorectal pull-through required subsequent dilatation.

Reviewing a personal series of 57 patients, Wright and Cord Udy reported similar rates of complication - 5 and 43% for cuff abscess and the need for dilatation. The mortality in this latter series was 3%.

It is clear that staged reconstruction is associated with an incidence of stoma related problems. However, it seems that in terms of early complications, primary pull-through is as safe as a staged procedure even in the newborn.

LONG-TERM COMPLICATIONS

The difference in outcome between published series is so great as to make one doubt that the same condition is being treated. A significant paper in this regard was published by Mishalany and Woolley in 1987. They studied a group of 62 patients who had agreed to attend up to 30 years after surgery. In this selected group of patients, three were totally incontinent (4.8%) and half the patients has varying degrees of fecal incontinence. The end result in terms of continence did not seem to be related to the type of pull-through performed.

It is difficult to reconcile this figure with, for example, Swenson’s own series which quoted 90% of patients with a normal bowel habit and 3.5% of patients who had soiling. Swenson further noted that no patient followed for more than 11 years had permanent soiling.

Others have reported similarly encouraging results in terms of bowel control. Polley reported 0% incontinence amongst 67 patients over three years of age. Sixteen of these patients had long segment or total colonic disease.

Rescorla et al noted that patient satisfaction improved with increased length of follow-up—from 58% being very satisfied at five years to 88% at 15 years. Whether this reflects improved functioning or improved acceptance is unclear but this feature has been noted in many series. Probably both factors are of importance. Rescorla et al further mentioned that up to 9% of patients had episodes of soiling at 5-10 years follow up but those followed for 15-20 years had no soiling. A more recent review from the same centre noted that at 15 years follow-up, 28% had constipation. Clearly therefore a number of patients have unsatisfactory bowel habits after surgery and these problems are, almost certainly, under-reported. From Melbourne Catto-Smith et al reported on a group of 60 patients with Hirschsprung’s disease, 8.9 years after reconstructive surgery. This was a study based on questionnaires, personal diaries and structured interviews and was not performed by the operating surgeons. Almost all had undergone an endorectal pull-through. Just over 50% had significant soiling. In great distinction to other reports, there was little tendency to improve with age.
Conversely, in a retrospective review, Yanchar and Soucy reported that in those under 15 years of age continence was poor in 50% but this figure had dropped to 8% over the age of 15 years.107 The exact number who had symptoms of constipation with a need for medical treatment is unclear although many series report substantial numbers of patients who required sphincterotomy. Figures vary widely from 9 to 29%.104,105 Presumably these children were the more severely affected. There is therefore evidence of seriously disordered bowel function in substantial numbers of children after surgery for Hirschsprung’s disease. These facts need to be understood by the family before embarking on treatment.

Management of Major Complications

Recurrent enterocolitis is usually associated with persisting obstruction. This may be the result of an anastomosis which is too proximal or abnormal innervation of the pull-through bowel. The treatment for this complication, as well as for intractable strictures and fistulae, is a repeat pull-through.

My own experience is that sphincterotomy is usually unhelpful—in the words of one parent ‘an operation usually followed by another operation’. This author would agree with Swenson et al and Wright and Cord-Udy that the results of sphincterotomy are disappointing.98,99 It is not clear to me that this operation has any part to play in the management of persisting constipation or recurrent enterocolitis in these patients.

Several patients from elsewhere have been encountered when sphincterotomy was performed through a posterior sagittal approach. All developed fistulae and none were relieved of their symptoms.

In those whose symptoms are not controlled by simple measures, a three stage approach is recommended—ileostomy, pull-through and later stoma closure. The results of this approach have been fairly satisfactory. The most satisfactory results were achieved when surgery was undertaken for structural/anatomical problems.108 The results from these patients were comparable to those expected after a first pull-through.

In a few patients, surgery was undertaken because of persisting incontinence after initial pull-through. No improvement was achieved in these patients and this is no longer regarded a valid indication for surgery.

Coran and colleagues from Ann Arbor have reported similarly encouraging results after repeat pull-through.109

It is not clear that aganglionosis ever recurs. West, Grosfeld et al have reported on five children with what they considered to be acquired aganglionosis.110 Reviewing the literature, they considered that ischemia was the etiology behind the disappearance of the ganglion cells. In discussion on this paper, Molenaar noted that experimentally, ganglion cells were resistant to ischemia. Others have never encountered recurrent Hirschsprung’s disease despite seeing substantial numbers of such patients (Mahour in discussion of the same paper). It is not clear that full circumferential examination of the apex of the pull-through bowel was undertaken in these children and an alternative explanation is that of a transitional zone pull-through.59 Similarly, a long transitional zone with irregular distribution of ganglion cells may be responsible for some of what are termed ‘skip lesions’.

ULTRASHORT SEGMENT
HIRSCHSPRUNG’S DISEASE

This is usually defined as a condition when manometry shows a Hirschsprung’s trace in the presence of normal histology. It is sometimes termed anal sphincter achalasia. Consequently, only those with access to anorectal manometry are in a position to diagnose this condition. Detailed immunohistochemical examinations have shown abnormalities of neuronal markers.111 Once diagnosed, the condition has been treated with sphincterotomy with variable success.

For those without the requisite technology the condition cannot be diagnosed and the patients must be treated symptomatically.

STAGED VERSUS PRIMARY PULL-THROUGH

Primary pull-through has been performed for many years. Swenson et al reported that, of their 470 patients, 50% had undergone a primary pull-through without protective stoma.98 Furthermore, the incidence of anastomotic leakage was not diminished by the presence of a stoma. In the event of leakage however, formation of a stoma was considered life saving. Their recommendation was that surgery be deferred until after the age of six months.
Much has changed in the care of young infants since that publication in 1975. It is clear that major surgery may be safely undertaken soon after birth. It is obvious that single stage reconstruction is dependent on accurate frozen section histology or histochemistry. As noted above, frozen section histology is not completely reliable under all circumstances.

In addition, a successful outcome after a primary pull-through presumes that the enteric nervous system is stable at birth and undergoes no further change. This may not be the case.

We have been performing single stage pull-throughs for some years and have reported no excess of surgical complications. With the passage of time however, we have a concern that these children have an increase in disorders of bowel habit requiring treatment. These patients are under ongoing review and at present we are not clear that a single stage procedure may in the end be the best option.

**OPEN VERSUS LAPAROSCOPIC PULL-THROUGH**

We have no experience with the transanal endorectal pull-through performed solely from the perineum. As only a very limited view of the mesocolon is possible with this approach there is clearly the possibility of performing an ischemic pull-through. Reported results are good but to this author at least, the technique has an in-built flaw—the inability to see and dissect the mesocolon.

All three procedures may be performed laparoscopically and early results are encouraging. In our experience, this probably represents the next advance in the treatment of Hirschsprung’s disease. The same operation may be performed laparoscopically as would be carried out at open surgery but without the trauma of access. Our preference again is for the Duhamel procedure. We have sited the camera port in the right upper quadrant and the working ports in the right iliac fossa, left upper quadrant and occasionally left iliac fossa as well. At this early stage, with fewer than 30 patients undergoing surgery, the results appear similar to the open procedure.

**INTESTINAL NEURONAL DYSPLASIA**

This disorder has been diagnosed primarily in Europe and its existence as a distinct entity is a subject of debate. Described initially in 1971 by Meier-Ruge its existence and relevance have been contested ever since. The pathological features include hypoplasia of nerve plexuses, increased Acht activity, heterotopic ganglion cells in the lamina propria and muscle coats, together with aplasia or hypoplasia of the sympathetic innervation of the myenteric plexus. From the literature there seems little correlation between symptoms and histological features and this will obviously impair surgical decision-making. The subject has been recently reviewed but remains confusing. In this hospital, the pathologists are not convinced of the existence of this condition. Nonetheless, it seems likely that there are other disorders of the enteric nervous system which remain to be defined.

13. Swenson 0, Bill AH. Resection of rectum and rectosigmoid with preservation of the sphincter for benign spastic lesions producing megacolon, Surgery 948;24:212-20.
96. Nixon HH. Personal communication.
The author’s personal experience with total colon aganglionosis includes a total of 45 patients seen over a period of 40 years. Since the first patient in 1959, the author has struggled both clinically and in the laboratory with several methods of preserving and utilizing a portion of the colon for the dual purposes of acting as a storage reservoir and at the same time, reabsorption of liquid in order to decrease stool frequency. A number of other investigators have contributed significantly to the pool of knowledge, reporting their experience and suggestions for modifications of the surgical approach.1-13 A side-to-side anastomosis of the entire colon to the ileum at one time appeared to be a satisfactory solution, but after several years persistent colonic distention proved to be a problem.14 Side-to-side anastomosis of the entire left colon and rectum to the distal ileum as an extended Duhamel procedure has been the author’s standard operation for a number of years, but occasional problems with incomplete evacuation and recurrent enterocolitis prompted further modifications.2,9,15-18 In our current method, the author has decreased the length of the reservoir and placed it entirely within the pelvis in an extraperitoneal location, which affords more effective evacuation. The author also excises more of the posterior portion of the internal anal sphincter because of the frequency of the tight internal sphincter syndrome if the entire sphincter is retained.19,20

**DIAGNOSIS**

The diagnosis must be considered in any child with suspected Hirschsprung’s disease.8,21,22 Radiographic examination with contrast enema demonstrating retention of contrast within a nondilated colon for 24 hours is further suggestive, but the diagnosis is confirmed by rectal biopsy. The proximal extent of the aganglionosis is determined at the time of operation by serial extramucosal seromuscular biopsies obtained at progressively more proximal levels from the colon wall. Appendiceal aganglionosis may occur in the presence of normal ganglia in the ascending and transverse colon and therefore cannot be relied upon when establishing the level of the transition zone.

**ILEOSTOMY**

The author prefers a 3-stage operative approach. The first operation confirms the diagnosis, determines the extent of the aganglionosis, and creates an end ileostomy. The author prefers a midline incision above the umbilicus. Seromuscular extramucosal biopsies are obtained from the sigmoid colon, then from progressively higher levels until dilated, ganglionated bowel is encountered. Each biopsy is carefully labeled and examined by frozen section technique. When ganglionated bowel is confirmed, which is generally at the level of the dilated bowel and within 10-25 cm proximal to the ileocecal junction, this point is selected for the ileostomy. The small bowel is transected and the ileostomy established through a separate incision to the right of the working incision. The working incision is matured by full thickness turnback and is located so as to most readily accommodate an appliance. The distal end of the ileum is exteriorized as a mucous fistula through the upper end of the working incision. This non-functioning stoma affords a convenient port for colonic irrigations and instillation of topical agents in preparation of this aperistaltic bowel for subsequent surgery. It also provides a vent
for decompression to help prevent fulminant diversion colitis which can develop in the totally diverted aganglionic colon and result in complete obliteration of the lumen or even loss of the entire full thickness of colon.

**DEFINITIVE OPERATION**

The author prefers to defer the definitive operation until the infant is near one year of age and weighs approximately 20 pounds (9 kg). The pelvis at this age, is of sufficient size to accommodate the mechanical GIA stapler for the pelvic anastomosis. Also, the author has found the rectal anastomosis (described below) which is the critical part of the operation, can be performed much more accurately and with superior results in the one-year-old as compared to doing the procedure on the newborn infant since the one-year-old is quadruple the size of a newborn. The elected age of one year allows ample time after the completed surgery for toilet training. During the interim period, before the definitive operation, enteral feedings are supplemented, if necessary, with parenteral alimentation.

To minimize gross contamination of the operative field, mechanical cleansing of the gut lumen is essential. Oral Go-Lytley®, or one of its variants, provides excellent preoperative mechanical cleansing of the functional small bowel, but cannot be depended upon to cleanse the distal defunctioned aganglionic bowel.

Preoperative mechanical cleansing of the aganglionic defunctioned distal ileum and colon is difficult to achieve because of the absence of peristalsis. Rectal irrigations, irrigations through the distal ileal mucous fistula, and installation of topical antibiotics are all employed; but after vigorous attempts at bowel cleansing, it may still be found upon opening the abdomen, that there is considerable residual stool within the aganglionic colon. Consequently, the surgeon must resort to intraoperative measures of mechanical irrigation as described below.

The patient is placed in the lithotomy position with the operating table in 10-12° Trendelenburg with the buttocks protruding 2-3 inches beyond the end of the table and elevated on one or two folded towels. The patient is prevented from slipping cephalad on the table with either shoulder straps or adhesive strapping over the shoulders behind the patient’s back, and attached to the foot end of the table. An indwelling Foley catheter is placed in the bladder and a nasogastric tube placed to empty the stomach and is either left in place postoperatively or replaced by a gastrostomy tube at the end of the procedure. We avoid using nitrous oxide anesthesia because of its association with uncontrollable intestinal distention. A #28 or #30 French size catheter is inserted into the rectum and taped in position. The antiseptic preparation of the skin of the abdomen includes the stoma in a widely draped operative field.

The abdomen is opened through the old midline scar, extending the incision around the umbilicus and distally as far as necessary to provide adequate exposure. Any residual inspissated stool found in the aganglionic colon must be removed without contamination of the operative field. To accomplish this, an assistant from outside the sterile operative field, instills physiologic saline solution through the indwelling rectal tube. The surgeon then manipulates the colon to detach the particles of stool and force them out through and around the tube. This procedure is repeated until the returns are clear and the colon is free of palpable stool. This is then followed by an irrigation once with an antiseptic solution then irrigate once with an antiseptic solution and the rectal tube is left open to drainage. The ileostomy is detached from the abdominal wall, and in order to provide sufficient length for the end of the ileum to reach the anus without tension, the mucosa of the ileostomy, which had previously been turned back for maturation is carefully unfolded. The mesentery of the terminal ileum is lengthened by incision, carefully preserving its blood supply. An opening is then created in the pelvic peritoneum posterior to, but immediately adjacent to the rectal wall. Blunt dissection is continued distally to the level of the levator muscles.

The surgeon then moves to the perineal portion of the operation. The rectum is further irrigated and the perineum is prepared and draped as a separate sterile field. Retraction sutures are placed to provide exposure. With electrocautery an incision is made through the mucosa only, at the level of the top of the columns of Morgagnii and extended around the posterior 180° of the anorectal circumference (Fig. 62.1). The transitional epithelium overlying the columns can be rolled downward by gentle gauze
traction with the left hand while the right hand dissects the mucosa from the underlying muscle layer, which is the internal sphincter. Dissection is continued distally as far as the level of the dentate line (distal extent of the anal columns). At the level of the dentate line, the muscle layer (internal sphincter) is incised transversely for the entire 180°; then the plane of dissection is directed upwards between the posterior rectal wall and the puborectalis sling to connect to the presacral dissection plane previously established from above. The objective is to remove the portion of the internal sphincter located above the dentate line throughout the entire posterior 180°. The overlying transitional epithelium is preserved in order to preserve sensation for autonomic, involuntary continence of liquid ileal stool. The author’s experience with the continence-preserving operation for over 200 patients with ulcerative colitis with liquid ileal stool has convinced us of the necessity for preserving this transitional epithelium which contains the sensory fibers of the autonomic reflex arc controlling involuntary night-time continence. The author’s experience also strongly suggests that removal of the portion of the internal sphincter above the level of the dentate line is necessary to minimize the problem of the tight postoperative sphincter associated with colonic distention with dilatation and postoperative enterocolitis. Removal of the portion of the internal sphincter above the dentate line has not interfered with continence in the author’s patients. The fibers located distal to the dentate line are adequate for control. In fact, postoperative manual dilatations are still sometimes required.

The end of the ganglionated ileum (ileostomy site) is then withdrawn through the pelvis with its mesentery directed posteriorly towards the sacrum. The posterior 180° of the open end of the ileum is anastomosed to the preserved transitional anal mucosa with interrupted absorbable sutures. Since this is a one-layer mucosal anastomosis, it is imperative that there be no tension on the suture line. The GIA stapler is then applied twice to cut out a triangular segment of the opposing walls of the rectum and ileum (Fig. 62.2). The base of the triangle includes the posterior 180° of the rectum and anterior 180° of ileum. The apex of the triangle is at the tip of the stapler. Because of the potential for septal regrowth and to further assure hemostasis, the author then oversews the staple line on each side with a continuous lock stitch of absorbable suture starting at the lower end. The suture line is easily retracted downwards by traction applied to the suture in order to provide exposure for progressively higher placement of each stitch and the suture line is continued upwards to within 1 cm of the apex.

The surgeon then returns to the abdominal field and with electrocautery a longitudinal incision is made in the adjacent (opposing) anti-mesenteric walls of the ileum and rectum, thus entering the lumen of each, extending the incisions distally to where the ileum and rectum are stapled together. A right angle clamp can then be inserted into one opening and passed beneath the septum represented by the apex of the triangle of

---

**Fig. 62.1:** Longitudinal section of rectum showing the level of mucosal incision in relation to columns of Morgagni and dentate line (level of incision of internal sphincter)

**Fig. 62.2:** Longitudinal section of rectum showing triangle of posterior rectal wall and opposing anterior wall of ileum to be excised with GIA stapler
rectal and ileal wall previously excised from below. This residual septum is divided with electrocautery and the surgeon can then continue the suture lines (which were started from below) proximally on each side to complete the long side-to-side anastomosis by either hand suturing or with multiple applications of the GIA stapler. The small bowel and colon can be intussuscepted through the enterotomy by traction for each subsequent application of the clamp. When the anastomosis has been completed as far as the junction of the sigmoid and the descending colon, the colon proximal to the completed anastomosis is resected, along with the attached segment aganglionic of ileum (Fig. 62.3). The aganglionic colon has defective peristalsis and if left in place, can fill with stool, which can inspissate, then calcify and cause ulceration and perforation of the colon.

The author’s usual postoperative routine has included a proximal diverting, divided ileostomy to divert the fecal stream and avoid any possibility of leakage of the long extraperitoneal anastomotic suture line. The ileostomy is closed after three months. A contrast enema is obtained to confirm the integrity of the anastomotic suture line prior to ileostomy closure. A digital rectal examination is also performed to confirm healing with pliable tissues and no bleeding and to determine that there has been no septal regrowth.

On three occasions when the remaining small bowel was short and the author was confident of the integrity of the anastomosis, the author has as an alternative to diversion, elected instead to utilize 10 days of total parenteral feedings and strict nothing by mouth with satisfactory results. The author feels more secure; however, with a temporary totally diverting proximal ileostomy, which is subsequently closed by resection and end-to-end anastomosis.

RESULTS

The operation as described above has evolved over a period of 40 years based on the author’s personal experience with 45 patients. In addition, the numerous reports, comments, and suggestions from friends and colleagues from around the world have been of great value in modification of the technique and improving the results.24,25

Numerous complications were encountered in our earlier experience but all patients recovered and are now leading essentially normal lives. In our more recent patients, the only problems encountered have been related to a tight sphincter in 25% of the patients. This has usually been easily overcome by insertion of a #38 French rectal tube at home by the parent and has occurred only during the first year.

For the first year or two following operation, bowel habits are often irregular, sometimes occurring only at night during sleep. By the age of approximately 5 years, however, all have complete control with movements two or three times daily. There have been no deaths related to the operation.

REFERENCES

The typical patient with Hirschsprung’s disease is a newborn presenting with delayed passage of meconium and abdominal distension or a young child presenting with severe chronic constipation. The diagnosis is confirmed by the histological and histochemical evaluation of suction rectal biopsies which demonstrate absence of ganglion cells in the submucosa and increased acetylcholinesterase (AChE) activity in the lamina propria. However, there are a number of patients who clinically resemble Hirschsprung’s disease despite the presence of ganglion cells in rectal biopsy. Various terms have been used to describe these conditions such as “chronic idiopathic intestinal pseudoobstruction”, “pseudo-Hirschsprung’s disease”, “neonatal intestinal pseudo-obstruction” and “intestinal hyperperistalsis syndrome”. There is a growing interest to further investigate these relatively rare functional bowel disorders, since the diagnosis and management of these patients continues to be a challenge for clinicians. Over the past two decades our group has focused its research interest into delineating variant Hirschsprung’s disease based on specific histochemical, immunohistochemical and electronmicroscopic studies.

Since 1981, it has been the author’s policy to obtain suction rectal biopsy specimens from patients who have severe chronic constipation or are suspected to have functional intestinal obstruction. The suction rectal biopsy specimens are obtained at 3, 5 and 7 cm from the pectinate line and examined by conventional hematoxylin and eosin (H&E) staining, histochemistry and immunocytochemical staining. If the results of suction rectal biopsy show normal AChE activity in lamina propria and muscularis mucosae with normally appearing ganglion cells or without ganglion cells, and the patient continues to have signs and symptoms of obstruction or severe constipation, we perform a full-thickness rectal biopsy. Immediately after the biopsy specimen is obtained, the tissue is divided into four parts and processed for H&E staining, AChE histochemistry, NADPH-diaphorase histochemistry, immunohistochemistry (PGP9.5, peripherin, nNOS, NCAM, NGFR and c-kit)and electronmicroscopic studies. If necessary further full-thickness bowel biopsies or seromuscular bowel biopsies are obtained for additional investigations using whole-mount preparation technique.

Between 1981 and 2003, full-thickness bowel biopsy or resected surgical specimens from 151 patients (61 boys and 90 girls) with clinical symptoms suggesting HD, were examined in our research laboratory. Their ages ranged from 1 day to 9 years. One hundred and three patients had onset of symptoms in the neonatal period. Eighty-three patients were from Ireland and in 68 patients, biopsy material was sent to our laboratory from other countries. Table 63.1 shows various functional bowel disorders diagnosed using different histological techniques.

INTESTINAL NEURONAL DYSPLASIA

Intestinal neuronal dysplasia (IND), a clinical condition that resembles Hirschsprung’s disease (HD), was first described by Meier-Ruge in 1971 as a malformation of the enteric plexus. In 1983, Fadda et al subclassified IND into two clinically and histologically distinct subtypes. Type A occurs in less than 5% of cases, is characterized by congenital aplasia or hypoplasia of the sympathetic innervation, and presents acutely in the neonatal period with episodes of intestinal obstruction, diarrhea and bloody stools. The clinical picture of Type B resembles HD and is characterized by malformation of the parasympathetic submucous and myenteric plexuses and accounts for over 95% of cases of isolated IND. IND occurring in association with HD is of Type B. The characteristic histologic features of IND B include hyperganglionosis of the submucous and myenteric plexuses, giant ganglia, ectopic ganglion cells, and increased acetylcholinesterase (AChE) activity in the lamina propria and around submucosal blood vessels.

The incidence of isolated IND has varied from 0.3 to 40% of all suction rectal biopsies in different centers. IND immediately proximal to a segment of aganglionosis is not uncommon and often presents as persistent obstructive symptoms after a pull-through operation for HD. Some investigators have reported that 25 to 35% of patients with HD have associated IND. However, others have rarely encountered IND in association with HD. The uncertainty regarding the incidence of IND has resulted from the considerable confusion regarding the essential diagnostic criteria. The diagnostic difficulty is centered on a wide variability encountered in the literature, not only in terms of age of the patient, the type of specimen examined and the stains performed, but also the diagnostic criteria used. Many investigators have raised doubts about the existence of IND as a distinct histopathologic entity. It has been suggested that the pathologic changes seen in IND may be part of normal development or may be a secondary phenomenon induced by congenital obstruction and inflammatory disease. One strong piece of evidence that IND is a real entity stems from animal models. Recently, two different Hox11L1 knockout mouse models have been generated. In both cases, homozygous mutant mice were viable, but megacolon developed at the age of 3 to 5 weeks. Histological and immunohistochemical analyses showed hyperplasia of myenteric ganglia, a phenotype similar to that observed in IND. However, the mutation screening of this gene in 48 patients with IND did not show any sequence variant, either causative missense mutation, or neutral substitution. More recently Von Boyen et al reported abnormalities of the enteric nervous system in heterozygous endothelin B receptor (EDNRB)-deficient rats resembling IND in humans. They showed that a heterozygous 301-bp deletion of the EDNRB gene led to abnormalities of the submucous plexus, such as giant ganglia, hyperganglionosis and hypertrophy of the nerve fiber strands. These findings support the concept that IND may be linked to a genetic defect.

Since the first description in 1971, most controversy surrounding IND has been regarding which histologic diagnostic criteria are required for definitive diagnosis. The presently recognized diagnostic criteria, previously reported by our group and supported by others, are hyperganglionosis and giant ganglia, in addition to the presence of at least 1 of the following on suction rectal biopsy: ectopic ganglia in the lamina propria, increased AChE-positive nerve fibers around submucosal blood vessels and in the lamina propria. However, Lumb and Moore feel that giant ganglia can be a normal feature in normal bowel having identified them in segments of adult bowel removed during surgery for colorectal carcinoma. To overcome the confusion in diagnostic criteria, Borchard et al, produced guidelines for identifying IND in mucosal rectal biopsies. These comprised two obligatory criteria (hyperplasia of the submucous plexus and an increase in AChE-positive nerve fibers around submucosal blood vessels) and 2 additional criteria (neuronal heterotopia and increased AChE activity in the lamina propria). In the author’s experience, hyperganglionosis and giant ganglia are the most important features for the diagnosis of IND in suction rectal biopsies, except in the newborn, where hyperganglionosis is a normal finding.

Another controversial area surrounding IND is whether the histologic findings are age-related. The recent description of hyperganglionosis, considered to be one of the most important criteria of IND, as an age-dependent finding, has caused further confusion. Recent studies have found that the enteric nervous system continues to develop in the postnatal period.
Wester et al investigated the number of ganglion cells per ganglion and ganglion cell density in whole-mount preparations of the submucous plexus of normal distal colon and found a marked decrease of ganglion cells density with increasing age, but the number of ganglion cells per ganglion remained constant. Knowledge of the ganglion cell density of the normal human enteric nervous system is scanty, apparent by the huge variation among reports of the normal neuron density in the myenteric plexus. The reported density varies more than 200 times among the different studies. This results in difficulties defining conditions such as hyperganglionosis. Schofield and Yunis reported that 8.3% of 456 investigated cases had features of IND, using increased AChE activity in the lamina propria and hyperganglionosis (defined as more than 5 ganglia per high-power field in the submucosa) as diagnostic criteria. These patients had a high incidence of prematurity, indicating that some histological features of IND may be related to age and development. Age-related alterations of the enteric ganglia were discussed further by Smith, who described a significantly higher number of submucous ganglia in children under 4 weeks of age compared with older children. It would be desirable with better knowledge of the enteric nervous system and also with quantitative diagnostic criteria of IND to distinguish normal variation from pathological conditions. Moore et al introduced a morphological scoring system based on the findings of hyperganglionosis, giant ganglia, maturity of neurons, heterotopic neuronal cells and AChE activity in the lamina propria, muscularis mucosa or adventitia of submucosal blood vessels. Hyperganglionosis and increased AChE activity of nerve fibers in the lamina propria were of major importance in this scoring system.

Suction rectal biopsy is the principal method for the diagnosis of disorders of intestinal innervation. It is necessary to include a sufficient amount of submucosa in the suction biopsy specimens. Traditionally, hematoxylin and eosin staining and AChE histochemistry (Figs 63.1A to C) in suction rectal biopsy specimens have provided the basis for the diagnostic evaluation of IND. However, there has been discussion about whether AChE histochemistry is sufficient for the accurate diagnosis of IND and other additional staining techniques have been proposed. Meier-Ruge et al suggest lactate-dehydrogenase histochemistry. In the author’s laboratory, newer neuronal markers currently are being used, such as reduced nicotinamide-adenine dinucleotide phosphate (NADPH) diaphorase histochemistry and immunohistochemistry using antibodies raised against neural cell adhesion molecule, Protein Gene Product 9.5 (PGP9.5), S-100, Peripherin and Synaptophysin. Ganglion-cell counting can be difficult. Standard Immunohistochemical techniques, using antibodies raised against neuron specific enolase or PGP 9.5, which are commonly used to display the enteric nervous system, are less suitable for cell counting because they stain not only the cell bodies but also the
axonal processes. Recently, cuprolinic blue staining has been proposed as the method that stains the largest number of ganglion cells.26 Furthermore, this method stains only the cell bodies and not the axons, which makes it relatively easy to distinguish the individual cells. The whole-mount preparation elegantly shows 3-dimensional morphology of the submucous and myenteric plexuses in IND, demonstrating markedly increased number of ganglion cells compared to controls.

Current treatment of IND Type B is in the first instance conservative, consisting of laxatives and enemas. In the majority of patients the clinical problem resolves or is manageable in this way. If bowel symptoms persist after at least 6 months of treatment, internal sphincter myectomy should be considered. Recently Gillick et al reported results of treatment in 33 patients with IND followed-up for periods ranging from 1 to 8 years (mean, 2.4 years).36 Twenty-one (64%) patients had a good response to conservative management and currently had normal bowel habits. Twelve patients (36%) underwent internal sphincter myectomy after failed conservative management. Seven of these patients now had normal bowel habits. Two patients were able to stay clean with regular enemas. Three patients who continued to have persistent constipation after myectomy and underwent resection of redundant and dilated sigmoid colon now have normal bowel habits. Scharli reported that 13 of the 22 cases required internal sphincter myectomy, which resulted in satisfactory results in 90% of the patients within 3 months. Resection and pull-through operation is rarely indicated in IND. The indication for surgery should not be determined on the basis of histopathological findings alone: rather the decision must be based on the individual patient’s clinical symptoms.

HYPOGANGLIONOSIS

Isolated hypoganglionosis is rare. Clinically, it resembles HD.5,37,38 Failure to pass meconium may be the first symptom in the neonatal period, whereas infants and older children present with chronic constipation. The diagnosis of hypoganglionosis by means of suction biopsy is difficult. Rectal suction biopsy results with absent or low level of AChE activity in the lamina propria and absence or reduction of submucosal ganglion cells may raise suspicion of hypoganglionosis. A full-thickness rectal biopsy allows the inspection of the myenteric plexus and is essential for the diagnosis of hypoganglionosis. The characteristic histologic features of hypoganglionosis include sparse and small myenteric ganglia, absent or low AChE activity in the lamina propria, hypertrophy of muscularis mucosae and circular muscle.39 Meier-Ruge et al performed morphometric measurements in resected bowel specimens from patients with hypoganglionosis and found a dramatic decrease in plexus area and nerve cell number in the myenteric plexus and an increase in distance between ganglia.40

Gut innervation has a complex, 3-dimensional structure, which is difficult to appreciate on thin sections. The whole-mount preparation technique produces a 3-dimensional picture to better show the structure of neuronal networks and their relationship of branching and inter-connecting nerve fibers to each other and to the neighbouring tissues.21 This technique therefore is especially useful for the investigation of pathologic changes in the submucosal and myenteric plexuses such as hypoganglionosis.41 The great advantages for the histologic evaluation become obvious when whole-mount preparations are compared with sections.

Recently, a marked reduction in myenteric and muscular c-kit positive interstitial cells of Cajal (ICCS) in the large bowel of patients with isolated hypoganglionosis has been suggested to contribute to motility dysfunction.42 Furthermore abnormality of the neuromuscular junction has been reported in hypoganglionosis which may further contribute to disturbances in gut motility.43

There is little information regarding the genetic basis of isolated hypoganglionosis. Inoue and coworkers performed mutation screening of RET and GDNF gene in children with hypoganglionosis but found no sequence variants, either causative missense mutation or neutral substitution.44

Treatment of hypoganglionosis is similar to Hirschsprung’s disease involving resection of the affected segment and pull-through operation.

IMMATURE GANGLIA

Immature ganglia are usually seen in the biopsy results from premature infants presenting with functional intestinal obstruction. Acetylcholinesterase staining of suction rectal biopsy specimens show small ganglia
and ganglion cells. However, AChE histochemical technique usually fails to distinguish small ganglia from nerve supporting cells (enteric glia). NCAM and NADPH-diaphorase staining methods can usually clearly show small ganglion cells that are same size as enteric glial cells. Cathepsin D has been further used to show the maturation of enteric ganglion cells. The histological proof of maturation of ganglion cells in the myenteric plexus of young infants was accompanied by the improvement of the bowel function, i.e. peristalsis. The treatment of patients with immature ganglia is conservative consisting of laxative and enemas.

INTERNAL SPHINCTER ACHALASIA

The internal anal sphincter (IAS), which is a specialized smooth muscle continuation of the circular muscle layer of the rectum, plays an important role in the maintenance of anorectal continence and in the pathophysiology of incontinence and constipation. The IAS relaxes in response to rectal distension, a phenomenon called the rectosphincteric inhibitory reflex, which is mediated by intramural nerves descending from the rectum to the IAS. The IAS receives adrenergic, cholinergic and nonadrenergic, noncholinergic (NANC) innervation. Several investigators have reported that IAS relaxation is brought about by the activation of intramural NANC nerves. Recently, it has been shown that nitric oxide (NO) is the NANC neurotransmitter mediating neurogenic relaxation of the human internal sphincter. Internal anal sphincter achalasia (IASA) is a clinical condition with presentation similar to Hirschsprung’s disease but with the presence of ganglion cells on suction rectal biopsy. The diagnosis of IASA is made on anorectal manometry, which shows the absence of rectosphincteric reflex on rectal balloon inflation. Previously, IASA has been referred to as ultrashort segment Hirschsprung’s disease (HD). The ultrashort segment Hirschsprung’s disease, which is a rare condition, is characterized by an aganglionic segment of 1 to 3 cm long and normal acetylcholinesterase (AChE) activity in the lamina propria and increased AChE activity in the muscularis mucosae. Many patients who are considered to have ultrashort HD on abnormal anorectal manometric findings show presence of ganglion cells and normal acetylcholinesterase (AChE) activity in suction rectal biopsies. Many investigators have therefore suggested that the term IASA is more suitable because it reflects more accurately failure of relaxation of the internal sphincter, which is the causative factor in this condition. The exact pathogenesis and pathophysiology of IASA is not understood fully. Altered intramural innervation has been reported in IASA and this is believed to be responsible for the motility dysfunction seen in these patients. Hirakawa et al reported absence of nitric innervation within the IAS muscle in patients with IASA and suggested that nitric nerve depletion may play an important role in the development of IASA. More recently, Oue and Puri reported defective innervation of the neuromuscular junction (NMJ) of the IAS in patients with IASA. If the NMJ is abnormal, the neurotransmitter chemicals synthesizing neurons cannot be transmitted to muscle cells, thereby causing motility dysfunction. Altered distribution of c-kit positive interstitial cells of Cajal (ICCs) has been reported in the internal sphincter of patients with internal sphincter achalasia which may further contribute to motility dysfunction in these patients.

Posterior internal sphincter myectomy has been recommended as the treatment of choice for patients with internal sphincter achalasia. De Caluwe et al reported bowel function in 15 consecutive patients with IASA 2 to 6 years after posterior internal sphincter myectomy. At the time of follow-up, 7 patients had regular bowel motions and were not on any laxatives. Six patients had normal bowel habits but were on small doses of laxatives. One patient was able to stay clean with regular enema regimen. One patient required resection of dilated and redundant sigmoid colon and now had normal bowel habits with laxatives.

Recently, intra-anal injection of botulinum toxin has been used to treat patients with IASA. This treatment modality has been found to be safe and effective but only short-term treatment in these children.

SMOOTH MUSCLE CELL DISORDERS

These patients who show no apparent innervation abnormalities in the pathologic specimens demonstrate abnormalities of smooth muscle cells on electron-microscopy. The outcome of smooth muscle disorders is usually poor. There are two main types of smooth muscle cell abnormalities (1) perinuclear vacuolation
and (2) “central core” degeneration. All total 22 patients in the latter group had Megacystis-microcolon intestinal hypoperistalsis syndrome (MMIHS).

**Perinuclear Vacuolation**

All 10 patients assessed in this group showed identical findings in the smooth muscle cells such as perinuclear vacuolation with well-preserved mitochondria and an increase in collagen, whereas neuronal components appeared quite normal ultrastructurally. Six of the 10 patients had marked lipofuscin deposition in smooth muscle cells. These patients usually have no peristaltic contractions in the bowel. Nine of the 10 patients in the author’s series have died.

**Megacystis-microcolon-intestinal Hypoperistalsis Syndrome**

Megacystis-microcolon-intestinal hypoperistalsis syndrome (MMIHS) is a rare congenital and generally fatal cause of functional intestinal obstruction in the newborn.\(^{54,55}\) This syndrome is characterized by abdominal distension caused by a distended non-obstructed urinary bladder, microcolon and decreased or absent intestinal peristalsis (Figs 63.2A and B). Usually incomplete intestinal rotation and shortened small bowel are associated. Although more than 100 cases have been reported in the literature, the etiology of this syndrome is not yet fully understood. Puri et al in 1983 reported two newborns with MMIHS in whom light microscopy of the intestine showed thinning of the longitudinal muscle coat and abundant amounts of connective tissue between the muscle fibers.\(^{56}\) Electron microscopic evaluation of the smooth muscle cells of the ileum and bladder showed disorganization of myofilaments, cytoplasmic central core “vacuolar type” degeneration and abundant interstitial connective tissue proliferation. These smooth muscle abnormalities are seen in all hollow viscera including urinary bladder and uterus. Since their report, a number of other investigators have confirmed the presence of thinning of the longitudinal muscular coat of the bowel and vacuolation and degeneration in smooth muscle cells of bowel and bladder in this syndrome.\(^{57}\) More recently, Piotrowska et al reported deficiency of contractile and cytoskeletal proteins in smooth muscle cells in MMIHS bowel and Rolle et al reported markedly increased collagen deposits within the bladder wall.\(^{58,59}\) Furthermore, MMIHS has been reported to be associated with loss or deficiency of interstitial cells of Cajal (ICCs) in the bowel of these patients.\(^{60}\) ICCs are pacemaker cells which are densely distributed throughout the whole gastrointestinal tract. ICCs have important functions in neurotransmission, generation of slow waves and regulation of mechanical activities in the gastrointestinal tract especially for co-ordinated peristalsis.

The management of patients with MMIHS is frustrating. A number of prokinetic drugs and gastrointestinal hormones have been tried without success. Surgical manipulation of the gastrointestinal tract has generally been unsuccessful. The outcome of this condition is generally fatal. The need for surgical intervention should be made carefully and individualized, in that most explorations have not been helpful and probably are not necessary.

**REFERENCES**

Variant Hirschsprung's Disease 707
In 1948, it was Orvar Swenson who recognized the cause of Hirschsprung’s disease-based on a series of clinical observations indicating that there was a defective segment of distal colon producing a partial bowel obstruction. Till then, people had thought the defect to be in the dilated and thickened bowel rather than in the distal and narrow segment. Swenson showed that peristaltic tracings from the dilated proximal colon were not able to enter the more distal narrow segment. He thus devised the operation in which the distal segment was removed and the intestinal continuity was restored by pulling down of the proximal colon and its anastomosis at the anus. After this, the bowel started functioning normally. The Swenson’s procedure was thus the first ever pull-through procedure described for treating the Hirschsprung’s disease, and later published by Swenson and Bill in 1948.

Prior to 1948, there was no clear understanding of the etiology of the disease. It is assumed that the absence of ganglion cells was known even earlier as the accepted cause of Hirschsprung’s disease and this had led to the concept of distal colon dysfunction and the basis for the distal colonic resection in the Swenson’s pull-through technique. However, Swenson denied this and reported that it played no role whatsoever in devising the successful operation. Since then, Hirschsprung’s disease has remained a subject of interest for research with new concepts in etiology, diagnosis and treatment.

The surgical principle is to remove the diseased portion of the bowel that is aganglionic distal rectum, and maintain the bowel continuity to allow normal defecation. The aganglionic segment is resected from the sigmoid colon down to the rectum, and an oblique anastomosis is performed between the normal sized (undilated) ganglionic colon and the low rectum.

**PREOPERATIVE ASSESSMENT AND PREPARATION**

A thorough history dating back to stool pattern at birth should be taken. All previous record of operative findings, procedures done and histopathology reports with emphasis on the area from which the biopsy samples have been taken should be studied. A skiagram abdomen may help to identify any fecaloma and also if the patient is constipated or not especially in cases with a single stage pull-through. A distal cologram to outline the adequacy of the distal bowel for pull-through without the need to mobilize the colostomy is essential. A good bowel preparation is essential before the pull-through procedure, especially if it is to be done as a primary procedure without a diverting colostomy. To achieve this, a mechanical cleaning of the distal colon and rectum is done with washes.

The technique demands meticulous dissection of the rectum down to within 2 cm above the ano-dermal junction. If the dissection moves off of the rectal wall, a significant incidence of injury to genitourinary innervations may occur. The results of a properly performed Swenson’s procedure are good; however, it is a technical demanding procedure and the results vary with the surgical expertise. Due to this reason, it is not as popular as the Duhamel or modified Soave (Boley Scott) procedures.

The operation has two components—an abdominal (to mobilize the bowel) and the perineal (to make the anastomosis with the rectum). Initially, the
Pediatric Surgery—Diagnosis and Management

anastomosis used to be completed at the anorectum. This resulted in high incidence of postoperative enterocolitis (early, 16%; late, 27%), and this was attributed to the too much of the aganglionic rectum that had been left behind. The procedure has since been modified by resecting virtually whole of the posterior rectal wall (and the very top most aspect of the internal sphincter), making an oblique anastomosis leaving about 1.5 cm of rectal wall anteriorly and only 0.5 cm of rectal wall posteriorly. This involves a meticulous end to end anastomosis in 2 layers that might be quite time consuming.

Recently, staplers have been used for completing the anastomosis. Following the transabdominal rectosigmoidectomy, the coloanal end to end anastomosis by means of a circular intraluminal stapler has also been reported as a safe and easy technique to treat Hirschsprung’s disease, allowing a deep rectal resection which is very difficult to achieve by manual suturing. As the anastomosis is located in an extraperitoneal position, there is minimum risk of peritoneal involvement even if there is anastomotic leakage. The reported outcome was fast recovery, good functional results and minimum complications. However, long term concern about the high rate of anastomotic stricture remains as one third of patients may develop strictures with the use of circular staplers. Just like a primary transanal endorectal pull-through (TEPT by Boley Scot approach), the entire procedure of Swenson’s pull through can also be performed through the transanal approach and the initial results have been quite satisfactory.

AGE AT SWENSON’S PROCEDURE

Swenson’s pull-through is mostly performed in stages and beyond the neonatal age, in children in whom a diversion has already been done. Though, the procedure can also be performed in the neonatal period as a primary procedure, there is a high risk of damage to the nerves and thus is not routinely advocated in the neonatal age. Carcassonne reported results on 98 infants less than 3 months of age, treated with single stage Swenson’s procedure. There were no deaths. There was only one anastomotic leak that also closed promptly under cover of the colostomy. The early definitive procedure in the neonatal period has the advantage of merging the period of incontinence with the normal period of bowel training.

In the series reported by Wilcox et al, 38 out of 51 patients operated with Swenson’s procedure were neonates with a mean gestational age of 39.6 +/– 1.7 weeks and weight 3.3 +/– 0.54 kg, at 10.3 +/– 5.8 days of age. The short and long-term results were reported as good. Majority of the surgeons still prefer to stage the procedure in the neonates diagnosed with Hirschsprung’s disease rather than doing the one stage procedure in the neonatal period (BAPS survey, 51% versus 41% ) with stoma formation in the neonatal period. The three stage Swenson’s procedure may be performed salery especially in all those children who present late with thick and dilated bowel. With changing times, the primary Swenson’s pull-through is being adopted increasingly by the experienced surgeons preferring this technique.

RELATIVE CONTRAINDICATIONS

Swenson’s procedure is not a good choice for a redo procedure (after failed Duhamel’s or Soaves procedure) unless compelled. A previous surgery leaves much fibrosis on healing and a further dissection outside the bowel may result in the damage to the nerves and other structures in the pelvis. If it has been decided to do a Swenson’s pull-through, then it should preferably be covered with a proximal colostomy as a diverting stoma to protect the neo anastomosis.

SURGICAL PROCEDURE

General anesthesia is used. It may be supplemented with caudal analgesia depending upon the anesthetists choice. The baby is placed in lithotomy position. The baby’s bottom is brought to the end of the operating table and raised with a towel or a small sand bag to improve the accessibility and the ease of perineal dissection. The abdomen, perineum, and thighs are prepared and draped in case an abdominal incision is needed. Appropriate sized Foley’s catheter is inserted into the bladder.

Anal Dilatation

The first step is to perform slow and gentle anal dilatation with one finger at a time and dilating according to the size of the bowel to be anastomosed and the patient’s age.
**Abdominal Part of the Procedure**

The classically described incision for the procedure was a left para-median incision. A modified hockey-stick incision in the left lower quadrant is now preferred by most. The skin, subcutaneous tissue and muscles are divided using diathermy. The peritoneal cavity is opened. The transition zone is identified and the part of the colon to be pulled down is marked with stay sutures. A biopsy is taken for frozen section to ensure the level of the ganglionic bowel. The left colon is dissected from the lateral parietal wall. The peritoneal folds at the peritoneal reflection are opened anterior to the rectum. The dissection may be commenced on the wall of the distal sigmoid or the upper rectum, in a plane close to its wall. The dissection advances distally and around the full circumference of the rectum. It is vital to remain close to the rectum on its anterior aspect to avoid any injury to the urethra.

The dissection may be facilitated by an upward traction applied on the aganglionic rectum and the bladder retracted anteriorly. Multiple blood vessels enter directly into the bowel wall. Each of these vessels must be dissected out and coagulated. Dissection is carried down to within 2 cm of the anal verge anteriorly and 1 cm posteriorly in an oblique fashion to avoid injury to the autonomic nerves.

The extent of the downward dissection is judged by inserting a finger in the anus. The bowel is transected a little above the peritoneal reflection and suture closed. The proximal segment of the redundant aganglionic rectum and the proximal ganglionic colon mobilized, as needed. At this stage the bowel is divided at the level chosen for the pull-through and the two ends suture closed temporarily.

**Anal Part of the Procedure**

Stay sutures are applied to mark all four quadrants at 3,6,9 and 12 o’clock position. The suture at 12 o’clock position is placed with care to remain close to the anal verge so as not to injure the urethra in male patients. The anocutaneous junction (Dentate line) is identified. Narrow right angled retractors, may be used to facilitate the procedure if needed. The closed apex of the dissected rectum is drawn out through the anus with the help of a grasper, everting the rectum (Fig. 64.1). If the dissection has been adequate the anus may be partially everted. An incision is made with the diathermy from 9 to 3 o’clock position anteriorly through the rectal wall, 2 cm above the dentate line.

Through this opening in the rectum, the ganglionic colon is pulled through with care to avoid torsion. The colon is opened at its apex and sutured full thickness to the cut edges of anorectum with interrupted absorbable 4/0 sutures. Classically, silk sutures were used, but nowadays these have been replaced with Vicryl or PDS sutures. The anastomosis is allowed to recede and is gently pulled upward from the abdominal wound. Posteriorly, the suture line should be about 1 cm above from the dentate line (Figs 64.2A and B). A rolled antibiotic ointment soaked paraffin gauze or sofratulle is placed in the anal canal to take care of the dead space between the muscular cuff and the pulled through bowel. The abdomen is closed in layers by the assistant at the abdominal end.

**Trans Anal Dissection for Single Stage Swenson’s Procedure**

A circumferential incision is given about 2 cm proximal to the dentate line anteriorly and 1 cm proximal to the dentate line posteriorly. It is marked with stay sutures all around to facilitate dissection. The stay sutures help to distribute equal tension and prevent the tearing of the rectal wall. Meticulous dissection requires experience and technical skills. The dissection proceeds around the full thickness of the rectal wall. The peritoneal cavity is opened as the dissection proceeds...
upwards. Attention is focused on the mesenteric attachments and the vessels running in the sigmoid mesocolon. This is continued till the transition zone is appreciated in the bowel hanging out of the anal verge. The bowel proximal to the transitional zone is biopsied and confirmed for the ganglion cells before anastomosing the same at the neo anus using vicryl or PDS interrupted sutures in two layers.

Though it is much easier to mobilize the full thickness bowel (full thickness rectum) from the perineal side, unlike fashioning a mucosal tube during the transanal endorectal pull-through (TEPT) procedure, yet the mobilization of the bowel all around deep in the pelvis has always remained a matter of concern to the surgeons for an inadvertent injury to the nerves, urethra and bladder, with long term sequelae.

COMPLICATIONS

Early Complications
1. Injury to the urethra and the bladder.
2. Bleeding due to the retraction of major vessels
3. Increased frequency of stool
4. Early coloanal stenosis
5. Anastomotic leak
6. Hematuria
7. Transient urinary retention
8. Enterocolitis, though partially preventable, yet can occur even after a technically correct procedure.

Late Complications
1. Enterocolitis.
2. Fecal Incontinence: There has been a concern about the effect of prolonged traction of sphincter muscle in single stage transanal Swenson’s procedure. If adequate care is taken to preserve the anal canal, incontinence should not occur. Postoperative soiling may be present without frank incontinence
3. Stenosis at the anastomotic site: This may occur more frequently if the three stage procedures has been adopted. Anal dilatation is helpful.
4. Residual disease due to error in the operative procedure or the histology frozen report.

LAPAROSCOPY

Laparoscopy has been used to complete the abdominal part of the dissection and remove whole of the aganglionic bowel and preparing the same for the anastomosis at the anal verge, using laparoscopic technique. Curran and Raffensperger first tried this technique in dogs to assess its feasibility and then used it successfully in a group of 8 patients, reportedly with a reduced morbidity and no complications. Kumar et al, reported the use of laparoscopic Swenson’s procedure for one stage primary as well as two stage secondary procedures, with good short-term results, and there was no difference in operating time between the primary and secondary pull-through procedures. George et al also reported the advantages of the
Swenson's laparoscopic approach with shorter lengths of hospital stay and fewer postoperative complications.\textsuperscript{25}

**OUTCOME**

The reported outcome following Swenson's operation varies in different series.\textsuperscript{26} Swenson himself had made various observations over the past 6 decades as to why everyone could not reproduce his results.\textsuperscript{27,28} One of the most serious complications of a Swenson's pull-through, is a leak at the anastomosis. In a combined series with 880 children from seven centres operated with Swenson's procedure, the leak rate was 5.6\%. The postoperative enterocolitis was 11\%. There was a need for a secondary re-operation (6\%) that stemmed from anastomotic leaks and anal strictures, requiring diverting colostomies.\textsuperscript{29} Others have also reported a similar complications with the need for secondary operations. However, there are authors who have been using Swenson's operation without encountering problems that required reoperation.\textsuperscript{30-33}

Though, the chances of injury to the pelvic nerves during Swenson's procedure have been high, yet if performed properly by a trained surgeon, there have been no problems with the urinary or the sexual function.\textsuperscript{29} Swenson, in 1975 reported the outcome in 80 patients who were married and collectively had 146 children.\textsuperscript{34}

The results of postoperative continence also vary in different series. Bai et al, reported a 8 to 16 year follow-up in 45 patients who had undergone Swenson's procedure, 23 patients (51.1\%) had bowel dysfunction and 17(37.8\%) had fecal soiling.\textsuperscript{35} Although, most patients had good or fair quality of life after surgical correction in this series, the long-term outcome was not as good. In another series with Swenson's pull-through procedure, the immediate postoperative recovery and long term anorectal functions have been reported quite satisfactory and compared well with other techniques.\textsuperscript{32,36}

Drossman et al, in a study on 800 normal adults who had no gastrointestinal complaints, determined the normal range of bowel movements as; at least 1 movement every three days and no more than 3 movements per day.\textsuperscript{37} Using this criterion, up to 96\% of the patients were reported to have normal bowel pattern and were continent following Swenson's pull through.\textsuperscript{29} The long-term incidence of postoperative constipation has been reported as 54\% after the Duhamel, 43\% after the Soave, and 4\% after the original Swenson's operation.\textsuperscript{38} With passage of time, most children with Hirschsprung's disease after pull through procedure significantly improve with respect to fecal continence, but this may not be until later adolescence.\textsuperscript{39}

The overall mortality rate after surgery for Hirschsprung's disease, in a series of 880 cases treated with Swenson's operation was 2.5\%. However, during the last 20 years the mortality has fallen to 1.25\%.\textsuperscript{29} Soave in his own series of 271 patients reported 4.5\% mortality.\textsuperscript{40} The mortality rate in 260 patients treated with the Duhamel modification was 6.2\%.\textsuperscript{41} Most series lately have reported no mortality with Swenson's procedure.

**REOPERATIONS**

There is very less need for the reoperations following Swenson's procedure if performed by experienced surgeons. In Pena's series of cases requiring reoperations for Hirschsprung's disease, the initial operations were Soave (20), Duhamel (15), Swenson (5), transanal endorectal (4), myectomy (3), unknown (3), and laparoscopic Swenson (1).\textsuperscript{20} The main indications for revisions following the Swenson's procedures are stricture unresponsive to dilatation, post-anastomotic leak and fecal fistula.\textsuperscript{42} For a redo following Swenson's procedure, a re-Swenson, Boley Scot or a Duhamel technique may be used.\textsuperscript{42} The re-do procedures should be done with proximal diversion of stools with a colostomy. If the anal canal is quite fibrosed and unyielding and there is no anal mucosa left, it is advisable to use the original Soave's pull through technique to avoid postoperative complications due to possible retraction of the bowel. Usually the results following the redo pull-through operations for Hirschsprung's disease may be as effective as primary procedures in terms of continence and stool frequency.\textsuperscript{43}

**COMPARISON WITH OTHER PROCEDURES**

It is not easy to make a precise comparison amongst different types of operative procedures used for pull through in children with Hirschsprung's disease. The complications and the outcome of the patient would depend on the age at presentation and the surgery,
degree of thickened bowel, level of the resection of the bowel, level and type of the anastomosis at the anal canal (oblique or circular, staplers or manual), length of the bowel involved with the disease, the experience of the surgeon and the episodes of enterocolitis before and after surgery.

Sarioglu et al compared the results of Swenson’s operation with the Duhamel’s technique in 138 and 59 patients respectively and found that only the anastomotic stricture rate was significantly higher in patients who had undergone Swenson’s procedure. The incidence of other complications like wound infection, dehiscence, anastomotic leak, adhesive intestinal obstruction, pelvic abscess, intra-abdominal abscess, mucosal prolapse, anastomotic stricture and fistulas were found equally common in both procedures. When urinary incontinence, enterocolitis, soiling and constipation were considered, there was no significant difference between these two groups.44 Yanchar and Soucy found that the Duhamel’s procedure was associated with more chances of constipation.39

The authors using the Boley Scot principle of soave’s technique in 111 children with HD, found the procedure quite good, with stricture (4.5 %), adhesive obstruction (4%) and wound infection (2.5%) as the main complications. The short and the long-term results were excellent for primary as well as for the redo cases. A proper selection of patient for a single or multistage procedure was found to be more important to achieve good results rather than the technique itself.45 Another series reported from the authors institute showed that the early complications were seen with equal frequency in patients undergoing Swenson and Duhamel operation. However, the late complications were seen less often with the Swenson’s procedure.36 The Boley Scot and the Swenson’s procedures do require patience and surgical expertise to master the skills, while the Duhamel operation being surgically simpler is considered a safer method for the beginners.44,46,47

In a survey done by the Surgical Section of the American Academy of Pediatrics, the leak rate after Boley Scot was 6.9%.48 Similar leak rate has also been reported following Duhamel procedure. The Duhamel modification has also been reported to have a rectal pouch problem that ranges from 10-25% consisting of impactions and at times bleeding.49,50

Soave modification has been associated with abscess formation between the retained aganglionic muscular sleeve, retraction of the pulled-through normal colon, and mucosal prolapse even years after the operation. Soaves procedure has been associated with the need for prolonged daily rectal dilatations. In a large review, it was reported that Soave modification had the highest incidence of postoperative enterocolitis followed by that of Duhamel and then the Swenson’s procedure.51

**STAGED VERSUS SINGLE STAGE**

The major advances that have occurred in the management of Hirschsprung’s disease include the definitive management in a single stage. Recently, Swenson’s Pena has been successfully performing Swenson’s procedure as a single stage in the prone position with the help of specially designed retractors52 (Personal communication) (Fig. 64.3). There have been no significant difference in complication rates reported between staged versus primary pull-through. A one-stage Swenson’s transanal pull-through has also been reported as a safe alternative with no increased instances of anastomotic leaks, wound infections or postoperative bowel obstructions.53 Some advocate
definitive management in the newborn period. However, others feel it risky to do a primary Swenson’s procedure in the newborn period, and other options like a primary Duhamel are more satisfactory. The authors feel a primary trans anal endorectal boley Scot is even safer. It is a matter of surgeons preference and the time of presentation of the baby. The bottom line remains, all techniques are as good and safe, with short and long-term satisfactory outcome, provided these are mastered well.

Duhamel’s Pull-through

Since the introduction of a definitive corrective procedure for Hirschsprung’s disease by Swenson and Bill in 1948, the surgical options have gradually been refined.1 Swenson’s technique consisted of resection of entire aganglionic colon and the proximal ganglionic colon being anastomosed to the rectum in an oblique fashion. The anastomosis is 0.5 cm proximal to the dentate line posteriorly and 1 cm proximal anteriorly. State’s operation was a low anterior resection leaving 7-10 cm of aganglionic rectum, while the Rehbein’s procedure left about 3-5 cm of aganglionic rectum. Both these procedures have now been abandoned as they resulted in a high incidence of residual symptoms. Bernard Duhamel in 1956 and Soave in 1964 devised procedures which eliminated much of the pelvic dissection. 2,3 Soave performed an endorectal mucosectomy distal to the pelvic peritoneum and pulled down the proximal ganglionic colon through the aganglionic muscular cuff of the rectum.

In the Duhamel’s procedure the pelvic dissection distal to the pelvic peritoneum is done retrorectally, with no dissection anteriorly thereby avoiding any damage to the nerve supply. The rational for Duhamel’s procedure included ease of performance, prevention of anastomotic leaks and strictures while eliminating the obstruction and preserving the sensory receptors. The operative principles of his technique included:

1. Minimal pelvic dissection.
2. Retrorectal approach for the pulled-through colon to the anal opening.
3. Partial disruption of the internal anal sphincter posteriorly.
4. Preservation of the anterior wall of the rectum and its nerve supply.
5. Elimination of colo-rectal septum with wide side-to-side anastomosis (stapled or crushed auto-anastomosis) between the anterior aganglionic rectum and the pulled down ganglionic colon.

Several modifications have been described to the original Duhamel’s procedure. Most of these pertain to:

1. Level of posterior rectal incision to anastomose the pulled through colon.
   a. **Duhamel I operation**: The original technique in which the anal incision was at the anocutaneous junction.2 This resulted in a higher incidence of soiling, because of complete disruption of the internal anal sphincter.
   b. **Grob’s modification**: The anal incision was above the internal sphincter thereby completely preserving the sphincter.4 There was no more soiling but fecal impaction due to inert anal sphincter became common.
   c. **Duhamel II operation**: Duhamel recognized the deficiency of his earlier procedure which he corrected by making the anal incision 0.5-1cm proximal to the dentate line thereby partially disrupting the sphincter. This ensured adequate continence to gasses and liquid feces and did not lead to constipation. This is practiced widely today.

2. Various techniques/clamps for the side-to-side anastomosis between the rectal stump and the pulled-through colon.
   a. **Kocher’s clamps**: Used in the original procedure.5,6
b. Various other clamps applied in a retrograde manner through the anus: Ochsner, Gross, Zachary, Sulamaa, Ikeda and many others.7-10

c. Stones enterostomy crushing clamps: These were applied in a prograde manner, through the colotomy in the pulled-through colon.11

d. GIA linear cutter.12 This is frequently used nowa days.12

3. Methods of obliterating the proximal blind rectal pouch.
   a. Closure of the proximal end of the rectal stump, as described originally by Duhamel, as low as possible leaving no common wall.
   b. Martin’s modification: In this modification the entire juxtaposed common wall between the anterior aganglionic rectum and the posterior pulled-through colon is eliminated, either by a long crushing clamp or staplers and the proximal open end of the rectal stump is anastomosed to the colotomy on the pulled-down colon in an end-to-side manner.

The patients with Hirschsprung’s disease who are to undergo Hirschsprung’s disease can be managed in three ways:
1. Primary Duhamel’s pull-through without a diverting colostomy: This is suitable in cases where the proximal ganglionic colon is not excessively dilated as in neonates and some infants. When this is attempted in an older child with hugely dilated colon, this entire dilated segment, which is actually normal ganglionic segment, will need to be resected.

2. Two stage procedure: The initial colostomy is performed at the junction of the ganglionic and aganglionic colon (leveling colostomy) after proper identification by frozen section biopsy. During the second stage Duhamel’s pull-through is done after taking down the stoma and using the proximal end for pull-through. The advantage of a two stage procedure needs to be seen against the following disadvantages:
   a. Need for frozen section biopsy at the time of the leveling colostomy to accurately site the stoma.
   b. The need to handle the stoma at the time of the pull-through procedure.

c. Absence of a proximal diverting stoma to protect the anastomosis at the time of pull-through.

3. Three stage procedure: Initially a proximal diverting stoma is made in the right transverse colon (in the usual short segment Hirschspring’s disease). This is usually sufficiently proximal in most cases to permit its preservation following the definitive operation. During the procedure for colostomy, seromuscular biopsies are obtained from the collapsed aganglionic colon and the distal most end of the dialated ganglionic colon. These sites are marked with silk sutures for easy identification during the definitive pull-through procedure. Second stage Duhamel’s procedure is done without touching the colostomy and 4-6 weeks later the colostomy is closed.

A three stage Martin’s modification of the Duhamel II procedure using a GIA linear cutter is performed most frequently now.13 More recently laparoscopy assisted Duhamel’s pull-through has been described.14

**INDICATIONS**

All confirmed cases of short segment and long segment Hirschspring’s disease.

All redo pull-through procedures following a failed Swensons’s and Soave’s pull-through.

**PREOPERATIVE EVALUATION**

1. **Barium enema:** Initial screening and diagnosis. Also indicates the extent of aganglionosis and the suitability for a primary pull-through. It also helps in deciding the suitable stoma site for diversion.

2. **Rectal biopsy:** This can be either a suction biopsy, a punch biopsy which are obtained from 3 and 5 cm proximal to the ano-cutaneous junction. The open biopsy is a full thickness rectal biopsy obtained under anesthesia. These are processed by routine H and E staining and also acetylcholine esterase stains.

3. Distal most level of ganglionic bowel is ascertained by obtaining a seromuscular biopsy from the colon at the time of the diversion and marking this site with silk sutures. If this has not been done then the level can be ascertained by frozen section biopsy during the pull-through procedure.

4. **Baseline evaluation:** Hemoglobin, serum proteins, renal functions.
PREOPERATIVE PREPARATION FOR PULL-THROUGH

A first generation cepahlosporin or ampicillin + gentamycin + metrogyl is started 24 hours prior to surgery. The mechanical bowel preparation differs slightly depending on the procedure:

1. For Primary pull-through:
   a. Twice daily rectal washes with normal saline starting at least a week or two prior to surgery.
   b. Low residue diet for three days prior to surgery.
   c. Gut irrigation using polyethylene glycol solution (70 ml/kg) on the day prior to surgery.
   d. On the morning of the surgery a rectal flatus tube is inserted to ensure complete evacuation of the colon.

2. For two stage procedure in which the leveling stoma has to be brought down:
   a. All the above steps are done except that to the initial rectal washes a distal colostomy washout is also added. This should be done with a flatus tube, positioned in the rectum and fluid instilled through the rectal tube.
   b. On the morning of the surgery a rectal flatus tube is inserted to ensure complete evacuation of the colon.

3. For three stage procedure in which the diverting stoma will remain untouched:
   a. Only rectal washes and distal colostomy washout as described previously for two to three days is adequate.
   b. On the morning of the surgery a rectal flatus tube is inserted to ensure complete evacuation of the colon.

PROCEDURE

General anesthesia supplemented with caudal analgesia is used. A nasogastric tube is inserted at the outset. The child is placed in lithotomy position with a folded towel under the lower back. The head end of the table is slightly lowered. Anal dilatation, appropriate for age is performed. The proximal diverting stoma is covered and excluded. The patient is cleaned and draped and a Foley’s catheter is placed into the bladder.

Left lower abdominal curved skin crease incision is made and the muscles and peritoneum divided. A midline or left paramedian incision may be more appropriate in adults and older children or when the disease involves long segment.

Sigmoid colon is identified and delivered into the wound. Silk sutures marking the previous biopsy sites is identified and the proximal level of colonic resection ascertained. If the proximal biopsy was reported as ganglionic then that becomes the level up to which colon is resected. If the proximal biopsy was also reported as aganglionic then more proximal seromuscular biopsies are obtained and sent for frozen section examination to ascertain the level of ganglionosis.

The peritoneum over the mesosigmoid is incised both laterally and medially and then joined anteriorly in the colo-vesical pouch. Both the ureters are identified so as to avoid injury.

Colon is mobilized distally up to the level of pelvic peritoneum. The superior rectal branch of the inferior mesenteric artery is preserved to supply the rectal pouch. Proximal mobilization is done so that the level at which the proximal transection would be done can be brought easily to below the pubic symphysis. This may sometimes need division of the left colic artery so that the colon that will be pulled down will be based on the left branch of the middle colic through the marginal artery of Drumond.

The mobilized colon is retracted anteriorly and cranially so as to expose the retrorectal space. A space is created by blunt finger dissection initially and then with a ‘peanut’ on a long Kelly’s clamp (Fig. 65.1). This is continued till the peanut is able to evert the rectum outwards to expose the posterior half of the dentate line. Care should be taken not to injure the superior rectal artery.

The rectum is transected just above the pelvic peritoneum between two non-crushing intestinal clamps. The proximal end of the colon to be resected, as identified by the presence of ganglion cells previously, is also divided between two non-crushing intestinal clamps and the resected segment is removed. If there are fecalomas, these can be manipulated into the bowel to be resected and removed with it. The distal end of the resected segment should be marked with a silk suture for easy identification by the pathologist.

The distal end of the ganglionic colon which is to be pulled, down is closed with a running silk suture, the ends of which are left long. The mesenteric and
The antimesenteric ends should be marked with different coloured sutures (e.g. Catgut and silk) to avoid rotation during pull-through.

The intestinal clamp is removed from the proximal end of the rectal stump and the rectum cleaned with povidone iodine solution. Four silk stay sutures are taken on this rectal stump at 3, 6, 9 and 12 o’clock positions.

The Kelly’s clamp with a ‘peanut’ is again passed into the retrorectal space so as to evert the dentate line out of the anal canal. Posterior 180° (half circumference) full thickness incision is made on the rectal wall, between silk stay sutures placed at 3, 6 and 9 O’clock positions. The incision should be 0.5-1.0 cm proximal to the dentate line (Fig. 65.2).

Another Kelly’s clamp is now used to grasp the protruding ‘peanut’ and the abdominal Kelly’s clamp is then withdrawn, thereby guiding the tip of the rectal Kelly’s clamp into the abdomen through the posterior rectal incision and the retrorectal space.

The stay sutures left long on the closed end of the colon to be pulled-down is grasped by this Kelly’s clamp and is gradually pulled out of the rectum, gently guiding the colon through the retrorectal space and out through the posterior half circumference rectal incision. During this maneuver the surgeon ensures that there is no twisting of the colon and that the mesentry of the pulled-through colon is posteriorly in the sagittal plane.

Posterior half circumference of the pulled down colon is then incised transversely about 1 cm proximal to the closed end and its proximal lip is sutured to the distal lip of the rectal incision with interrupted vicryl sutures.

The remainder of the half circumference of the pulled-down colon is incised and the tip of the pulled-down colon is removed for histopathological examination. Stay sutures are taken on this anterior half circumference of the pulled down colon along with the anterior lip of the half circumference rectal incision, at 3, 12 and 9 o’clock. At this juncture there are two juxtaposed loops of bowel in the perinium. Anteriorly is the aganglionic rectum and posteriorly the pulled down ganglionic colon. The common wall between the two is the posterior wall of the rectum and the anterior wall of the colon (Fig. 65.3).
Stay sutures are taken on the pulled-through colon, in the abdomen, just opposite the open rectal stump and a longitudinal colotomy on the pulled-down colon is made. The lumen of both the rectum and colon is irrigated and cleaned.

GIA linear cutter 55 or 75 is then inserted through the anus with one blade in the aganglionic rectum and the other in the pulled-down ganglionic colon. Care is taken so that the entire length of the two colon walls is included and the tip of the stapling device is protruding well beyond the rectal stump and the colotomy in the abdomen. The stapler is then fired to complete the longitudinal anastomosis and the division of the common wall. In case the entire common wall is not divided, the same needs to be completed by another firing with the stapler now applied from the abdominal end in a prograde fashion.

The other alternative for dividing the common wall between the rectum and the pull-through bowel is by using the Stone’s enterostomy crushing clamp (Fig. 65.4). The clamp has a box junction and two blades of either three inches or four inches in length. This is applied from the abdominal side with one of the blades being positioned into the pull-through bowel through the colostomy as described earlier and the other into the proximal open end of the retained rectal stump with the hinge of the clamp in the colon at the colostomy site. The tips of both the blades is seen from the rectal end and a ring retainer is placed on it and the screw tightened to gently crush the common wall.

The open proximal end of the rectal stump is anastomosed to the colotomy on the pulled-through colon in an end-to-side fashion (the so called Martin’s modification). This anastomosis is extraperitonealized after placing a small pelvic drain of corrugated red rubber. The peritoneum on both the medial and the lateral aspects of the pulled-through colon is repaired taking care not to injure the ureters. The abdominal wound is closed in layers with vicryl for the peritoneum, muscles, sheath and the Scarpa’s fascia and subcuticular absorbable sutures for the skin.

All stays are removed from the perinium, which is then cleaned and a rectal pack of paraffin gauze inserted. This is to be removed after 24 hours. The abdominal wound is cleaned and dressed. The completed anatomy of the rectum has anteriorly aganglionic bowel and posteriorly pulled-down ganglionic bowel.

In cases where the crushing clamp has been applied, on the first postoperative day, the screw on the ring retainer is fully tightened to crush the common wall. Auto-anastomosis between the two walls takes place and the clamp slips out of the rectum in 5-7 days (Fig. 65.5). The completed anatomy is just as when staplers are used. The main disadvantage of using the clamp is that the patent needs to be in the hospital till the clamps slip out. The advantage of using the enterostomy crushing clamp is that the same instrument can be used again and again in many patients. The advantage of using the enterostomy crushing clamp instead of the classically described Kocher’s clamp is that its blades are longer and so it can easily crush the entire common wall. Further, just the tip of the blades and the ring retainer protrudes
out of the rectum, allowing the child to be ambulatory in the postoperative period.

**COMPLICATIONS**

1. Wound infection
2. Anastomotic disruption
3. Early dislodgement of the clamps
4. Non-dislodgement of clamps
5. Failure of stapled suture line
6. Injury to the ureters
7. Enterocutaneous fistula
8. Recurrent or residual symptoms
9. Fecal soiling or incontinence
10. Enterocolitis
11. Adhesive intestinal obstruction
12. Fecaloma formation especially when Martin’s modification is not done.

HISTORICAL BACKGROUND

Endorectal pull-through technique was first described by Franco Soave in 1964 for patients with Hirschsprung’s disease.\(^1\) He was inspired by the work of Rehbein and Romualdi (1959) on the treatment of cases of High Anorectal Malformation (ARM) with rectourethral fistula. This procedure was based on removing the mucosa and submucosa of the rectum and pulling the ganglionic bowel through the aganglionic muscular cuff, and leaving it hanging beyond the anal verge, till adhesions developed between the two segments of bowel. The excess of the bowel was later excised may be after 2 weeks or so. Thus, there was no formal anastomosis at the anus in this original Soave’s procedure. This procedure was considered practical and life saving in critically ill children in that era, especially in those children who were quite sick and the bowel was not healthy. However, Soave in 1964, published another paper with his modification. It consisted of making a circumferential cut, through the muscular coat of the colon at the pelvic peritoneal reflection. Working in an intramural plane, the mucosa was separated from the muscular coat down to the anal canal. The freed mucosa was excised and the proximal normal colon was pulled through this retained viable spastic aganglionic muscular sleeve. A telescoping type of anastomosis was then made that added an extra layer of colon wall at the anastomosis.\(^2\)

The procedure was later modified by Boley Scot and published in 1964 and 1968.\(^3,4\) He performed an extrapelvic anastomosis between the anal canal mucosa and the mucosa of the normal colon. Marks reported cutting the sleeve posteriorly, a practice now widely used.\(^5\)

Further modification was suggested by Coran and Weintraub, with the eversion of the mucosal-submucosal tube on to the perineum to facilitate the performance of anastomosis.\(^6\)

The endorectal pull-through has evolved from a transabdominal dissection to a transanal approach. Transanal mucosal proctectomy was described by Parks for low rectal malignancies (1972).\(^7\) Rintala et al (1993) used this technique for the operative treatment of Hirschsprung’s disease (HD).\(^8\) Since then, there have been many modifications. Transanal approach has been used either alone or in combination with the laparotomy in difficult situations.

Endorectal pull-through by complete transanal dissection was described by de la Torre-Mondragon and Ortego-Salgado in 1998.\(^9\) Georgeson et al in 1999 described the laparoscopic assisted mobilization of aganglionic colon, along with trans-anal dissection.\(^10\)

SCIENTIFIC BASIS OF ENDORECTAL PROCEDURE

This procedure is based on the belief that by remaining within the muscular cuff of the aganglionic segment, injury to the nerves is avoided and the integrity of the internal sphincter is preserved.

INDICATIONS OF ENDO-RECTAL PULL-THROUGH

1. All confirmed cases of short-segment and long-segment Hirschsprung’s disease.
2. Total colonic aganglionosis with ileoanal endorectal anastomosis.
3. All redo pull-through procedures following a failed Swenson, Duhamel or Endorectal pull-through.
PREOPERATIVE EVALUATION FOR DIAGNOSIS

1. **Baseline investigations**: Hemogram, liver and renal function tests.
2. **Barium enema**: This is used for initial screening and diagnosis of Hirschprung’s disease (Fig. 66.1). It also helps in determining the suitability for a primary pull-through procedure. A massively dilated ganglionic bowel will preclude the endorectal pull through procedure and necessitates diversion of stools with a proximal appropriate colostomy. A lateral film and a late film after 24 hours must be the part of barium study to gain maximal information.

   A properly performed barium study also gives information about the level of the transition zone, indicating the extent of aganglionosis and planning for the appropriate type of pull through operative procedure.

3. **Rectal biopsy**: This is the gold-standard test for confirming the diagnosis of HD and all patients must have a proof of diagnosis as far as possible, before undergoing pull-through procedure.

4. **Anorectal manometry**: Absence of recto-sphincteric relaxation reflex suggests Hirschsprung's disease. This is not routinely performed in all cases of HD but the study is extremely useful in patients with ultrashort variety of HD, to establish the diagnosis when rectal biopsy has remained unhelpful.

SURGICAL PROCEDURE

The Soave’s pull-through can be performed as a single stage surgery or it can be staged into two or even three stages, depending on the experience of the surgeon, extent of the disease, the condition of the baby (anemia, enterocolitis, epsis, fecolomas) and the degree of the dilatation of the bowel.

In the three-stage procedure, first a proximal diversion is done. The site of diversion varies according to the level of aganglionosis found on barium study. The authors prefer a "right transverse colostomy" for the standard type of rectosigmoid HD. The normal bowel distal to colostomy remains out of circulation and decreases in size remarkably in due course of time, may be a few months. For the technical reasons and to avoid any loss of healthy colon during the definitive surgery, a "leveling colostomy" (after confirming with frozen biopsy) is preferred in patients who have the long segment HD, involving the descending colon or the splenic flexure.

In the patients with total colonic aganglionosis (involving not only whole of the colon but also the terminal ileum extending for about 10-25 cm proximally from the ileoceaecal valve in 50% cases), a "leveling ileostomy" is performed. A frozen seromuscular biopsy proves quite helpful and should always be done while constructing the stoma as the "Leveling diversion". Also, before discharging the patient, the parents should be taught the technique of distal stomal and rectal washes, to avoid stool deposition and fecoloma formation.

At the time of second admission for pull-through procedure, distal stomal and rectal washes are continued as in-patient to make the bowel absolutely clean for the pull-through. Taking down of the stoma will be required in case of long segment Hirschsprung’s disease. If the long segment disease is suspected then child is given low residue diet for 3-4 days. Only clear fluids are allowed the day prior to surgery. Polyethyleneglycol (75-80 ml/kg) orally or through nasogastric tube is also given the day prior to surgery to ensure that the bowel to be pulled down is found absolutely clean during surgery.

The neonates do not require anything other than saline enema to prepare the bowel for pull-through. Intravenous antibiotics should be started 24 hours prior to surgery and continued in the postoperative period.
In older children, a barium enema should be done, preferably after 12 weeks of initial diversion to confirm the resolution of the faecaloma and the decrease in the size of dilated proximal bowel. In case the bowel is found still dilated and unfit for pull through, the definitive surgery is further delayed and the distal wash outs are continued more effectively.

**SINGLE-STAGE PROCEDURE (PRIMARY PULL-THROUGH)**

Primary pull-through is rapidly gaining acceptance since the successful report by So et al in 1980. The pull through procedure is performed as a single stage without the need for a diversion. This is suitable in cases where the proximal colon is not excessively dilated as in the neonates and also in some infants and children with effectively decompressed bowel. This is discussed in detail in the next chapter.

**TWO-STAGE PROCEDURE**

Leveling colostomy is done in the first stage. Stoma is made at distal most part of normal ganglionic bowel. Left lower quadrant oblique incision is made, and the transition zone is looked for. Seromuscular frozen section biopsy is taken from the hypertrophied bowel just proximal to the grossly visible transition zone. A seromuscular layer is dissected off the underlying submucosa for about a cm and sent for frozen biopsy. It is important to remember that the transition zone may extend for several centimeters. Along this zone, ganglionic cells may be present on one side of the circumference but may not be on the other. Thus, it is safer to place the stoma at a more proximal distance. Part of the colon used in the colostomy should contain adequate number of ganglion cells and absence of hypertrophied nerve bundles.

Colostomy can either be loop or divided. Loop colostomy with an adequate spur is preferred by most surgeons. Appropriate sized red rubber catheter (RRC) is passed through small hole in mesentry closer to the wall of the bowel avoiding the injury to the marginal vascular arcade. A spur is made by taking seromuscular stitches between the adjoining ascending and descending limbs of the hooked bowel loop.

**Advantages of Spur while Making a Colostomy**

1. Helps in complete diversion of stoma.
2. Prevents stomal prolapse.
3. Prevents stomal retraction.

Dismantling of the stoma and the pull-through of ganglionic bowel is done as the second stage definitive surgery.

**THREE-STAGE PROCEDURE**

Short segment Hirschsprung’s is the most common (75-80%) type. The right transverse colon can be used for fashioning the colostomy in all such cases as the first stage. During this procedure, multiple seromuscular biopsies are taken from the suspected aganglionic, ganglionic and the normal colon, proximal to gross transition zone to identify distal most part of the ganglionic bowel. Biopsy sites are closed with silk sutures so as to facilitate identification during the pull-through procedure. In the second stage, the pull-through procedure is completed. The colostomy closure is done as the third stage surgery.

**Advantages of Three-stage Procedure**

1. Colostomy can be made even when frozen-section facility is not available.
2. Colostomy allows the decompression of the distal bowel, making it fit for pull through procedure.
3. Under the colostomy cover, the child grows well and improves nutritionally.
4. Pull-through procedure is completed without the need to mobilize the colostomy.
5. The anal anastomosis is well protected by the colostomy, in the immediate postoperative period after the second stage.

**Disadvantages of Three-stage Procedure**

1. Requirement of multiple admissions and operations places a significant burden on both the family and the health care system.
2. The level of the colostomy may not allow the second stage of the pullthrough without mobilization of the colostomy in cases with the long segment disease.
3. The distal segment of the colon may undergo disuse atrophy if left for long or the child is lost for follow-up and thus may not function properly after the colostomy closure in the third stage.

**Cuff length**– The recommended length of the cuff has progressively shortened. There has been a concern that
long cuff may increase the incidence of constipation or enterocolitis. Presently most surgeons prefer to limit the seromuscular cuff length to about 3-5 cm only.

Pull-through—In this chapter the modified Soave or the Boley Scott transabdominal pull through procedure will be discussed.

Determining the part of bowel to be pulled down—If the leveling colostomy had been done at the first stage, then the stoma should be pulled down during the pull-through.

If the right transverse colostomy and sero-muscular biopsy was done in first stage then report of the sero-muscular biopsy, proximal to the gross transitional zone is important. If it showed presence of the adequate number of ganglion cells along with the absence of the hypertrophic nerve fibers, then the bowel just proximal to biopsy site can be pulled down safely during the second stage. If the seromuscular biopsy showed the absence of ganglion cell, then a frozen section biopsy will be required intra-operatively. Similarly, during the primary pull-through procedure, the level of the ganglionic bowel should always be confirmed by the frozen section biopsy.

SURGICAL TECHNIQUE

General anesthesia supplemented with caudal analgesia is used. Child is placed in the lithotomy position. It enables the surgeon to achieve abdominal and perineal approach easily. Child's buttock's are brought to the end of the operating table and raised with a small roller or the sand bag to improve the accessibility of the anal region for dissection.

Abdomen, perineum, and thighs are prepared and draped. Appropriate sized Foley's catheter is inserted into the bladder. An adequate hockey-stick or left lower abdominal curved skin-crease incision is made (Fig. 66.2). Incision incorporates the colostomy take down in a two-stage procedure. The abdominal muscles are divided and peritoneum is opened to enter the abdominal cavity. The diagnosis is reconfirmed. The level of the ganglionic bowel is determined.

The lateral peritoneum over the mesosigmoid is incised laterally to mobilize the colon. Both the ureters are identified so as to avoid an inadvertent injury. Colon is mobilized proximally and also distally upto the reflection of the pelvic peritoneum. The vascular supply to the ganglionic bowel is preserved carefully. The bowel is freed and dissected of the pelvic peritoneum from anterior and lateral sides. Traction is applied with the atraumatic clamps on either side of distal bowel. The ganglionic bowel is mobilized proximally, preserving the marginal vessels. Adequacy of mobilization is ascertained by the ability to bring the ganglionic bowel over to the pubis bone easily to have a tension free anastomosis. This usually matches with the length of the bowel sufficient to reach the anal verge. Occasionally, the mesentery is foreshortened and it is necessary to ligate the inferior mesenteric artery and or the left colic artery, so that the vascular supply of the descending colon is based on the left branch of the middle colic artery alone or supplemented by the left colic artery or its ascending branch, through the arcades forming the marginal artery of Drummond. Given an opportunity, the inferior mesenteric artery and its continuation as the superior rectal artery, is preserved to maintain the rich blood supply to the sero-muscular cuff in the pelvis.

Endorectal dissection is then started about 2 cm. below the peritoneal reflection (Figs 66.3A and B). Soave in his original description used the infiltration of local anesthesia into the seromuscular coat of rectosigmoid segment to facilitate the endorectal dissection. Endorectal dissection begins by completely clearing the mesentery and the fat over a 2 cm. length of bowel. The seromuscular layer is incised transversely all around with the diathermy, taking care not to go deep and enter the mucosa. This requires
experience to get into the submucosal plane of dissection. Once the submucosal layer is reached, the seromuscular layer is dissected down gradually circumferentially. Cotton tip applicator is used to separate the seromuscular layer bluntly from the deeper submucosal layer.

As the muscular cuff begins to develop, a uniform traction is applied to the mucosal tube with right angled clamps. This dissection is facilitated by a well co-ordinated traction and counter-traction to the mucosal and seromucular tube. Communicating vessels in the submucosal plane are picked up individually and cauterized carefully, preferably with the bipolar forceps to avoid mucosal perforations. All bleeding points in the muscular cuff are cauterized. Previous history of enterocolitis and the rectal biopsy cause some difficulty in mucosal tube separation. Dissection is carried from the abdominal side in the pelvis to reach 1-1.5 cm. above the dentate line. As one goes deeper down in the pelvis, the dissection becomes more difficult near the attachment of the anal sphincter with the anal mucosa. At this stage, one may stop the dissection from the abdominal side and plan to complete the final part of the dissection from the perineal route under vision (described as below).

The bowel is transected above the peritoneal reflection in between clamps. The aganglionic bowel is now excised and the edges of the ganglionic bowel are cleaned with povidone iodine and readied to be delivered to the perineum through the seromuscular tube. The posterior wall of the seromuscular cuff is slit open for 3-4 cm in the midline to prevent ring effect.

**Perineal Stage**

The anal dilatation is done as the first important step. Then the anal mucosa is everted with thick silk sutures and anchored at four corners in position. A circumferential incision is given in the anal mucosa with the diathermy, about a cm from the dentate line. This is just to mark the lower limit of the dissection of the mucosal sleeve and the level of the coloanal anastomosis.

Narrow retractors are placed in the anal canal and the transected end of the mucosal tube is everted out onto the perineum by a Kelly’s clamp. The mucosa is separated from the underlying muscle, if any, till the circumferential incision already marked. With a Kelly's
clamp, the ganglionic bowel is brought down. The assistant at abdominal end holds the cut edges of the muscular cuff and ensures that the bowel is not twisted while it is being pulled down. To avoid the possibility of retraction, the outer (seromuscular) wall of the pulled colon is sutured with the inner (muscle) wall of the cuff, about half a cm above the coloanal anastomosis at 6-8 places. The coloanal anastomosis is then completed using fine interrupted Vicryl/PDS absorbable sutures between the full thickness of the pulled colon and the cuff and the mucosa junction (Fig. 66.4). The colon is now pulled back in the abdomen to invert the neorectum back into its position. The muscular cuff is sutured with the pulled through colon at the anterior and the lateral edges.

A Penrose drain used to be placed in the past in between the pulled colon and the cuff to avoid an hematoma or the abscess formation. With the availability of better antibiotics and refinement in surgical techniques, it is not practiced now. Similarly, the abdomen wound is closed without any drain, unless the dissection has been difficult resulting in gross contamination.

**POSTOPERATIVE CARE**

Postoperative monitoring of vital parameters is done. Adequate pain relief is ensured. Postoperative hemoglobin, blood urea, and serum electrolytes are monitored. Patient is kept on maintenance intravenous fluids. Intravenous broad spectrum antibiotics are given as per the institutional protocol. Patient is kept nil per orally and on continuous nasogastric drainage till the return of the bowel movement. Patient is discharged once the oral intake is adequate. Rectal examination is performed after 3 weeks very gently to assess for the anastomosis. The parents are taught to start anal dilation starting twice a day. The size of dilator is increased every week till the appropriate sized dilator is reached. The frequency of dilation is then reduced gradually over the weeks. The diverting colostomy is closed 6-8 weeks following the pull-through procedure.

**COMPLICATIONS**

**Intraoperative and Early Complications**

1. **Bleeding**– This may be troublesome if the patient has had enterocolitis or the child is older with good musculature and if there is a faecoloma in the dilated bowel. The authors feel that Xylocaine with Adrenaline may lead to postoperative hemorrhage and derangement of the muscle plane and thus do not recommend its use.

2. **Rotation of bowel**– Stool does not come out, can pass a finger from below. Can be diagnosed with a cutoff sign on Barium.

3. **Inversion of the cuff**– if one is not careful. This may lead to obstructive symptoms. It may be diagnosed as a lump on per rectal examination.

4. **Injury to the ureter.**

5. **Injury to the vas.**

6. **Intestinal obstruction.**

7. **Cuff abscess.**

8. **Wound infection.**

9. **Early anorectal stenosis.**

10. **Anastomotic leak.**

11. **Perineal excoriation/Edema.**

12. **Frequency of stool.**

13. **Faecal fistula.**

14. **Mucosal prolapse:** This happens if the extension of dissection is done upto the cutaneous ring. It results in visible mucosa and mucosal secretions and wet perineum.

15. **Stricture at the cuff level**– It takes time to develop and may become apparent on per rectal examination performed after 3 weeks or later. It is best avoided by slitting the cuff vertically in the midline posteriorly.
Complications Specific to Classical Soave

1. Nuisance—bowel is hanging out, requiring redo surgery to excise the redundant bowel. However, the procedure has merit in cases with anticipated risk of retraction.
2. Septicemia.
3. Ischemia.
4. Putrefaction of bowel.

Late Complications

1. Enterocolitis.
2. Incontinence.
3. Constipation.
4. Intestinal obstruction.
5. Urinary and sexual dysfunction.
6. Residual disease.
7. Ischemic aganglionosis.
8. Stricture.

Enterocolitis—The incidence of enterocolitis post pull-through ranges from 2-40% but is typically between 20-30%.

Incontinence—A properly performed pull-through procedure in a mentally normal child, should not have complication like incontinence. Still, the incidence of incontinence ranges from 3-8% in various series. A higher incidence of postoperative incontinence is noted in mentally retarded patients. Yanchar, et al studied the long-term outcome in Hirschsprung’s disease patients undergoing endorectal pull-through in 37 patients. Only 64% patients were interpreted as having normal stooling habits. Most children had significant improvement in fecal continence with time. Fortuna et al also found that though short-term continence was less than 50%, all of them (100%) became continent by 15 years after pull-through surgery. So, et al found that 79% of operated children had normal bowel control following pull-through. There has been a concern about the effect of prolonged traction of sphincter muscle during transanal approach.

Kvan Leeuwen et al did not find any difference in the number of stools per day or manometric findings between perineal and abdominal approach. Other series also suggest reasonably good outcome. In general, the continence improves with age.

Constipation—Incidence of constipation has been reported up to 30% after a pull-through, but most of the patients can be managed by dietary modification and oral medication. Mechanical causes, e.g. stricture, twist of the bowel, ischemia resulting in fibrotic anorectum, should be ruled out in all such cases. The retained muscular cuff may also contribute to obstruction as it might form a ring around the pulled colon.

Sexual and urinary dysfunction—As the endorectal dissection remains mainly inside the muscular cuff, the procedure is not associated with the risk of nerve injury so, the incidence of sexual and urinary dysfunction is almost nil.

OUTCOME AND COMPARISON BETWEEN DIFFERENT PROCEDURES

Fortuna et al analyzed complications and long-term outcome following operative treatment for Hirschsprung’s disease and found more complications following the Soave pull-through than the Duhamel pull-through. Minford et al compared the morbidity and medium term functional outcome of the Duhamel operation and the transanal endorectal pull-through.
The functional outcome was similar in both the groups. Klein MD et al. published their 30 years experience of Hirschsprung’s disease and found highest incidence of post-pull-through enterocolitis with the Duhamel procedure, less with the Swenson, and least with the endorectal pull-through. In contrast, the incidence of complications other than enterocolitis, was highest with the Swenson, and least with the transanal endorectal pull-through.28 Yanchar et al. (1999) did not find significant difference among the types of pull-through procedures except constipation, which was found more following Duhamel pull-through.22,25

**REDO FOR SOAVE-REDO PULL-THROUGH**

Redo pull-through may be required for retained segment of aganglionic bowel, acquired aganglionosis due to ischemia, severe anastomotic stricture, or intestinal neuronal dysplasia. Overall outcome following redo pull-through is not as good as after initial pull-through. If there has not been any incidence of severe enterocolitis then redo endorectal pull-through can be attempted. Otherwise, Duhamel or Swenson procedure is chosen as redo endorectal pull-through. According to Langer JC et al. Duhamel procedure is the preferred redo procedure for technical reasons.29 Gobran et al. evaluated the safety and efficacy of transanal endorectal pull-through for patients with persistent symptoms after pull-through for Hirschsprung’s disease.30 There were no anastomotic deaths or anastomotic leakage.

**AUTHOR’S EXPERIENCE WITH THE SOAVE’S PROCEDURE FOR HD**31-38

A total of 128 patients of HD were treated between 1981-2005 by various techniques of Soave’s endorectal (Boley Scott) procedure (Table 66.1). The diagnosis was based on barium enema, rectal biopsy and preoperative frozen section. Immunohistochemistry was used only in few selected cases with diagnostic challenge. Anorectal manometry was useful in diagnosis of Ultrashort segment HD, 7 in this series. The age of the patients ranged from 2 days to 24 years. Majority of them (70%) presented beyond infancy and the male to female ratio was 10:1. The rectosigmoid region was involved in 101, rectum in 10, transverse or ascending colon in 3, total colon in 12 and whole gut in 2 cases. Associated anomalies included hypospadias (2), and hydrometerocolpos, undescended testis and colonic atresia in one each. Three children required sigmoid colotomy as the initial procedure to remove the large and hard fecoloma that had failed to be cleaned by all other methods. Of the 128, endorectal pull-through procedures, 7 were post-myectomy for HD done elsewhere and 12 were cases of total colonic aganglionosis (4 our own and 8 referred from outside). A Martin’s modification of ileocolic anastomosis and ileoanal endorectal pull through was done using the only the ileum for the anastomosis at the anal verge (Figs 66.5A and B). The classical Soave’s procedure was done in the beginning of the series in only 10 patients. Recently, 16 patients were selected for the transanal endorectal pull-through.

Two cases underwent modified technique of ileal loop endorectal pull-through, for the complicated type of rectosigmoid variety of HD. A carefully selected ileal loop based on its pedicle was bridged in between the ascending colon and the anus, as described and published by the authors in 1989. Both these cases had undergone transverse colostomy for rectosigmoid type of HD under 1 year of age. They were then lost for follow-up while still being on colostomy, for 12 and 7 year respectively. Distal cologram showed the colon distal to the colostomy site quite thin, narrow in caliber and shortened. At surgery, the distal unused colon was found atrophied and the blood supply was quite fragile making it unusable for the pull-through procedure, despite being ganglionic. The whole of the atrophied colon was excised. A segment of the ileum, appropriate in length on its vascular supply, was selected and bridged in between the ascending colon (proximal to the transverse colostomy) and the anal verge. The ascending colon stoma was closed later.
Soave’s (Boley Scot) Endorectal Pull-through

Sixteen of these underwent redo pull-through (12 of these referred from outside to our center with various complications). Anal dilatations were advised in all for about 3 months after surgery. However, surgery related complications included anastomotic stricture in 2, anastomotic stenosis in 1, adhesive obstruction in 3, wound infection in 2, residual disease in 2, fecal fistula in 1, ureteral injury in 1 (case of long segment HD undergoing multiple surgeries), bleeding in 1 requiring a redo laparotomy and the bowel rotation in another who had continued with constipation. In this case, the finger could be negotiated beyond the anal verge. The rectal washout could be performed but there was no return. It was the barium study that showed a twist in the bowel in the pelvis. A de-twist and redo colocolic anastomosis (without dismantling the pulled through anastomosis) was successful.

In the authors’ experience, an endorectal (Boley Scot) procedure was always found feasible for all types of failed cases of HD including Duhamel and Swenson, requiring redo procedures.

Average frequency of stools in the initial postoperative period was 5.6 per day which gradually reduced to 2.4 at 3 months. Nine of the patients were treated after the age of 15 years, one of them aged 24 years after marriage. All these were performed as the staged pull-through with an initial proximal transverse colostomy. Incidentally, HD related enterocolitis has not been common in our practice and so also the postoperative incontinence or the constipation.

The authors, the parents and the patients have been quite happy with the procedure and the outcome. However, two patients with total colonic aganglionosis undergoing endorectal pull-through had high frequency of stools, recurrent enterocolitis, perianal skin excoriation and incontinence, requiring many hospital admissions, blood transfusions, antibiotic courses. The life has truly been miserable in both these. They have been advised for permanent diversion.

The transanal endorectal pull-through (TEPT) procedure was described by De la Torre and Ortega in 1998. All the components of the pull-through procedure starting from mucosectomy, colectomy, and anorectal anastomosis were performed in five patients with Hirschsprung’s disease (HD), only by transanal route. The authors reported their initial results using this approach, all with normal bowel movements. The procedure of doing a primary pull-through in patients with HD, without any diversion, has gained a wide acceptance, since its successful report by So et al in 1980.

**INDICATIONS FOR TEPT**

1. Classical Short segment Hirschsprung’s disease, involving rectosigmoid region.
2. Ultrashort segment Hirschsprung’s disease.

**There is a selection criterion before the patient could be considered for TEPT**

These include:

1. The TEPT procedure can be done at any age, including even in the neonatal stage. However, the operation is most commonly performed in infants as the proximal bowel is still not much dilated.
2. A barium enema study must suggest the diagnosis of HD and also the level of aganglionosis in the A-P, lateral films and the late films. In newborns, the presence of residual barium in the 24 hour delayed film is suggestive of Hirschsprung’s disease (Fig. 67.1).
3. The rectal biopsy should confirm the diagnosis of HD should have been confirmed by.
4. The HD disease should be a short segment disease, limited to the rectosigmoid region. Rarely, the HD disease that extends up in the descending colon, can be approached with TEPT but this is not a commonly considered indication for TEPT (Fig. 67.2).
5. The patient with thick and dilated bowel is normally unfit for this procedure. However, most infants with HD should be fit to undergo TEPT, as the bowel is still not much dilated.
6. TEPT can also be performed in children who have dilated bowel, but as a part of three stage procedure. First, a proximal colostomy should be done to decompress the bowel. Then after about 3 months, size of the bowel is assessed by barium study. Once confirmed that the bowel has reduced in size, a TEPT can be performed as the definitive
procedure. Then, the colostomy is closed after 6-8 weeks as the final stage.

CONTRAINDICATIONS FOR TEPT

1. Operated case of Hirschsprung’s disease with Duhamel or Swenson procedure.
2. Grossly dilated bowel in an older child.
3. Patient without a confirmed diagnosis of HD.
4. Patient with a long segment Hirschsprung’s disease.
5. Patients with total colonic aganglionosis (TCA).
6. Any history of bleeding disorders.

Relative Contraindications for TEPT

1. Obese child with fat laden mesentery. It is difficult to manage the thick mesentery by transrectal route.
2. The blood vessels in severely anemic patients with hypoproteinemia, are fragile and easily get torn during manipulations, resulting in bleeding and hematoma formation.
4. Disease extending beyond the rectosigmoid upto the descending colon.

PREOPERATIVE ASSESSMENT

1. The diagnosis is confirmed with a rectal biopsy.
2. A barium enema establishes the extent of the disease. TEPT is feasible only for short segment disease and if the proximal colon is not grossly dilated. If the bowel is dilated, bowel washes are given regularly for about a week to allow the dilated bowel to shrink so that the same could be accommodated at the anus for the colorectal anastomosis.
3. If the bowel remains grossly dilated on a repeat Barium performed after adequate preparation for 3-6 months, then it may be worthwhile to perform a three stage procedure and allow the distal bowel to shrink. If the patient has had repeated episodes of enterocolitis, then also a three stage procedure is preferred.
4. Children referred with a colostomy, if the bowel is not too dilated, TEPT may be planned, followed by the colostomy closure after 6-8 weeks.

PREOPERATIVE PREPARATION

1. To remove the fecalomas, if any,
2. To prepare the colon with bowel wash outs.
3. Only clear fluids are allowed the day prior to surgery to keep the colon clean.
4. Polyethylene glycol (Peglec-75-80 ml/kg) orally or through nasogastric tube over 3-4 hours is also given the day prior to surgery to ensure that the bowel is clean during surgery. If the colon is loaded with fecal matter, Polyethylene glycol may be given for two days.
5. In older children, half the dose of Peglec, may be repeated on the same day too. Clear water may be allowed even after the polyethylene glycol so that the remnants are washed off and do not stick to the bowel.
6. Serum electrolytes may be monitored on daily basis and on the morning prior to surgery and corrected accordingly.

The TEPT procedure should preferably be done only by the trained pediatric surgeons with some experience in the field of treating patients with HD. Each step is important, specially the initiation of the formation of the mucosal tube through the transanal route. It requires surgical technique, expertise, patience and acumen for decision making, to perform mucosectomy, colectomy and the endorectal pull through. One should not hesitate to combine with the abdominal approach, if the need be, to avoid complications. To achieve this purpose, Takegawa et al in 2005 developed an experimental model in
rabbit, for purposes of training and improving the surgical techniques for TEPT, described by de la Torre and Ortega.4

**SURGICAL TECHNIQUE**

General anesthesia is used. It may be supplemented with caudal analgesia depending upon the anesthesiologist’s choice. The baby is placed in jack knife or the lithotomy position, depending on the surgeon preference. However, in babies with the possibility of the additional use of abdominal incision, a lithotomy position is preferred. The baby’s bottom is brought to the end of the operating table and raised with a small support or a sand bag to improve the accessibility of the anal region for dissection. The abdomen, perineum, and thighs are prepared and draped, so that in case an abdominal incision is needed, the field is available and easily accessible. Appropriate sized Foley’s catheter is inserted into the bladder.

The first step is to assess the cleanliness of the rectum. If in doubt, rectum should be cleaned with savlon or povidone iodine gauze swabs. The next step is to perform a gentle and slow anal dilatation with one finger at a time and dilating according to the patient’s age and the bowel size.

Stay sutures are applied to mark all four quadrants at 3, 6, 9 and 12 o’clock position. The suture at 12 o’clock position is placed with care to remain close to the anal verge so as not to injure the urethra in male patients. Retractors are placed to show the analmuco-cutaneous junction. Initiation of dissection at the anal verge to separate the mucosa from the muscle coat is the most difficult part of the TEPT. This requires experience, patience and technical innovative skills.

The Dentate line is identified and the mucosa deep circumferential incision is given about 1-1.5 cm, proximal to the dentate line. Mucosa may be marked with stay sutures all around to facilitate dissection. The stay sutures help to distribute equal tension and prevent the tearing of the mucosa.

The dissection proceeds in the submucosal plane slowly all around tackling the vessels as they come, taking care not to injure the mucosa (Figs 67.3A and B). This is done cephalad upto the level of the peritoneal reflection. When the dissection has reached this level, there is a loose fold of tissue that can be well appreciated at the posterior limit of the dissection. At this point, the muscle cuff is incised transversely in between the stay sutures. Then it is incised all around circumferentially and the peritoneal cavity is entered.

A vertical incision is made in the muscular cuff in the midline posteriorly from above downwards to make it V shaped as the edges of the muscle cuff separate out. It is now stretched with the fingers to achieve adequate space in the pelvic for further dissection of the bowel from now onwards.

The dissection is made full thickness all around the bowel. The attention is focused on dealing with the mesentery of the sigmoid colon and the vessels...
running in it. With a gentle pull on the bowel, the mesenteric vessels are identified and divided either by ligation or cauterized securely, making sure that the vessels do not get retracted. This is the critical step and is repeated till all the main vessels in the mesentery have been divided, sufficient length of the bowel has been mobilized well above the transition zone, which can be visibly appreciated.

The level of dissection can be assessed clinically as well as confirmed with a frozen biopsy taken from the seromuscular coat proximal to the visible transitional zone. Enough margin of error should be given to the stretching caused during the process of mobilization of the bowel. That is why, when the transanal endorectal pull-through is performed in the neonates, the gross examination and sampling is more accurate, as the dissection and mobilization is much easier (Fig. 67.4). This leads to a clearer pathology report.³

The limitation of this process is due to the fixation of the descending colon in the retroperitoneum that does not allow further mobilization of the colon by transanal route.⁵ Ideally, TEPT procedure has the advantage of avoiding injury to the pelvic muscles and nerves.⁶

The coloanal anastomosis is begun after ensuring hemostasis inside the muscular cuff. The sutures are placed in one quadrant at a time through the edge of the mucosa of the anal canal and the full thickness of the pulled-through bowel (Fig. 67.5).

A rolled paraffin gauze or sofrotulle soaked with povidone iodine or antibiotic ointment is gently placed in the rectum for next 24 hours. This serves as a repellent at the neo-anastomosis, helps in achieving hemostasis and avoiding the dead space in between the muscular cuff and the pulled-through ganglionic bowel.

Postoperative monitoring of vital parameters is done. Adequate pain relief is ensured. The rectal pack is removed 24 hours after surgery. Patient is kept nil orally and on continuous nasogastric drainage till the ileus subsides. This may take 1-3 days. The patient is kept on maintenance intravenous fluids and intravenous broad spectrum antibiotics. Perineal hygiene is maintained. Patient can be discharged once the oral intake is adequate and the bowel has moved satisfactorily.

**AIIMS EXPERIENCE ON PRIMARY TEPT**

Primary TEPT was performed in 14 cases from the period 2003-2006. The age range of the patients was 1 month to 7 years. The indications were classical rectosigmoid Hirschsprung’s disease in 11 cases, ultrashort segment Hirschsprung’s disease in 2 cases and a suspected ultrashort segment Hirschsprung’s disease in one case. There was no problem in 11 cases apart from the area where the rectal biopsy had been taken previously in 3 cases. There were problems in reaching the transition zone and the abdomen needed to be opened in 3 cases that were of the older age group. The reasons included a thick mesentery due to chronic anemia in 2 and a missed long segment HD and dilated bowel in one case that was initially suspected to be a case of ultrashort segment Hirschsprung’s disease.
FOLLOW-UP

The rectal examination is done after 3 weeks and the need for anal dilatation is assessed. Dilatation is usually not needed for single stage TEPT as the anal canal has been dilated adequately during operation and the daily passage of stools act as natural dilator. Moreover, the babies have an increased frequency of stool during the initial postoperative period due to the anal dilatation. A weekly calibration may be required for about 6 weeks to prevent anal stricture.

Anal dilatation program is however, very essential in patients undergoing TEPT for the three stage procedure. The anal calibration is done after 2 weeks and the parents are taught to start anal dilation after 3 weeks. The dilatation is first started twice a day. The size of dilator is increased every week till the appropriate size of the dilator is reached. Frequency of dilatation is then reduced gradually. The diverting colostomy is closed 6-8 weeks following the pull-through procedure.

COMPLICATIONS

Early complications

1. Inadvertent mobilization of full thickness of rectal wall.
2. False positive rectal biopsy for ganglion cells.
3. Bleeding per rectum, hemoperitoneum, hematoma formation.
4. Cuff abscess/infection.
5. Increased frequency of stool.
7. Anastomotic leak.
8. Perineal excoriation, redness and Edema.
9. Transient urinary retention.7
10. Pneumoperitoneum.8
11. Peritonitis.8
12. Urethral injury.8
13. Enterocolitis.5

Late Complications

1. Enterocolitis.
2. Fecal Incontinence: There has been a concern about the effect of prolonged traction of sphincter muscle during transanal approach.9 Fecal incontinence is a preventable complication that is likely because of anal canal damage.10 If adequate care is taken during TEPT, to preserve the anal canal, incontinence should not occur. Postoperative soiling is not uncommon and may be present without frank incontinence.11
3. Constipation if the muscular cuff is longer than 10 cm or not incised in the midline posteriorly. The muscular cuff on healing may form a fibrotic ring encircling the pulled colon. This is manageable with dilatation program either with the finger or with the metal dilators. However, utmost care is needed while doing the dilatations as bowel perforations have resulted. Constipation can be managed by dietary modification and oral medications.
4. Stenosis at the analcolic anastomotic site is more common in patients undergoing three stage pull through procedures. Anal dilatation is helpful.
5. Residual disease may be left if the surgeon has not been careful and has pulled the “normal looking bowel” without confirming the frozen section biopsy report. Sometimes even the frozen biopsy may deceive. The biopsy not only should confirm the ganglion cells but also ensure absence of hypertrophied nerve fibers.

OUTCOME

The anorectal functions after TEPT surgery are reported as normal. The stooling disorders are seen in a few and are probably related to the—(a) decrease or disappearance of the sigmoid loop, (b) dysfunction of the “neo-rectosigmoid”, (c) an open and fixed anorectal angle and (d) achalasia of the internal anal sphincter.7,11 This has also been confirmed on postoperative defecography.11

Patients with TEPT also have increased frequency of stool. The postoperative mean total gastrointestinal transit time (TGITT), the left colonic transit time (LCTT) and rectosigmoid colonic transit time (RSTT) measured in 58 patients, have shown to be significantly shorter than the preoperatively values (P < 0.01) and similar to the control group. The rectoanal inhibitory reflex is regained in due course of time but only in some patients.11 A gradual recovery could be noted in the stooling patterns with the passage of time after surgery.12 The stooling disorders are less common and the recovery is also faster in patients with short segment involvement of the bowel and if the surgery has been done at the younger age.12 The normal
urodynamic studies are reported in children 6 months after single stage transanal endorectal pull through.\textsuperscript{7}

The integrity of the anorectal sphincter after TEPT is a poorly understood and controversial issue. Recently, three dimensional, vector manometric studies have been done to assess the same.\textsuperscript{9} The computerised 8-channel vector manometry allows a segmental, 360 degrees analysis of muscular defects along the anal canal. It has been reported that TEPT preserves the functional integrity of the anorectal sphincter complex and has a favourable clinical and manometric outcome.\textsuperscript{9}

Early results show that primary transanal endorectal pull-through is feasible and safe for the majority of the cases of HD with the rectosigmoid variety.\textsuperscript{12-14} Although follow up is still relatively short, the preliminary results seem quite favorable and cost effective.\textsuperscript{15} TEPT, no wonder, has become popular and the first choice of the experienced surgeons.

The long-term outcome following TEPT remains obscure. A hidden mortality has been reported during the long-term follow up of patients after this procedure. The possible causes for death are metabolic problems, enterocolitis, severe pneumonia and septic shock of unknown etiology. Some patients have died suddenly without a cause being found.\textsuperscript{16} Thus, a close follow-up of all patients is strongly recommended after the one stage transanal endorectal pull-through especially those with general poor health and belonging to the poor socioeconomic region.\textsuperscript{16}

Transanal Endorectal Pull-Through (TEPT) is characterized by no scars, shorter operating time, less bleeding, less postoperative pain and less discomfort, shorter hospital stay, less morbidity and earlier recovery than the similar abdomino-perineal pull-through procedures.\textsuperscript{14,17} There is also a low incidence of operative and postoperative complications in experienced hands.\textsuperscript{14} The hazards and the morbidity associated with laparotomy and diversion colostomy may be avoided with a one-stage technique adopted in majority of children (70-80\%) with the rectosigmoid variety of Hirschsprung’s disease.\textsuperscript{13,17}

**REDO TEPT**

The TEPT can also be used for the redo procedures and has been reported to be successfully performed in 18 symptomatic patients requiring redo procedures for residual aganglionosis.\textsuperscript{18} This TEPT approach may be combined with transabdominal mobilization of the intestine, if the need be depending on the length of the residual aganglionic segment.\textsuperscript{18,19} A diversion colostomy should be seriously considered for the redo cases, either as the preliminary procedure or combined with the main pull-through. It makes the procedure safer and complication free.

**THE MUSCULAR CUFF**

The use of a long muscular cuff of 8-10 cm is not unusual while performing the TEPT procedure. However, it must be slit open posteriorly to give it a V shape. There is a recent trend to use a short muscular cuff for the TEPT. Rintala et al and Langer et al, have used a shorter cuff of only 2-3 cm, without the need for a slit in its posterior wall, and with similar postoperative results.\textsuperscript{20} Whether this is important to reduce the postoperative complications, especially the incidence of enterocolitis, is debatable. However, may be that a long rectal muscular cuff might increase the incidence of postoperative enterocolitis and constipation. This may be obviated by a simple modification and perform the transanal pull-through procedure with an oblique mucosectomy and an oblique anastomosis, with a short and split muscular cuff. This has been associated with much less postoperative anastomotic stricture as compared to that with the conventional transanal procedure.\textsuperscript{21}

Complete bowel continence at one year followup after operation was also better (92.1\% v/s 86.6\%).\textsuperscript{21} An experimental study has been done to compare the results of transanal endorectal pull-through with the laparoscopic assisted transanal pull-through.\textsuperscript{22}

Langer et al reported the experience with the use of Laparoscopic assisted TEPT in 1999.\textsuperscript{23} The results showed that laparoscope was helpful to confirm the orientation of the bowel and achieve adequate hemostasis. Though, the transanal colectomy can be performed with or without the laparoscopic assistance, the advantages of laparoscopic assistance include: 1) more exact determination of transitional zone; 2) easier separation of peritoneal reflection, 3) better control of final position of the colon; 4) minor traction on the perineal muscles. This procedure also gives excellent clinical results and permitted early postoperative feeding. The hospital stay is also short.
Langer et al compared the results of open versus laparoscopic assisted pull-through and the primary transanal versus laparoscopic assisted procedure. It was found that with the TEPT, the hospital stay was short, treatment cost was less and there was no increased risk of complications. It was also highlighted that the routine use of laparoscopic visualization or mini-laparotomy was not always necessary but should rather be reserved for children who are at higher risk for missing the long segment Hirschsprung’s disease.24

The short-term results after TEPT are the same as seen after the transanal mucosectomy combined with abdominal approach.20 When compared with the Duhamel procedure, the TEPT also had similar medium-term functional outcome. TEPT is however, more suitable for single-stage neonatal treatment of HD due to less dilatation of the bowel.25,26 Al-sawaf et al showed that the stool pattern and enterocolitis scores were somewhat better in the TEPT group as compared to the open group.27 As TEPT requires more stretching of the anal sphincters, the postoperative continence score has been found better with the use of the abdominal approach.27 In most series, the overall functional outcome following properly performed TEPT in selected group of patients has been highly satisfactory and comparable with other established procedures.17,24,28-33

HISTORICAL OVERVIEW

Chronic interstitial enteritis has been documented in the literature since the nineteenth century. Crohn, Ginzberg and Oppenheimer first classified the clinical and pathological manifestations of "regional ileitis" in 1932.\(^1\) Subsequently, the protean intestinal and extra-intestinal manifestations of Crohn's disease (CD), with its inconsistent response to medical therapy and its strong recurrent tendency despite surgical removal of all obvious disease, has been well described. However, etiology remains obscure and directed therapy absent. Treatment remains broadly symptomatic, supportive and suppressive. While mortality rates have decreased, morbidity remains high.

Although there are many similarities with the disease as it occurs in adults, various aspects of diagnosis and management differ in childhood, including the effect and treatment of the disease with regards to growth and development.

EPIDEMIOLOGY

Symptoms of CD begin during childhood or adolescence in 20-25% of all patients, with a peak incidence in the second and third decades of life.\(^2\) Since the original description of CD, its incidence relative to ulcerative colitis (UC) has increased dramatically. In studies of Scottish and Welsh children under 16 years of age, the incidence of CD has risen from 1.3-3.1 per 100,000 with UC remaining stable at 0.7 per 100000.\(^3,4\) The age-specific incidence of CD in North America in 1984 for 10 to 19-year-olds was approximately 3.5 per 100000 and of UC, 2.0 per 100000.\(^5\) In 1993, the prevalence of CD in a British childhood population was 16.6 per 100,000 and of UC, 3.4 per 100000.\(^3\) There is no evidence that the age of onset of CD is decreasing.\(^6\) Most pediatric cases occur between ages 16 and 20 years, with less than 5% of cases occurring under 5 years of age and with only rare reports of CD in infants.\(^7\) There is an equal incidence of inflammatory bowel disease in males and females.\(^6\)

ETIOLOGY

The etiology of both CD and UC remains obscure. Familial and ethnic predisposition to these diseases has led to an intense investigation of genetic associations. At the time of diagnosis, the likelihood of detecting inflammatory bowel disease in a first-degree relative of a proband is 5-25% and the risk to siblings of patients with CD is 17-35 times greater than the general population.\(^7,8\)

Support for an autoimmune basis for CD comes from reports that bone marrow transplantation following myeloablation appears to cure CD. In a long-term follow-up study, four of five patients with leukemia and CD remain disease-free up to fourteen years after bone marrow transplantation.\(^9\) The one patient who had a relapse of CD two years after transplantation had mixed host/donor hemopoietic chimerism with persistent host immunity. An autoimmune etiology would also explain the familial and ethnic preponderance of inflammatory bowel disease.

Since the recognition of CD, attempts have been made to link its cause to a variety of environmental agents and microorganisms.\(^10,11\) However, to date, no persistent direct link to a multitude of transmissible agents or soluble mediators of inflammation has been established.
Pediatric Surgery—Diagnosis and Management

It is more likely that CD is a genetically based autoimmune disease that becomes clinically activated by an environmental trigger. Genetic analysis may someday be used to prognosticate the course of an individual's inflammatory bowel disease and provide specialized therapy or avoid ineffectual treatment.12

PATHOLOGY

In children and adults, CD may manifest as an acute, subacute or chronic inflammatory condition transmurally affecting the gastrointestinal tract anywhere from mouth to anus. Three general patterns of gross bowel involvement dominate: (a) the terminal ileum with variable segments of right colon is affected in 50-60% of children; (b) approximately 30-35% have small bowel involvement only, mostly in the terminal ileum; (c) isolated involvement of the colon and rectum is seen in 10-15% of cases.13 Perianal and perineal involvement occurs in 25% of children, often preceding intestinal symptoms, but occurs less frequently than in adults.14 Biopsy of macroscopically uninvolved areas frequently reveals evidence of microscopic inflammation.15 There is a high incidence of upper gastrointestinal tract involvement in children with CD with up to 42% having lesions of the esophagus, stomach and duodenum.16

Macroscopically, the mucosa has a cobblestoned appearance interspaced with normal appearing skip segments. Aphthous ulcers may be seen in the mouth. The intestine appears thickened secondary to inflammation with creeping fat. Strictures causing obstruction, fistulas and abscesses may be encountered. Microscopically, the entire bowel wall thickness is involved with a chronic non-caseating granulomatous process that differentiates the disease from UC. Giant cells may be seen.

Gastrointestinal Manifestation

Initial mild inflammation may be heralded by vague symptoms such as early satiety, anorexia and behavioral change. More severe disease presents with anemia, weight loss, abdominal pain or diarrhea, but symptoms manifest according to the affected site. Malabsorption secondary to mucosal inflammation or bacterial overgrowth results in diarrhea. Children with small bowel disease may have altered enterohepatic bile salt circulation exacerbating their diarrhea, and an increased incidence of mineral and vitamin deficiencies.19 Colonic involvement presents with diarrhea, abdominal cramping and tenesmus. Rectal bleeding occurs in 20-30% of cases and may be indistinguishable from UC. Perianal disease is often associated with Crohn’s colitis and may help to distinguish between CD and UC.20-22

Alternatively, patients may present with complications of the disease such as bowel obstruction, fistulas, abscesses or perforation.

Extraintestinal Manifestation

Pathology of every system in the body has been described in association with CD.17 The majority of CD children (50-80%) have systemic manifestations such as fever, fatigue and weight loss.18 Bone and joints involvement occurs in 13-22% of patients. Skin disease occurs in 10-14%, and the oral mucosa is often affected by aphthous stomatitis that follows the course of intestinal disease.23,24 Ocular disease is found in 30% of children. Long-term ophthalmic surveillance is recommended in all children with inflammatory bowel disease.25 Liver disease is less common in children than adults. but 15% of children will have abnormal serum transaminases during the course of the disease.17,26 Kidney and gallstones may occur secondary to malabsorption. Hypercoagulable states with thrombocytosis are commonly associated with active disease and hematological parameters may be used to monitor disease activity.23,27

Growth Abnormalities and Nutritional Deficiencies

Extraintestinal manifestations with growth retardation result in more subtle presentation. These patients may have poor growth and delayed puberty with non-
specific signs of intestinal inflammation such as anorexia and general malaise. The pubertal growth spurt accounts for about 16% of normal adult height with a doubling of body weight. Such accelerated growth requires increased nutritional intake that cannot be met by children with active disease, often resulting in permanent deficits in adult height and maturation. Delayed sexual maturation is also a common feature.

Inadequate caloric intake is the single most important factor in the pathogenesis of growth failure. Fever and sepsis increase energy requirements, but most patients have normal basal energy requirements. Vitamin and trace element deficiencies are seen in 20-40% of children with CD. Endocrine hormone levels are generally normal and are not the cause of growth failure. Therapeutic interventions, such as extensive small bowel resection and prolonged corticosteroid and immunosuppressive drug administration, contribute significantly to malnutrition and growth failure. Growth failure needs to be aggressively treated and should influence acute and long-term medical and surgical management decisions.

DIAGNOSIS

Early diagnosis of CD in a child requires a high index of suspicion. The most frequent presenting symptoms include diarrhea with discharge of blood or mucus, abdominal pain, nausea, vomiting, weight loss, fever and general malaise. Signs of malabsorption are found in 60% of children and 10% are growth retarded at diagnosis.

History and Physical Examination

A detailed history including gastrointestinal and extraintestinal manifestations, growth, sexual development, family history, recent infections and antibiotic use should be obtained. Physical examination should include a careful abdominal examination including inspection of the mouth and perineum. Signs of extraintestinal manifestations such as uveitis, clubbing, skin rashes and arthritis should be elicited. A detailed assessment of growth, development and nutritional status, often neglected in surgical practice, should routinely be performed in the diagnosis and follow-up of all inflammatory bowel patients. Height, weight, percent height for age, growth velocity and standard anthropometric measurements should be recorded at each visit.

Laboratory Assessment

Laboratory tests are not diagnostic in inflammatory bowel disease and cannot differentiate between Crohn’s colitis and UC. However, they are useful in monitoring disease activity, nutritional state and effect of therapy, and may exclude other causes of mucosal inflammation such as infectious agents. Anemia (70% of cases), leukocytosis (60%), thrombocytosis (60%), elevated erythrocyte sedimentation rate (80%) and hypoalbuminemia (60%) are most commonly seen in active CD. More specialized tests of disease activity are indicated in clinical studies but not routinely used in patient management.

Nutritional status is monitored by measuring serum proteins with rapid turnover (albumin, pre-albumin, retinol binding protein, transferrin), vitamin (B12 and A,D,E,K) and trace element levels (folate, iron parameters, calcium, phosphate, magnesium and zinc) as well as liver function tests.

Infectious diseases may mimic inflammatory bowel disease. The presence of infectious pathogens mandates treatment, but does not exclude the diagnosis of inflammatory bowel disease.

Endoscopy

Endoscopy with biopsy is more sensitive than radiographic studies for initial diagnosis, and detection and monitoring of mild mucosal disease. In the diagnosis of CD, endoscopy should include visualization of the entire colon and terminal ileum. Esophagastroduodenoscopy should also be performed because of the high incidence of upper gastrointestinal disease in children. Biopsies from multiple sites should be obtained to characterize the extent of the disease and to differentiate between CD and UC. Although the histopathologic features of the two are characteristic, none are pathognomonic.

Radiology

Contrast radiographic imaging remains the cornerstone in the detection of fistulas, strictures, perforations and the depth of ulceration. In most
tertiary care centres, double contrast barium enema is reserved for complicated colonic disease or where colonoscopy has been suboptimal.

Small bowel contrast radiographic imaging is important in the initial evaluation and subsequent monitoring of the child with CD. This may be done by upper gastrointestinal series with small bowel follow-through using orally ingested contrast material and insufflation of air per rectum to improve visualization of the terminal ileum, with a sensitivity of 42%. Alternatively, enteroclysis, a small bowel enema with tube placement in the third part of the duodenum, may be used with a sensitivity of 100% and specificity of 98.3%. The former approach is considerably more comfortable for the patient, but the latter allows more detailed imaging of the bowel, especially if combined with esophagogastroduodenoscopy.

Computed tomography, transabdominal and transrectal ultrasonography are useful in identifying extraluminal and pelvic complications such as abscesses, phlegmons and fistulas. With improvements in interventional radiology, both of these modalities may be used therapeutically as well as diagnostically.

MEDICAL AND NUTRITIONAL MANAGEMENT

The goal of medical and surgical therapy is to control symptoms and prevent complications while minimizing toxicity, affording the patient a reasonable quality of life. Because the disease cannot be eradicated, the patient's clinical condition rather than laboratory data or evidence of placebo. Although pediatric data is lacking, following the adult experience, high dose maintenance therapy is required (50-60 mg/kg/d). This may be tapered slowly at about a year until a critical dose is reached where patient symptoms recur.

A variety of immunosuppressive agents are used in treating CD. Corticosteroids are able to induce remission in most patients with small or large bowel disease. Steroids should be used when disease is refractory to other agents, in extensive small bowel disease, in acute severe or fulminant disease, in extraintestinal complications and for postoperative recurrence. High dose steroid therapy is associated with significant side-effects and is usually not effective in maintaining remission of CD. Prolonged use of steroids is not recommended. The only long-term indication is to control chronically active disease resistant to other drugs. In this instance, alternate day low dose steroid therapy after induction of remission with daily steroids, is recommended. Steroid effect on growth is variable. Some patients grow only after steroids induce disease remission, while others only grow once disease is in remission and steroids are tapered.

Side-effects often limit the use of systemic corticosteroids. Budesonide, a new corticosteroid with high topical anti-inflammatory activity and low systemic levels because of rapid hepatic metabolism, is efficacious against active CD in adults. Side-effects are less than with prednisone, but pediatric effects have not yet been determined.

Other immunosuppressive agents include 6-mercaptopurine, azathioprine, methotrexate and cyclosporine. These drugs are used in cases of steroid dependency, steroid toxicity and for medical intractability (particularly when surgery is not feasible). With the exception of cyclosporine, early effects. A variety of 5-aminosalicylate (5-ASA) agents are currently used to induce remission and to prevent recurrence after surgery in CD (17). The action of 5-ASA is topical. Various carrier agents have been compounded to the 5-ASA moiety, which are split off by gut or bacterial action to allow delivery of the active drug at a particular site in the intestine, preventing more proximal metabolism. After inducing medical or surgical remission of CD, a two-year follow-up study showed that these drugs reduced disease recurrence by 50% compared with placebo (48, 49). Although pediatric data is lacking, following the adult experience, high dose maintenance therapy is required (50-60 mg/kg/d). This may be tapered slowly at about a year until a critical dose is reached where patient symptoms recur.

Pharmacologic Therapy

The pharmacologic management of CD often realise on the use of multidrug therapy with synergistic effects. A variety of 5-aminosalicylate (5-ASA) agents are currently used to induce remission and to prevent recurrence after surgery in CD (17). The action of 5-ASA is topical. Various carrier agents have been compounded to the 5-ASA moiety, which are split off by gut or bacterial action to allow delivery of the active drug at a particular site in the intestine, preventing more proximal metabolism. After inducing medical or surgical remission of CD, a two-year follow-up study showed that these drugs reduced disease recurrence by 50% compared with placebo (48, 49). Although pediatric data is lacking, following the adult experience, high dose maintenance therapy is required (50-60 mg/kg/d). This may be tapered slowly at about a year until a critical dose is reached where patient symptoms recur.

A variety of immunosuppressive agents are used in treating CD. Corticosteroids are able to induce remission in most patients with small or large bowel disease. Steroids should be used when disease is refractory to other agents, in extensive small bowel disease, in acute severe or fulminant disease, in extraintestinal complications and for postoperative recurrence. High dose steroid therapy is associated with significant side-effects and is usually not effective in maintaining remission of CD. Prolonged use of steroids is not recommended. The only long-term indication is to control chronically active disease resistant to other drugs. In this instance, alternate day low dose steroid therapy after induction of remission with daily steroids, is recommended. Steroid effect on growth is variable. Some patients grow only after steroids induce disease remission, while others only grow once disease is in remission and steroids are tapered.

Side-effects often limit the use of systemic corticosteroids. Budesonide, a new corticosteroid with high topical anti-inflammatory activity and low systemic levels because of rapid hepatic metabolism, is efficacious against active CD in adults. Side-effects are less than with prednisone, but pediatric effects have not yet been determined.

Other immunosuppressive agents include 6-mercaptopurine, azathioprine, methotrexate and cyclosporine. These drugs are used in cases of steroid dependency, steroid toxicity and for medical intractability (particularly when surgery is not feasible). With the exception of cyclosporine, early
reports of the efficacy of these drugs in children are promising, but more detailed studies are required.56-60
Antibiotics such as sulfasalazine, metronidazole and ciprofloxacin are effective against acute inflammatory flare-ups especially in the colon and perianally, but are less effective in small bowel disease.61 Broad-spectrum antibiotics are used to treat acute infections and their complications such as abscesses. An empiric course of antibiotics in patients with fever and localizing symptoms suspicious for microperforation is useful. Addition of ciprofloxacin to metronidazole synergistically enhances its efficacy in the treatment of terminal ileal and perianal disease.62 Ciprofloxacin is not recommended in children younger than 10-12 years. Metronidazole therapy should be restricted to 6 months as it may cause peripheral neuropathy.63
Developments in immunotherapy appear to be a promising new step in the goal-directed medical therapy of chronic active CD. Proinflammatory cytokines play a significant role in CD. Neutralization of cytokines secreted by cells in the immune system, such as tumor necrosis factor-alpha (TNFα), may prove useful in decreasing bowel inflammation and aid in the closure of fistulas. Alternatively, upregulating or administering immunosuppressive cytokines such as IL-10, has shown great potential in treating CD.64-66
Prospective multicenter randomized trials of the anti-TNFα drug, infliximab (Remicade), a chimeric monoclonal antibody form of anti-TNFα, given over short courses, have demonstrated a high degree of benefit lasting 8-12 weeks after termination of drug administration. Infliximab has been effective in the short-term reduction of chronic active inflammation as well as rapid closure of fistulae in children.64,65 Similar trials using IL-10 have demonstrated significant clinical benefit over placebo. However, return of disease activity suggests that combination drug strategies may be required for long-term effect.66

**Nutritional Therapy**

Enteral nutrition is no longer recommended as primary treatment for active CD.67 But, nutrition as an adjunctive therapy to prevent or reverse malnutrition and micronutrient deficiencies and to maintain remission, is integral to the management of the child with CD to regain and maintain metabolic homeostasis, replace ongoing losses, promote catch-up growth to premorbid percentiles, and promote progression through puberty.20,53 Particular attention to complete nutritional supplementation should be paid when children are placed on bowel rest or elemental diets, or when they have unusual losses secondary to their disease or therapy.

In children undergoing elective surgery for CD, the risk of developing postoperative complications is directly related to their nutritional status.68 Preoperative parenteral and enteral nutritional support in malnourished patients significantly reduces the risk of developing postoperative complications.69

**SURGICAL MANAGEMENT**

**Indications for Operation**

Indications for operation vary with the site of disease: In small bowel disease, 80% of operations are for obstruction and internal fistulas. In colonic disease, persistent acute or subacute bleeding, fulminant colitis with or without toxic megacolon, obstruction, perforation, abscess, internal and external fistulas and perianal disease are indications for surgery. However, with improved medical, endoscopic and radiologic interventional skills and equipment, many of these complications are treated without the need for operative intervention.70 Obstructive hydronephrosis due to chronic phlegmonous inflammation may require surgical release. Surgery is also required for refractory symptoms, including growth failure, despite maximal medical and nutritional therapy. Steroid dependency and toxicity are also an indication for surgery, although the use of immunosuppressive agents may offer an alternative in such patients.

CD patients are often tolerant of complications of their disease. Symptomatic discomfort from a complication is more often an indication for surgery than simply the presence of the complication. Surgeons should consider disease in the context of symptoms rather appearance and should also be perceptive to quality of life issues. Ongoing active CD may lead to social invalidism, especially during adolescence, which may be an indication for operative intervention.

Protein-energy malnutrition due to insufficient caloric intake has been identified as the primary reason for growth failure. In active CD, children are often food intolerant because of early satiety, abdominal pain, partial bowel obstruction, diarrhea related to
malabsorption and a central anorexia mechanism. Nutritional supplementation may reverse growth failure, but does not address the reason for insufficient caloric consumption. Surgical resection should induce remission from disease and symptoms, allowing children to increase caloric intake, regain metabolic homeostasis and achieve premorbid growth percentiles.

Patients with CD for more than 10 years are at increased risk of developing both small bowel and colorectal cancer. A strict regime of endoscopic and radiological surveillance should be maintained, and any evidence of dysplasia or carcinoma is an indication for surgical resection.71-73

Surgical Approaches

Prior to elective surgery, the extent and nature of the disease should be determined by endoscopy and contrast radiography. The patient’s preoperative nutritional status should be optimized. If inflammatory masses or local peritoneal signs are present, preoperative bowel rest and intravenous antibiotics may reduce the extent of surgery and postoperative complications.

Minimally invasive surgery is becoming increasingly useful as a diagnostic tool with therapeutic advantages and greater acceptance among physicians and patients. As technical expertise is gained, minimally invasive procedures will dominate surgery in these patients, especially those undergoing their first operation.

Bowel Resection

Two broad categories of diseased bowel are found at surgery. Firstly, when the surgery is performed for acute complications, the bowel is inflamed and edematous, often with abscess formation or fistulization. Anatomy is difficult to identify, with poor tissue plane separation. It is imperative to adopt a minimalist approach in this scenario. Extensive dissection and adhesiolysis often results in iatrogenic injury and sacrifice of bowel that would have had the potential to ‘cool off and recover function. Disease recurrence is inevitable, but multiple anastomoses or short bowel syndrome is a disaster. In this situation, a period of preoperative bowel rest is of great benefit to the surgeon and patient. In the second instance, surgery is performed for chronic symptoms such as growth failure, recurrent obstruction due to stricture or chronic fistulas. The serosa and mesentery are not acutely inflamed and tissue planes are identifiable. Resection or repair of an isolated segment is feasible without compromising uninvolved bowel.

Midline laparotomy is the best approach in children as it allows for dealing with unexpected findings, access to the pelvis, better stoma placement and easier access in the event of recurrent surgery.

Resection margins should be just sufficient to provide grossly normal bowel for anastomosis or stoma. There is no role for microscopic evaluation of resection margins as microscopic involvement does not affect the rate of anastomotic disease recurrence. Resection back to microscopically normal bowel results in unnecessarily radical resection.74,75

A proximal diverting ileostomy should only be used if the tissues are so edematous and inflamed that distal anastomoses warrant such protection or if the remnants of an abscess wall would come to lie adjacent to a suture line. However, ileostomy is associated with a significantly lower early recurrence rate than following anastomosis. Therefore, it should be considered in patients with aggressive disease or after multiple operations for recurrence.76

Crohn’s toxic megacolon should be treated with partial colon resection without anastomosis.70 In the presence of generalized peritonitis (free perforation or abscess rupture), limited resection is preferred with exteriorization or anastomosis depending on the degree of contamination. Surgical drains are best avoided but may be used for discrete, mature abscesses when, after debridement, residual contamination is suspected. However, uncomplicated abscesses are nearly always amenable to guided percutaneous drainage. Postoperative abscesses may occur in up to 10% of cases, and these too, may be drained percutaneously.

Duodenal CD is seen more frequently in children than adults. Differentiation from peptic ulcer disease is difficult, even in those patients with known CD. Full medical management for both peptic ulcer and CD should be attempted before elective operative repair is considered. Chronic obstruction, hemorrhage, perforation or recurrent pancreatitis are indications for surgery. Gastrojejunostomy with or without selective vagotomy to prevent marginal ulcer while...
preventing postvagotomy diarrhea, is the procedure of choice, although stricturoplasty has been used.\textsuperscript{77}

It is difficult to predict the postoperative frequency and consistency of bowel movements. Patients should be monitored closely until fluid and nutritional homeostasis can be maintained. If growth failure was an indication for surgery, placement of a gastrostomy at the time of surgery may be of great benefit in the postoperative period.

**Stricturoplasty**

The concept of minimal surgery for extensive CD is relatively new. Stricturoplasty epitomizes this concept and is the new approach to the surgical management of CD. Short strictures (5-8 cm long) are widened using a Heineke-Mikulicz pyloroplasty-type procedure, while longer narrowed segments (up to 30 cm), including the ileocecal valve and previous anastomotic sites, may be widened using the Finney technique.\textsuperscript{78,79} Guidelines indicating the tightness of strictures requiring stricturoplasty are well documented in the adult literature, but clearly do not apply to children.\textsuperscript{80} In view of the safety of stricturoplasty, 'prophylactic' stricturoplasty may be performed on all recognizable strictures except for those sites where the luminal caliber is not compromised. Several groups have adopted this practice despite a lack of documented evidence.\textsuperscript{80}

In addition to surgical stricturoplasty, two endoscopic techniques, divulsion and ablation, have been developed for treating strictures. Divulsion techniques dilate the stricture by tearing tissue at the weakest section, thus providing a larger lumen. Dilatation of esophageal, gastroduodenal, ileocecal, colonic, anorectal and anastomotic strictures is accepted practice among therapeutic endoscopists. More recently, ablation techniques using electrocautery or laser have employed with success in treating chronic fibrous strictures. Multiple therapies combining dilatation and ablation may reduce the risk of injury and improve the chances of successful endoscopic stricturoplasty.\textsuperscript{81} Long-term results of these endoscopic techniques in pediatric CD have not been reported.

**Management of Granulomatous Colitis**

The initial management of acute Crohn’s colitis is identical to that of acute UC. Marked colonic dilatation with mucosal islands or a perforation mandates immediate surgery. If the radiologic picture is less severe, further investigation and medical management with daily abdominal views is instituted. Surgery is performed if the clinical or radiological picture deteriorates. In Crohn’s colitis, perforation may occur without preceding dilatation. At surgery, the rectum should be preserved leaving a distal mucus fistula or tacking a Hartmann pouch subcutaneously. Perforation or leakage from an intra-abdominal Hartmann pouch stump may cause significant morbidity. Only if there is no other option because of disintegrative rectal disease or massive bleeding from an undefined site, should primary proctectomy be performed. However, despite rectal conservation, the likelihood of subsequent anastomosis is low and secondary proctectomy high. Initial operative conservatism also allows an opportunity to confirm the diagnosis of CD which is not known in more than half the cases. If it turns out to be UC, ileoanal restorative surgery may be performed.\textsuperscript{82}

The unpredictability of findings despite preoperative investigations and the possibility of a stoma, either temporary or permanent should be discussed with the patient and family before any abdominal operation for CD. The results of surgery for CD of the colon are less than satisfactory and surgical intervention should be limited to those patients who have complications severe enough to justify an operation.

**Management of Intestinal Fistulas**

The presence of an internal fistula is not an indication for surgery. However, in 'high-low' fistulas that produce torrential diarrhea, and fistulas that connect to the urinary tract, surgery is recommended. En bloc resection of the diseased intestine and fistula with primary anastomosis is the preferred treatment, but temporary exteriorization of the intestinal ends should be undertaken in those patients compromised by extensive sepsis or profound malnutrition.\textsuperscript{83} Duodenal fistulas are the exception, where failure to heal following primary closure occurs more frequently with disastrous results. Duodenal fistulas should be closed primarily, then protected by a jejunal serosal patch. This buttresses the defect increasing the healing potential, but should breakdown occur, preferential duodenojejunal fistulation occurs rather than retroperitoneal leakages.\textsuperscript{83}
Proximal temporary loop colostomy should be used to protect repairs of fistulas in diseased colon or rectum, but primary repair is feasible when these structures are not grossly diseased.

Although medical management of external fistulas has good early results, recurrence is common and local management unpleasant and painful. Therefore, early operative treatment is recommended. Bowel resection is required and the chronic granulation tissue of enterocutaneous fistula tracts should be cored out and the adjacent peritoneum closed from within the abdomen. The external opening is left open to heal by secondary intention.

Diagnosis of rectovaginal fistulas in premenarchal girls is difficult and a high index of suspicion is required, often requiring evaluation under anesthesia to demonstrate the communication. All fistulas secondary to CD are considered complex. Up to 50% of rectovaginal fistulas will close with aggressive medical management of rectal disease, including the use of nocturnal rectal budesonide infusion, metronidazole and immunosuppressive agents. Surgical repair is elective and should not be done in the presence of active local disease. Failure of medical control of rectal disease may require a diverting colostomy prior to repair of the fistula.

Management of Abscesses

Percutaneous ultrasound or CT-guided drainage of abscesses is a useful option as primary therapy or as a temporizing measure to allow acute inflammation to settle prior to surgery. Drainage without subsequent resection has a high recurrence rate. Local antibiotics within the abscess cavity have not shown to be of any benefit, but long-term administration of broad-spectrum systemic antibiotics has been effective in eradicating abscesses and decreasing recurrence rates. Patients and their families should be made aware that abscess recurrence and fistula development following abscess drainage should always be expected in CD.

Management of Perianal Disease

In the initial management of perianal and perineal disease the presence, extent and location of bowel involvement should be established by performing endoscopy. The incidence of perianal disease increases in association with colonic involvement and is highest in patients with active rectal disease. Local CD should be aggressively treated, including the use of topical steroid preparations. Surgery is indicated for failure to heal, anal stenosis and fissures associated with abscesses. The presence of an underlying fistula should be excluded. Anal sphincterotomy is the operation of choice. The fissure, sentinel pile and enlarged anal papilla should not be excised. Dilatation is not recommended in CD patients because it is generally more traumatic and less effective.

CD is a common cause of anorectal strictures resulting in a stiff, non-compliant anorectum and anal incontinence: Surgical management ranges from four quadrant incisions through scar tissue followed by internal sphincterotomy and dilatation to anoplasty with a Y-V advancement flap. The most important criterion for success is the absence of active anorectal disease at the time of surgery.

Recurrent perianal abscesses are often a presenting feature of CD and are managed the same way as in patients without CD. Rectal CD should be treated along with abscess drainage. Oral metronidazole and ciprofloxacin (in older children) may be used until the abscess is healed, irrespective of the presence of rectal disease. Up to 30% of patients will be left with a fistulous tract after abscess drainage. Surgical treatment of fistula-in-ano is based on the patient’s symptoms. Many children have minimal symptoms from their fistulas, and as long as the tract is kept clean without recurrent abscess formation, no fistulotomy is required. The disease rarely progresses and spontaneous healing may occur. In patients with significant symptoms or recurrent abscesses, those with active CD require systemic treatment before perianal surgery (abscesses should be drained). Postoperative oral antibiotic therapy appears to decrease recurrence. A 63-68% primary healing rate after fistulotomy may be achieved in this way.

In complex fistula-in-ano or in patients with chronic rectal disease despite full medical therapy, temporary fecal diversion via colostomy followed by definitive fistulotomy may improve the chances of healing. Setons are useful in complex or high fistulas to facilitate staged surgical fistulotomy or prolonged drainage while minimizing impairment of continence by avoiding external anal sphincter disruption. Alternative management of high fistulas including the use of endorectal advancement flaps and wide external drainage, or posterior approaches such as those...
described by York-Mason and Kraske have high morbidity and low success rates and should only be undertaken with the knowledge that the next step is proctectomy.

While failure to heal the fistula is the commonest complication, the gravest one is to injure the sphincter mechanism resulting in fecal incontinence. In CD, as in non-inflammatory perianal disease, incontinence is likely to be the result of aggressive surgery, not of aggressive disease, creating social invalids out of these children. Of all patients with any type of perianal fistula coming to surgery, 8-12% will end up having a proctectomy and end-colostomy.

**Management of Extraintestinal Manifestations**

A myriad of nonspecific inflammatory conditions involving almost every organ and system in the body has been described as part of the extraintestinal manifestations of inflammatory bowel disease. Treatment involves a combination of close monitoring, organ- or system-specific therapy. Management of the underlying intestinal inflammation and generalized supportive measures.

Joint involvement is the most common extraintestinal manifestation of CD, with an incidence of up to 25%. Treatment is aimed at the underlying intestinal disease. Acetaminophen is the drug of choice for pain relief. Aspirin and nonsteroidal anti-inflammatory agents which may exacerbate the CD should be avoided. Ankylosing spondylitis and sacroileitis occur less frequently in CD than UC. There is usually no improvement with treatment of the underlying bowel disease, so that therapy is primarily supportive.

Up to 4% of CD patients may develop primary sclerosing cholangitis. Ursodeoxycholic acid may slow progression, but there is no proven cure for the disease. Many of these patients ultimately come to liver transplantation. Granulomatous hepatitis is seen in 1% of patients and is part of the spectrum of somatic granulomatous disease associated with CD. Treatment is that of the underlying bowel disease. The incidence of cholelithiasis is increased in CD, and gallstones develop at a younger age, especially in adolescents with terminal ileitis or after ileal resection and disturbance of enterohepatic bile circulation. Laparoscopic cholecystectomy is the operation of choice.

Mucocutaneous lesions seen in children with inflammatory bowel disease should be biopsied. Treatment includes that of the underlying intestinal disease as well as topical and intralesional corticosteroids.

Uveitis and iritis occur in 2-4% of children with predominantly colonic CD and if left untreated may progress to scarring and blindness. Episcleritis is seen more commonly, but does not lead to permanent injury. Regular surveillance and prompt treatment of eye involvement is recommended for all children with CD.

**PROGNOSIS**

No reliable criteria are available to identify patients likely to have early symptomatic recurrence (within 36 months of surgery) once their disease is in remission due to medical or surgical intervention. Nearly 75% of patients have peri-anastomotic recurrence within 1 year of resection of macroscopically diseased bowel. Patients requiring an ileostomy have significantly lower early recurrence rates than those having single or multiple anastomoses. The number of anastomoses and the presence of microscopic disease at the resection margin in patients having multiple anastomoses also results in a significantly increased incidence of early recurrence. Multiple site disease has a three-fold increased recurrence rate over single-site disease.

Restoration of the fecal stream seems to have a significant effect on the development of early recurrence. In children with a temporary diverting ileostomy, recurrent distal disease usually develops after closure of the stoma.

In a long-term study of children and adolescents with CD, 69% of patients had at least one surgical intervention within 7.7 years of diagnosis. In a similar study, 95% of patients with ileocolonic, 83% with colonic and 56% with small bowel disease underwent surgery over a 15 year follow-up period. The mean interval between diagnosis and surgery was 1.7 years for ileocolonic and 4 years for colonic disease. The time between the onset of symptoms and the first operation is shorter in children compared with adults. While surgeons have become more aggressive in terms of earlier operative intervention in children, maximal bowel conservation should be practiced.
The long-term risk of recurrence increases with disease duration before surgery, and relapse occurs earlier in patients undergoing surgery for failed medical therapy as opposed to specific complications. Rates of reoperation are high depending on the site of disease, varying from 50% at 10 years for disease limited to the small bowel to 65% when the colon is involved.

**SMALL AND LARGE BOWEL RECURRENCE AND COMPLICATIONS**

Anatomic location of disease, indication for surgery and preoperative duration of symptomatic disease are the most important factors influencing the rate of postoperative symptomatic recurrence of CD in childhood. Children with diffuse ileocolonic disease (50% at 1 year) have the quickest recurrence, while isolated small bowel disease (50% at 5 years) is slowest to recur. Failure of medical therapy as the indication for surgery results in significantly earlier recurrence than when surgery is done for specific intestinal complications. If patients require surgery within one year of diagnosis, the majority have a long disease-free interval with only 30% recurrence by 8 years, compared with 50% recurrence in 3 years if duration of disease is more than 4 years. When these results are combined with the knowledge that significant postoperative catch-up growth in prepubertal children will occur if they remain in remission, a strong argument can be made for early operative intervention in newly diagnosed patients with limited disease.

CD of the terminal ileum recurs in a predictable sequence proximal to the ileocolic anastomosis after resection. Pre-anastomotic endoscopic recurrence is seen within 3 months of resection in up to 74% of CD patients. At 3 months, aphthous ulcers are seen in the neoterminal ileum with progression to larger ulcers and stricture in most patients. This pattern occurs irrespective of whether anastomosis occurred at the time of resection, or if there was an intervening ileostomy period. This signifies new inflammation rather than persistent disease or incomplete anastomotic healing. Recurrent disease causes anastomotic stricture; disease recurrence is not due to a stricture or tight anastomosis. However, only one third of patients with endoscopic disease recurrence are symptomatic.

The length of bowel resected is statistically correlated with disease recurrence. Technically adequate resections of 25-50 cm of small bowel or combined small and large bowel are associated with a decreased probability of disease recurrence or reoperation. Longer resection (50-100 cm) does not correlate with lower recurrence rates. This statistic reflects the improved outcome of surgery in patients with limited small bowel disease as opposed to those with diffuse or colonic disease and does not mean that by limiting the length of resection, a given patient will have a better outcome.

Several studies have demonstrated that the reoperation rate for pediatric CD is related to the site of the initial disease, because the site of disease is directly related to disease recurrence. Diffuse or panenteric disease usually recurs after surgery, and in 95% of cases requires more re-operations. In children with colitis, recurrence and reoperation depends on the type of initial operative procedure. Staged colonic resections with primary anastomoses or ileostomy with fecal diversion have disease recurrence or persistence in more than 90% of cases with reoperation rates between 62-88%. In contrast, subtotal colectomy with ileostomy as the primary procedure remain well 89% of the time, and require surgery in less than 1% of cases. Patients with limited small bowel or ileocolic disease have sustained remission in 85 and 80% respectively, with reoperation rates even lower. In a small series of children with limited terminal ileal and right colonic disease, early resection resulted in 91% (10 of 11 children) long-term remission with no postoperative morbidity or mortality. Other subgroups of disease location have not met with similar success after early surgery. These excellent results with early resection in this subgroup emphasize the importance of accurate preoperative disease identification and location. The study also substantiates the need for differential management strategies based on the predicted nature of the disease in each subgroup.

In a cohort study comparing CD parameters in a group of adults with a similar group of children, it has been noted that the incidence of toxic megacolon is significantly higher in children than in adults (9.5% versus 0.4%), which the authors explained by a more aggressive pattern to CD occurring at a younger age. In the adult group, 50% of patients had their first bowel...
resection within 6-8 years of the onset of symptoms. In the pediatric group, with approximately the same frequencies of localization, 50% of children had their first resection within 3 years of initial symptoms, again arguing for a more aggressive disease pattern.

Acute CD of the colon requiring emergency surgery is uncommon but may be increasing in frequency. In a large adult study, of 215 patients requiring surgery for acute inflammatory bowel disease, only 18 had CD (8%), with similar results reported in the pediatric population. Only 2 of these 18 patients do not have a stoma, and 10 of 16 patients with a stoma have required proctectomy. Thus, despite a policy of rectal conservation, it is very unlikely that acute colonic CD will be amenable to restorative surgery.\textsuperscript{82}

In colonic CD, prolonged (greater than 15 years) spontaneous or drug-induced remission occurs at all sites: Right-sided disease (11%), extensive colonic disease (21%) and left-sided disease (38%). Prolonged remission may also occur after resection for CD, however, the overall reoperation rate is 76%.\textsuperscript{102}

In a 7-year follow-up period of juvenile onset CD in Scotland, 79% of patients underwent a total of 135 operative procedures (71 major, i.e. intra-abdominal, 64 minor). In several similar series, major operative rates ranged from 62-80%. In the Scottish study, 50% of patients had one major operation within 5 years of diagnosis, and 94% by 15 years, with 59% of these patients requiring a second major procedure within 5 years of the first. Within 7 years of diagnosis, 20% of juveniles have a permanent stoma. Overall mortality is between 0 and 3% at 5 years and 10-20% at 20 years from diagnosis. The common causes of death include overwhelming sepsis following acute perforation and postoperative complications such as perforation, obstruction, hemorrhage and sepsis.\textsuperscript{94}

In comparing this juvenile onset group with an adult onset group, the younger group had significantly more diagnostic laparotomy (17% versus 2% of all major operations), fewer total small bowel resections and fewer abdominoperineal resections as the first procedure. In the juvenile group, 88% of patients having a diagnostic laparotomy required a second major operation with resection. No patient having only small bowel resection has required colonic surgery, despite several requiring repeat small bowel resection. Of 7 patients whose first operation was colectomy with ileostomy, none have had disease recurrence. However, recurrence of disease after total proctocolectomy depends on whether the terminal ileum was involved at the time of surgery. Nearly 70% of patients with ileal disease have relapse within 10 years of surgery compared with less than 10% with disease limited to the colon.\textsuperscript{103}

The long-term success (mean follow-up 8 years) of ileorectal anastomosis is directly dependent on the presence or recurrence of proctitis. When mild or no proctitis is present distal to the anastomosis, all patients retained a functioning anastomosis, however, when moderate to severe proctitis recurred, 81% had either a proctectomy or defunctioning stoma. Although the indication for rectal excision or exclusion was disease distal to the anastomosis, 63% of these patients also had small bowel disease compared with 11% in the group that had a functional astomosis. In this series, 88% of patients with intestinal, perforation required permanent ileostomy, whereas only 23% of patients with non-perforating colorectal disease required permanent ileostomy.\textsuperscript{103}

Symptomatic recurrence rates as high as 60% at five years and 94% at 15 years, with re-operation rates of 10-40% at 10 years are not unusual in the literature.\textsuperscript{104}

Within 20 years of the diagnosis of CD, the cumulative risk of having any stoma is 41%, and 14% of all patients will have a permanent stoma (40% of patients with colonic disease). Revision surgery for stomal complications is more common after colostomy than ileostomy. Increased risk of having any stoma is associated with rectal inflammation, perianal fistula or abscess and absence of small intestinal disease. Interestingly, despite a higher rate of disease recurrence, long-standing symptomatic disease before the first operation reduces the risk of having a stoma. The likelihood of stoma reversal is 75% when used for anastomotic protection or avoidance, 79% after postoperative complications and 40% for perianal disease or rectal inflammation.\textsuperscript{105}

Patients with diffuse or pan-enteric disease, representing about 20% of children with CD, pose major problems in medical and surgical management with high morbidity and mortality (up to 15% in this subgroup). Surgery is more often for complications such as chronic obstruction due to stricture within diseased segments of bowel rather than resection of diseased bowel to attain remission. Therefore, disease...
recurrence and reoperation is very common and this group is at the highest risk for developing short bowel syndrome. Everything possible should be done to avoid this complication, including stricturoplasty, endoscopic divulsion or ablation of strictures instead of resection for obstruction, and tolerance of mild to moderate symptoms to avoid repeated surgeries. Nevertheless, over 60% of these children are permanently growth and height retarded.97

Short bowel syndrome is characterized by steatorrhea, mineral and vitamin losses and undernutrition. Parenteral hyperalimentation is required initially to achieve nutritional homeostasis, and then is used chronically to supplement inadequate gastrointestinal absorption. Parenteral hyperalimentation is fraught with problems and complications that add to those of the underlying CD. Effective management depends on accurate determination of nutritional deficiencies and a carefully supervised, highly specialized oral feeding program. Long-term uninterrupted control permits physiologic adaptation of the residual bowel and may decrease the need for medication and dietary limitations. The degree of morphologic and physiologic intestinal adaptation after small bowel resection or colectomy is dependent on the length of residual bowel and the age of the child. Younger children have a large adaptive capacity which is another reason for earlier surgical intervention in preadolescent children with CD, which may result in restoration of complex bowel functions not possible in older patients. If the residual bowel is too short to allow effective adaptation, small bowel transplantation, although still experimental, has become a viable option. Immunosuppressive drugs required for the transplanted bowel may have the added effect of suppressing CD in these children. Until the etiology of CD is elicited and specific therapy can be developed, bone marrow transplantation may be the last resort in salvaging those few patients with unrelenting resistant disease. Having stressed the benefits of surgery, it is important to recognize the potential for postoperative complications, most commonly sepsis, fistula formation, obstruction, short bowel syndrome and recurrence.

Crohn’s ileitis or ileocolitis may first be diagnosed at laparotomy or laparoscopy often performed for suspected appendicitis. After incidental appendectomy the, fistula rate is about 50% in CD patients as opposed to 0.3% in normal patients, but most of these fistulas are from the terminal ileum rather than the appendiceal stump. Indeed, laparotomy alone is associated with a 10-39% risk of fistula formation, whereas the fistula rate after bowel resection for CD is 2-5%. The debate on the role of incidental appendectomy in CD continues, but if the cecum is soft, pliable and uninvolved, most surgeons would perform an appendectomy.105,106 Unexpected chronic CD (fat wrapping, fibrosis, woody thickening and fibrosis with a short thickened mesentery and possibly a mass or fistula) should be dealt with—according to the patient’s symptoms and gross evidence of complicated disease or stricture. A conservative approach to the unexpected finding of CD at laparotomy is best.106

Crohn’s colitis must be differentiated from UC because of the implications of management. However, diagnostic error occurs in 6-10% of patients.107,108 Evidence of non-colonic CD, endoscopy and histology are used to differentiate between the two diseases. The rectum is always involved in UC, whereas 40% of Crohn’s colitis children have rectal sparing, irrespective of anal involvement. Toxic megacolon and perforation is rare in CD, usually occurring early on and may be mistaken for UC.

Proctocolectomy with end-ileostomy is the conventional operative approach for the treatment of granulomatous colitis involving the rectum or anus. Another approach in patients with mild to moderate rectal involvement, is to create a temporary diverting ileostomy and rectal mucus fistula or Hartmann, pouch with delayed ileorectal anastomosis if the anorectal disease heals. If the anorectal disease does not heal, an abdominoperineal or perineal proctectomy may be performed later. In patients in whom Crohn’s colitis was initially mistaken for UC, and who underwent ileoanal anastomosis, complication rates are very high.107,108 Based on results of these studies, the creation of ileal pouches and ileoanal anastomosis is contraindicated in patients known to have CD. The creation of a continent ileostomy such as a Kock’s pouch is also controversial because of the high complication and failure rates.109 Recurrence of CD following proctocolectomy when the disease was confined to the colon, is between 10 and 20%.

For patients with colonic CD and rectal sparing, colectomy and primary or delayed ileorectal anas-
tomosis is the optimal procedure. For children and adolescents, avoidance of an ileostomy during the years of their physical and emotional development is desirable even though one third of these children will subsequently develop severe enough disease to warrant proctectomy or diversion.

**Perianal Disease**

Treatment failure of perianal and genital fistulous disease is the commonest indication for primary stoma creation (64% of all patients with stomas). Considerable controversy exists on the rate of success of temporary fecal diversion in the management of complicated perianal or refractory rectal disease. Once patients require fecal diversion, 20-66% will have some improvement, although new fistulas may arise despite diversion. The best criterion of success is restoration of intestinal continuity. This is successful in only 10-31% of patients. Even after proctectomy, fistulas or genital problems may persist and continue to impair quality of life. Nevertheless, it is often psychologically better not to perform non-reversible procedures such as proctectomy as long as there is hope of life without a permanent stoma. A Hartmann procedure followed later by perineal proctectomy (if required) once the patient has come to terms with the inevitability of a permanent stoma may be of significant psychological benefit for patients living with this chronic illness. However, in a study of three groups of children with CD, a stoma group, an ileorectal anastomosis group and a non-surgical group, no difference was found in psychosocial adjustment, self-esteem and quality of life. Children seem far better able to cope with the sequelae of early onset CD than when the disease presents in late adolescence or later.

**Growth Failure and Sexual Maturation**

Linear growth following surgery is directly related to pubertal status. Following surgery, Tanner Stage I and II patients achieve normal or near normal height velocity and regain their pre-illness height percentiles within 1-5 years. Tanner Stage III patients have a growth spurt after surgery, but usually not to full pre-illness percentiles, whereas Tanner Stage IV and V patients had no increase in height velocity. Patients with limited, surgically resectable disease in whom surgical remission with symptomatic relief is possible, will benefit most in terms of growth failure. Persistence or early recurrence of active disease negates the benefit of surgery for growth failure. Nutritional supplementation should continue following surgery, providing 120-30% of the age-recommended daily nutritional requirements. Placement of a gastrostomy for postoperative nutritional supplementation should be considered at the time of surgery. Postoperatively, steroids should be tapered and discontinued, but maintenance 5-aminosalicylate therapy has been shown to prolong remission. When patients with CD and growth failure are prepubertal and surgery is performed primarily because of failure of medical therapy or other complications, a postoperative growth spurt may be expected within one year. Despite the almost inevitable postoperative recurrence of disease, the potential for a period of remission makes early surgical intervention justifiable for carefully selected patients with localized disease.

Chronic disease refractory to medical and nutritional therapy is the main indication for surgery in most pediatric series. Patients with localized disease have the best outcomes. In children with preoperative evidence of linear growth retardation, surgical resection of localized CD, followed by adequate nutritional support results in catch-up growth and a prolonged symptom- and drug-free period in most patients, although this may be limited by their age or stage of puberty.

Fertility of either sex is unaffected by CD unless malnutrition or inflammatory damage to reproductive organs occurs. Disease activity is usually not affected by pregnancy, but occasionally may improve. Exacerbation may occur following delivery. There appears to be no risk of maternal disease affecting the fetus, although medications should be reviewed and may need to be altered.

Although morbidity is high, mortality is low and most children with CD can expect to grow and mature relatively normally, leading productive lives with good general health. Sexual function may be affected on psychological grounds of altered body image, especially in patients with a stoma. However, patients in whom CD developed in childhood are far better adapted in terms of body image than when the onset of disease occurs in adulthood.
Carcinoma

The risk of developing adenocarcinoma of the small or large bowel is increased in patients with longstanding CD. Carcinoma usually develops within a site of chronic disease including along fistulas tracts. The risk for colon cancer is between 4 and 20 times greater than the general population. In patients whose CD was diagnosed before 21 years of age, the risk of developing colorectal cancer is 20 times the general population.116 The risk of developing small bowel carcinoma is estimated at 114 times the general population, but these data are skewed because of the low incidence of the disease in the general population. Historically, 40% of small bowel carcinoma occurred in excluded loops of small bowel, and since this practice is now almost obsolete, the overall incidence of cancer of the small bowel should be much lower.104 Patients with CD are also at greater risk of developing extraintestinal carcinoma. Unlike UC, the association of colonic mucosal dysplasia with carcinoma is not sufficiently established to warrant prophylactic colectomy.

A subgroup of CD patients has been identified for being at greatest risk for the development of colorectal carcinoma. These patients are typically diagnosed before the age of 40, have long-standing proctocolitis of more than 10 years duration and frequently have co-existing strictures, fistulas and bypassed segments. Because of their background disease symptomatology, the development of colorectal cancer often goes unnoticed until well advanced and is consequently associated with poor survival. Surveillance coloscopy with biopsy is recommended in these patients and appears to impart a significant survival benefit since mortality rates from cancer are decreasing with current surveillance strategies.73

CONCLUSION

In a 15-year long-term follow-up study of children with CD presenting before the age of 16 years, two of three had no evidence of residual disease, one in four were clinically well, although evidence of macroscopic disease was present, and one in ten were symptomatic.97

The management of CD in children is complex. A positive attitude and the patient’s willingness to become actively involved in disease management, as well as a trusting relationship between physician and patient, especially through the demands of adolescent development, is essential to the long-term care and outcome of this disease.

HISTORICAL OVERVIEW

Ulcerative colitis (UC) was first described as an inflammatory bowel disease distinct from infectious colitis by Wilks and Moxon in 1875, but it was not until 1960 that criteria were established to differentiate UC from Crohn’s colitis.1,2 Today, there remains a significant overlap between the two diseases, with up to 15% of colitis cases being assigned an indeterminate diagnosis, suggesting a similar etiology and pathogenesis.3 UC is an idiopathic chronic relapsing inflammatory disease limited to the colonic and rectal mucosa, and is associated with significant extra-intestinal manifestations.

Early management strategies for severe UC included intestinal diversion which provided good initial results, but was a poor long-term solution. This was followed by appendicostomy and antegrade lavage, which also had marginal success. In 1913, Browne revisited the concept of bowel rest by total fecal diversion using an ileostomy and this became the standard of care.4 In 1944, Strauss described proctocolectomy with ileostomy for management of severe UC.5 Technical and staged improvements in this approach were described by Cattell in (three-stage procedure) and Gardner in 1951 (two-stage procedure).6,7 In 1952 and 1954, Ripstein and Goligher respectively, described a one-stage ileostomy with proctocolectomy approach, which together with the Brooke ileostomy described in 1952 has become the current elective standard curative operation for UC patients.8-10

Together with advances in the surgical treatment of UC came advances in stomal care that have been instrumental in improving the quality of life of UC patients and has led to greater acceptance of the surgical cure for this disease. Major advances have included the Brooke eversion ileostomy creation, improvements in nursing care and stomal appliances. In 1969, Kock described a technique for creating a continent ileostomy using an internal reservoir and nipple valve that requires interval tube irrigation without the use of stomal appliances.11 Although associated with a high complication rate, the Kock’s pouch has benefited a significant number of patients requiring permanent stomas. While it is recognized that total proctocolectomy is curative for UC, anal sphincter-saving alternatives to permanent ileostomy have been sought for over 50 years. Early efforts included ileosigmoidostomy and ileoproctostomy. In a 1985 meta-analysis of 17 studies on patients with ileoanal anastomoses for UC. Parc reported excellent functional results in terms of number of bowel movements per day (4.5) and continence (>99%).12 However, 5% of patients required proctectomy for recurrent disease and up to 20% of patients developed carcinoma of the retained large bowel. This operation is now reserved for special circumstances only.

Complete proctocolectomy with sphincter-saving ileoanal anastomosis was initially unsuccessful because of unacceptable frequency and urgency. Even when Ravitch and Sabiston modified the ileoanal anastomosis by including a rectal mucosectomy functional results were mostly unacceptable in terms of quality of life.13 However, in 1973, Safaie reported successful results in familial polyposis patients using a straight ileo-endorectal pull-through procedure.
Ulcerative Colitis

(ERPT) that included a distal rectal mucosectomy that was based upon the success of the Soave endorectal pull-through developed for Hirschsprung’s disease. This procedure was further improved by Martin in 1977 and most recently by Coran. Concerns remained in terms of frequency, urgency and soiling because of the lack of a neorectal reservoir. In 1955, Valiente developed an ileal pouch proximal to the ileoanal anastomosis. Various modifications of this concept have developed over the years, including S, W and J shaped pouches. Such pouches were combined with rectal mucosectomy by Parks in 1978 to create the current standard ileoanal pouch anastomosis. The physiology and relative merits of the various pouch configurations have been extensively reviewed. Most large series report a high degree of patient satisfaction regardless of the type of ERPT.

The final improvement to this restorative proctocolectomy has come with the advent of minimally invasive surgical techniques where the proctocolectomy is performed laparoscopically with the rectal mucosectomy and ileoanal anastomosis performed via a perineal approach. Ileal pouch construction may be performed through a small Pfannenstiel incision.

ETIOLOGY

UC is an idiopathic inflammatory bowel disease. The most plausible current etiology is an inappropriate response to environmental factors resulting from direct or indirect dysregulation of the immune system at a genetic level. Genetic predisposition is supported by HLA-W27 testing in patients with UC, ankylosing spondylitis and uveitis. An altered cytokine response to an environmental trigger may result in an inflammatory cascade causing the disease. An autoimmune etiology is given weight by the finding of autoantibodies in over 70% of UC patients. A genetic/autoimmune etiology would explain the extraintestinal manifestations of the disease as well. Confounding factors such as psychosocial and psychosomatic effects, while not causing the disease, may have a significant exacerbating influence.

PATHOLOGY

UC is defined by inflammation limited to the rectal and colonic mucosa. The rectum is involved in all cases with proximal extension into the colon in 90%. The colon may be involved for varying distances towards the ileocecal junction, but inflammation is continuous from the rectum proximally. Pancolitis is more common in children than adults, while 15% have isolated rectal involvement and 20% have limited left-sided disease only. Perianal involvement is so rare that should it occur, a diagnosis of CD must be entertained. Although, by definition, the small bowel is not involved, a phenomenon of ‘backwash ileitis’ has been described to explain the finding of macroscopic inflammation in the terminal ileum in up to 15% of patients with pancolitis. ‘Backwash ileitis is a clinical finding described as nonspecific chronic inflammation microscopically, and is therefore not a pathological entity. However, if polymorphonuclear leukocytes are seen in the lamina propria of the terminal ileum, the diagnosis of CD must be considered. Pathological examination of biopsies from clinically inflamed terminal ileum should distinguish ‘backwash ileitis’ from true ileal inflammatory bowel disease.

In active colitis, crypt abscesses lead to mucosal ulceration on a background of diffuse continuous inflammation with hemorrhage and edema. Islands of regenerating epithelium developing into pseudo-
polyps may be present. Because inflammation is limited to the mucosa, disease activity is usually underestimated when viewed from the serosal surface at operation. However, the bowel becomes distended with little peristalsis. The disease may acutely progress to toxic megacolon. In chronic UC, the repeated inflammatory episodes result in fibrosis of the muscularis with thickening, shortening and loss of haustral folds. The mucosa becomes atrophic and may develop dysplasia or neoplastic changes. Diagnosis and disease activity is confirmed by mucosal biopsy.

**CLINICAL MANIFESTATIONS**

**Gastrointestinal Manifestation**

Over 95% of patients with UC present with gastrointestinal manifestations of varying intensity resulting in early diagnosis of inflammatory bowel disease. The majority present with insidious onset diarrhea, mild rectal bleeding, and vague abdominal pain without systemic signs or symptoms. Such disease tends to be localized to the left colon and rectum and the course usually remains mild. About 30% of patients have moderate disease with pus and bloody diarrhea, cramps, abdominal tenderness, urgency and tenesmus. Systemic symptoms include anorexia, weight loss, low-grade fever and mild anemia. Severe colitis requiring hospitalization and occasionally emergency surgery occurs in about 10% of patients. This disease is usually a fulminant pancolitis characterized by five or more bloody stools per day, diffuse abdominal tenderness and distension, fever, tachycardia, anemia, leukocytosis and hypoalbuminemia with weight loss and malnutrition. In less than 5% of patients, extraintestinal features dominate the clinical picture as is commonly seen in CD. These patients may present with growth failure, arthropathy, erythema nodosum or liver disease such as sclerosing cholangitis and mayor may not have active colitis at the time of presentation.

Limited disease usually maintains its course but occasionally may extend beyond its initial involvement. In most cases, the course and severity of disease activity are similar in intensity to that of its onset. The course of UC in most patients is one of remission with periodic relapses often related to emotional stress or intercurrent infection. Fewer than 8% of all UC patients will require surgical intervention before 20 years of age. However, up to 50% children with pancolitis will require surgery. A single attack with complete remission never requiring surgical intervention is seen in less than 10% of all children.

The incidence of carcinoma is 3% in the first decade of disease, with a 10-15% increment in each subsequent decade. While carcinoma rarely presents in children, it is most common in patients where the diagnosis of UC is made early in life, in those with pancolitis or in those with frequent acute recurrences. Surveillance colonoscopy with biopsy is recommended for all patients.

**Extraintestinal Manifestation**

Extraintestinal manifestations of inflammatory bowel disease may involve any system or organ in the body, lending credence to the autoimmune etiology theory. Bone and joint involvement occurs in 20-25% of patients, more commonly than with CD. Osteoporosis and osteomalacia occurs secondary to poor calcium and fat soluble vitamin absorption, while nephrolithiasis occurs due to chronic dehydration secondary to diarrhea.

Dermatologic lesions such as pyoderma gangrenosum and erythema nodosum often present during an exacerbation of gastrointestinal disease activity. Pyoderma gangrenosum is a progressive deep ulceration that may complicate healing of surgical incisions and stoma sites. It may be refractory to medical therapy, occasionally requiring excision and skin grafting. Aphthous stomatitis is common during flare-ups. Sclerosing cholangitis is the most severe extraintestinal manifestation of UC. Its course is generally progressive and independent of the activity of the bowel disease. Ursodeoxycholic acid may slow the progression, but ultimately patients will require liver transplantation for long-term survival.

Routine ophthalmic surveillance is recommended in the management of all children with inflammatory bowel disease because of the frequent occurrence of uveitis, episcleritis, conjunctivitis and steroid-associated eye problems.

Growth abnormalities and nutritional deficiencies seen in UC children are thought to be due to a combination of anorexia, rapid intestinal transit, malabsorption and psychosomatic disturbance. Delayed sexual maturity may be as a result of low levels of gonadotrophins. These conditions are seen
far less frequently than in CD because of the lack of small bowel involvement.

**DIAGNOSIS**

**Clinical Examination**

A detailed history and physical examination directs the physician to the lower gastrointestinal tract in over 95% of cases. Growth and maturation, irrespective of disease activity, should carefully be monitored. Radiologic and endoscopic findings confirm the presence of inflammatory bowel disease, but the diagnosis of UC can only be made by recognizing the pattern of disease manifestation and excluding other causes of inflammation such as infections. Occasionally, the presence of infectious agents such as *Clostridium difficile* may mask underlying UC. About 15% of cases are labeled indeterminate colitis because the distinction between CD and UC cannot definitively be made, and in 2-5% of patients the wrong diagnosis is made which may lead to inappropriate management decisions. An important pitfall to avoid is to underestimate the severity of the colitis. The presence of fever, orthostatic hypotension, dehydration, focal abdominal tenderness or masses indicates severe disease requiring hospitalization.

**Laboratory Assessment**

There are no laboratory tests for inflammatory bowel disease. Anemia occurs in two thirds of patients and an elevated erythrocyte sedimentation or prolonged prothrombin time is common. Nutritional status may be monitored by following levels of serum proteins such as albumin. Iron and magnesium stores may be low because of chronic blood loss.

Gastrointestinal bacteria, viruses, fungae, ova and parasites should be excluded as a cause for the bowel inflammation. In particular, *Clostridium difficile* enterocolitis is more prevalent in UC patients than the general population, and should be screened for whenever disease activity changes. The identification of a pathogen requires specific treatment but does not exclude the diagnosis of UC. Indeed, infectious agents may often trigger acute flare-ups of disease in patients known to have inflammatory bowel disease.

**Endoscopy**

Flexible colonoscopy into the terminal ileum with mucosal biopsies at varying sites along the bowel including the ileum, provides the most sensitive and specific evaluation of intestinal inflammation and may make barium contrast studies unnecessary. Full colonoscopy of pediatric patients of all age groups, including infants, is now possible. In long-standing disease, surveillance for dysplasia should include full colonoscopy in all patients regardless of the extent of disease, because of the high incidence of dysplasia in the ‘normal’ proximal colon. For the same reason, any child with UC undergoing colonic surgery should have a total colectomy irrespective of the extent of proximal extension of the disease. Colonoscopy is contraindicated in acute severe colitis and toxic megacolon because of the risk of perforation and hemorrhage. Bowel inspection should be limited to proctosigmoidoscopy with minimal air insufflation.

The mucosa of active UC is diffusely edematous, erythematous and friable. The distal colon is usually most severely affected, but this is not always the case. Rectal sparing is suggestive of CD, but may be seen following topical treatment of proctitis. Histology of endoscopically normal areas may reveal acute cryptitis or chronic changes such as architectural distortion of crypts or granulomas. Such detail is especially important in evaluating patients who have been medically treated on the basis of a clinical diagnosis of UC in whom surgery is being contemplated. Where doubt exists, upper endoscopy and biopsy may be performed. Children with atypical features of UC or CD are categorized as having indeterminate colitis (10-15%). Patients in this group should be restudied at intervals. If no specific diagnosis can be assigned, they should be treated as a separate group.

**Radiology**

With the emergence of flexible endoscopy, radiology has assumed a confirmatory and back-up role in the diagnosis and management of inflammatory bowel disease. Abdominal radiographs are useful in establishing a baseline for later comparisons. In acute severe UC and toxic megacolon, daily abdominal series are useful to monitor progress of the disease and diagnose complications such as perforation. Contrast...
studies should be avoided in acute severe disease because contrast medium may exacerbate edema and inflammation. Barium enema is useful as an adjunct to colonoscopy when the latter is poorly tolerated or technical difficulty precludes passage of the endoscope to the terminal ileum. Barium enema in chronic UC may show a narrow shortened rigid colon with loss of haustral folds and pseudopolyp formation.

An upper gastrointestinal series and small bowel follow-through with fluoroscopic study of the terminal ileum or enteroclysis is useful to diagnose small bowel involvement and exclude a diagnosis of UC. Barium is the contrast of choice, and the study is only deemed complete once contrast is seen in the right colon.  

In complicated inflammatory bowel disease, ultrasound or computed tomography is useful diagnostically and therapeutically for identifying phlegmons and draining abscesses, although such complications are more commonly associated with CD.

Before surgery, the diagnosis of inflammatory bowel disease should always be revisited. A specific diagnosis should only be assigned when complete histological, clinical and radiological evaluation of the entire intestinal tract is in agreement. Although the histopathologic features of the two forms of inflammatory bowel disease are characteristic, none are pathognomonic. When doubt exists, inappropriate surgery may have severe consequences.

**MEDICAL AND NUTRITIONAL MANAGEMENT**

The goal of medical therapy in children is to control disease, prevent relapse and allow for normal growth and maturation. Steroids, 5-aminosalicylate compounds and antibiotics remain the primary pharmacological agents for treatment of UC.

Several 5-ASA products that deliver the active 5-ASA to the colon are available with differing properties, side effects and tolerance levels. Budesonide, a rapidly metabolized steroid with decreased systemic toxicity is being used more frequently, although it has not yet been adequately evaluated in children. Corticosteroid preparations are useful in disease exacerbations but should be weaned as soon as possible. Steroid use should be accompanied by gastric acid inhibitors. Immunosuppressive agents may be administered as adjuncts to steroid therapy, Methotrexate, azathioprine and its active metabolite, 6-mercaptopurine, may be useful in refractory colitis or to decrease steroid dependency. While most children do respond, median response time is 3 months, and the drugs are not indicated for acute flare-ups. Cyclosporine is effective in treating severe UC with a mean response time of seven days, but efficacious use in children requires such high doses as to preclude its use in this population group. The antibiotic metronidazole significantly increases remission rates following exacerbation of colitis and is useful in combination with 5-ASA products and steroids. Ciprofloxacin may also have a synergistic effect when used with metronidazole in age-appropriate children.

Antidiarrheal medications such as diphenoxylate hydrochloride with atropine sulphate (Lomotil) or loperamide hydrochloride (Imodium), or opiates such as codeine are useful to reduce cramping and frequency, but may induce toxic megacolon. Dietary manipulation and supplemental (elementary) nutrient formulas have an important role in managing UC. In addition, patients may occasionally require blood and albumin infusions. Psychotherapy and support groups also play an important role in the overall well being of UC patients to reduce emotional stress that may trigger a flare-up.

Medical management of colitis depends upon the severity and extent of colonic involvement proximal to the rectum. Mild colitis is managed at home with a low residue diet and 5-ASA products in incremental doses. Response time is approximately two weeks, with reduction in cramps, bleeding and stool frequency.

Moderate colitis with systemic signs is managed in hospital. Bed rest, with initial bowel rest and total parenteral nutrition or a low residue elemental diet and oral steroids are the mainstay. As an adjunct, 5-ASA products may have an additional benefit and once disease is controlled and steroids are tapered, these agents may be useful in maintaining remission. Patients should be monitored for anemia and malnutrition.

Severe disease with copious bloody diarrhea, malnutrition and weight loss, fever, abdominal distension and tenderness, anemia and leukocytosis should be treated as a medical emergency. Patients require intense fluid, electrolyte and blood product management, parenteral nutrition, high dose...
intravenous steroids, and broad spectrum antibiotic coverage. Frequent radiographic monitoring is required. Colectomy should be performed for failed initial response to treatment, life-threatening complications such as toxic megacolon, severe hemorrhage or perforation. Patients with persistent severe disease refractory to treatment after 2-3 weeks should also be considered for colectomy. Our experience has shown that an emergency colectomy and ileo-anal pull-through can be done without mortality or increased morbidity.34 If the operation needs staging, a subtotal colectomy and ileostomy with a Hartmann turn-in or mucus fistula should be done initially. One of the disadvantages of this approach for severe rectal disease or hemorrhage is postoperative continuation of symptoms. Acute severe exacerbation of UC is a relative indication for surgery, and most patients should be considered for early colectomy and ileodistal anastomosis following resolution of such a flare-up.

Localized rectal and left-sided disease may be managed topically with 5-ASA suppositories or enemas or non-absorbable steroid enemas or foam. Budesonide may also be given topically via a fine-bore rectal catheter as a rectal infusion.

While nutritional support is less likely to induce remission in UC than CD. Correction of nutrient deficiencies and maintenance of adequate nutritional status to ensure appropriate growth and development is essential. During exacerbation of disease, nutritional balance may only be achieved at 140-150°/n of recommended daily allowance, usually requiring enteral supplementation with elemental diets or total parenteral nutrition. Following surgery, enteral intake is usually resumed within one to two days when an ileostomy is created.

**SURGICAL MANAGEMENT**

**Indications for Operation**

All patients with UC will eventually come to colectomy. Total proctocolectomy is curative for gastrointestinal disease. Medical management is used initially, while surgery is reserved for failure to respond to full medical therapy, complications of medical therapy or prolonged steroid requirement, nutritional and growth failure, dysplasia or carcinoma, or long-standing disease (usually greater than 15-20 years). Such elective surgery should be performed when epiphyses are still open to allow for adequate catch-up growth and maturation. In 20% of children, surgery is performed emergently for acute complications such as acute fulminant colitis or toxic megacolon, perforation, severe hemorrhage or bowel obstruction secondary to stricture.

Preparation for surgery includes optimization of nutritional and electrolyte abnormalities. Children should be fully prepared mentally for postoperative changes including dealing with a stoma. Formal bowel cathartic bowel preparation should be avoided as it may cause a flare in disease. Children should be placed on clear fluid restriction 48 hours prior to surgery. Oral antibiotics such as erythromycin, neomycin and metronidazole should be used in the 24 hours before surgery, while intravenous broad spectrum antibiotics should be administered 2 hours preoperatively. Most children are on steroids at the time of their surgery. While one-stage proctocolectomy and ileoanal anastomosis without temporary ileostomy may be used in stable children off steroids, we recommend temporary diverting ileostomy for children who are malnourished or those on steroids at the time of surgery. This is to avoid higher incidence of complications, specifically abscess formation and poor wound healing.

**Surgical Approaches**

**Colectomy with Ileoanal Pull-through**

*Straight pull-through: A large experience with ERPT for the definitive management of Hirschsprung’s disease has been reported.15,17,35 The first significant experience with straight ERPT for the management of UC in 17 adolescents was published by Martin in 1977.16 We have pursued this approach using ERPT and straight ileoanal anastomosis as the primary alternative to abdominal wall ileostomy in children requiring total colectomy for UC (Figs 69.1A to H).*

In children, the operation is usually performed as a two-stage procedure with initial total colectomy, rectal mucosectomy and ileoanal anastomosis with a protective diversionary loop ileostomy which is closed at 8-12 weeks. Under less optimal conditions, a subtotal colectomy, ileostomy and sigmoid mucus fistula or Hartmann’s turn-in may be performed acutely, followed weeks to months later by rectal mucosectomy and ileoanal anastomosis.36,37
Fig. 69.1A: The endorectal dissection is carried out between the submucosa and muscularis of the rectum.

Fig. 69.1B: The rectal mucosal-submucosal tube is everted outside the anal opening.

Fig. 69.1C: The everted mucosal-submucosal tube is incised anteriorly at the pectinate line.

Fig. 69.1D: A clamp is passed through the opening in the inverted tube in order to grasp the terminal ileum.

Fig. 69.1E: The anterior wall of the terminal ileum is incised.

Fig. 69.1F: An anterior anastomosis is created between the terminal ileum and the anorectal mucosa.

Fig. 69.1G: The anastomosis is completed and a drain may be left between the rectal cuff and the ileum.

Fig. 69.1H: The top of the rectal cuff is tacked to the ileum.
The endorectal dissection may be performed via an abdominal approach or transanally, although it is more difficult to remove an intact mucosal-submucosal tube using the latter approach. A 4-5 cm rectal muscular cuff is left and the terminal ileum is brought down through the rectal muscular cuff and anastomosed to the rectal mucosa at the dentate line. This technique affords optimal protection to the nervi erigenti, seminal vesicles in boys and vagina in girls, since the endorectal dissection is started proximally just below the peritoneal reflection and the entire distal dissection occurs within the wall of the rectum.

Anal continence is defined by the ability to defer defecation voluntarily, maintain control nocturnally and have the ability to discriminate between flatus and stool in the neorectal vault.

The anatomic and physiologic requirements for normal anal continence include preservation of the anorectal angle by the levator muscle complex and puborectalis sling, maintenance of the anal sphincter function, anorectal sensation and the presence of reservoir capacity compliance within the rectal ampulla. These requirements are all preserved or recreated after ERPT (Fig. 69.2).

Pouches

A major factor in early continence is the size and compliance of the neorectal reservoir. Anorectal continence may also be affected by stool frequency, i.e. the regularity and rapidity with which stool collects in the neorectal ampulla, as well as by the consistency of that stool. Reservoirs have been adapted to increase rectal capacity and alter prograde peristaltic waves reaching the anus, thereby reducing stool frequency. Four types of reservoir configuration are used clinically: the J-shaped double loop reservoir (most widely used), the S-shaped triple loop reservoir (useful to reduce mesenteric tension in reaching the anus in long thin patients), the W-shaped quadruple reservoir and the lateral side-to-side or isoperistaltic reservoir. Irrespective of the type of pouch used, care must be taken to construct short pouches (<12 cm long) and to avoid leaving a spout that results in stasis and prevents complete evacuation resulting in pouchitis.

Usually, when pouch procedures are employed, unlike the straight ERPT procedure the rectal dissection continues on the outside of the rectum all the way down to the dentate line. This dissection increases the likelihood of injury to the parasympathetic nerves as well as to the posterior wall of the vagina or seminal vesicles. As the pouch is placed in the pelvis, the pouch suture line may lie against the dissected posterior wall of the vagina, increasing the likelihood of pouch-vaginal fistulae. In addition, full-thickness ileal pouch is anastomosed to full thickness distal rectum, and this is often a stapled anastomosis, increasing the likelihood of pelvic fistulae and abscesses as well as low fistulae to the vagina, since the protection afforded by the rectal cuff is not present. If an endorectal dissection is employed, care should be taken to avoid constriction by the muscular cuff or leaving a spout that may result in pouch obstruction and inflammation.

Irrespective of the type of ileoanal anastomosis, care should be taken to avoid tension on the mesenteric vessels as ischemia may result in leaks, poor healing or anastomotic structuring. Careful dissection of the superior mesenteric vessels and opening distal arcades will reduce anastomotic tension.

If a temporary ileostomy is constructed, this should be of the loop type, with the proximal end Brooked, and the distal end sutured level with the skin. This will allow some stool to spillover into the distal limb over time and allow the patient to maintain anal sensation and continence. It will also maintain mucosal integrity, preventing atrophy.

Steroids are tapered postoperatively and once the patient is off all medication, the ileostomy is closed. Following closure of the ileostomy, patients may be maintained on metronidazole and combinations of anti-diarrheal and anti-peristaltic medications as

![Fig. 69.2: Barium enema demonstrating a neorectum 1 year following straight endorectal pull-through and ileoanal anastomosis](image-url)
needed. Commonly used drugs include diphenoxylate hydrochloride, loperamide hydrochloride, codeine and kaopectate. Perineal barrier creams are also vital to prevent excoriation of the perianal skin. Dilatation of the anastomosis may be necessary.

Other Procedures

The authors do not recommend subtotal colectomy with ileorectal anastomosis, end-ileostomy or Kock continent ileal reservoir as a primary procedure in UC patients. Subtotal colectomy with ileoproctostomy may be appropriate in older patients, but it is not a procedure that should be considered in the pediatric population because of its attendant risks of ongoing inflammation, medication and the risk of cancer. Permanent Brooke end-ileostomy is associated with a 30% complication rate. Complications of end-ileostomy include adhesive bowel obstruction, dehydration and malnutrition, and local stoma problems including retraction, herniation, prolapse and obstruction. Kock’s continent ileostomy procedures involve the creation of an S-shaped pouch with the exit site on the abdominal wall. The incidence of complications with Kock’s pouches is 64% with a high morbidity rate often resulting in the loss of the Kock’s continent ileostomy with concomitant loss of the small bowel required to create the pouch.38,39 These procedures should be used in cases of failed ileoanal anastomoses or when such an anastomosis cannot be performed.

SURGICAL OUTCOME

In a recent report by Telander, the primary indications for colectomy in a group of 100 children with UC included intractable disease (64%), refractory growth failure (14%), toxic megacolon (6%), massive hemorrhage (4%), perforation (3%) and cancer prophylaxis (2%).40

While there are several large series reporting results with ileal pouch-anal anastomosis in adults, the University of Michigan Medical Center (UMMC) straight ERPT series and the UCLA Medical Center ileal pouch-anal anastomosis series are the only ones large enough to permit statistical comparison in children.41-46 In the UMMC review of 164 patients, 116 patients underwent straight ERPT for UC, while UCLA reported 116 children younger than 19 years of age of which 94 had UC. Both procedures are safe. The operative mortality rate was 1% in both series. Of all the deaths, only one patient died as a direct result of the operative procedure, namely postoperative sepsis in the UCLA series.

In the UCLA series, 52% of patients developed complications, including ileoanal stenosis with reservoir outlet obstruction (16%), elongated ileal spout (2.3%), elongated ileal reservoir greater than 15 cm (4.6%), where a combination of outflow obstruction and reservoir enlargement caused stasis, and adhesive intestinal obstruction (8.6%). Further complications included pelvic abscesses and fistulas, wound infection, incisional hernias anal stricture, rectovaginal fistulas and pouch hemorrhage. The reoperation rate was 32%. Sixty per cent of complications occurred in the first 30 patients. Only three of the last 40 patients had reoperation. Four children (two with Crohn’s disease) returned to a permanent ileostomy (4.9%); 10 had a temporary ileostomy. Five straight pull-throughs were converted to a reservoir because of stool frequency; 22% underwent reservoir reconstruction because of stasis. However, 91% of children are well following their surgery and resolution of complications.

In combined adult and pediatric series from the Mayo and Cleveland Clinics, pelvic sepsis following pouch creation occurred in 5-8.2% of patients with 2.5-6% of patients requiring operative drainage of abscesses. This resulted in pouch loss in 2% of patients. Overall, septic complications were noted in 18.3% of all patients in the Cleveland study. This is significantly higher than the 1.8% reported pelvic sepsis rate in straight ERPT in whom 1% had operative drainage and none required removal of the ERPT. This is one of the key factors in our decision to perform straight pull-throughs rather than creating pouch reservoirs.

Pouch excision and conversion to end-ileostomy occurred in 3.4-5% of patients, with an additional 1% having non-functional pouches. Between 0.7 and 1% of pouch excisions were performed for incapacitating fecal incontinence, while 0.1% of patients had pouch infarction. By the nature of the procedure, no patients required pouch excision in the straight ERPT group, but 3.5% were converted to end-ileostomy, 2% because of increased stool frequency. However, resection of a pouch results in significantly greater small bowel loss than does conversion of a straight ERPT.
All pouches in the Mayo study had handsewn ileal pouch-anal anastomoses, while two thirds of the Cleveland series pouch-anal anastomoses were stapled with preservation of the anal transition zone 1-2 cm above the dentate line. This group has reported fewer complications and better postoperative sphincter pressures using the stapled technique because it involves less anal sphincter manipulation. However, because of the residual mucosal cuff, these patients require annual biopsies of the transitional zone to exclude dysplastic and malignant changes. All of the straight ERPT anastomoses performed at the University of Michigan have been handsewn with resection of the mucosa to the dentate line. A 2.9% anastomotic leak or separation rate was noted in the Cleveland group, while the straight ERPT group only had a single iatrogenic anastomotic separation caused by postoperative passage of a rigid sigmoidoscope.

From the patient’s perspective, the most significant determinants of a successful operation are stool frequency and continence. Frequency, as assessed by the number of bowel movements in 24 hours, ranged between 4-8 stools per day for patients with pouches, while stool frequency 3 years after straight ERPT was 7.4 stools per day. Two percent of straight ERPT patients were converted to end-ileostomy because of dissatisfaction with high stool frequency (10-15 per day). All of these patients were continent during the day and night. Stool frequency for patients having straight ERPT for total colonic Hirschsprung’s disease was 3.5 per 24 hours. These patients were operated on at a significantly younger age (20.6 years for UC patients versus 17 months for Hirschsprung’s patients). This decreased stool frequency is a good representation of increased bowel adaptability when the operation is performed at a younger age.

Perfect fecal continence without inadvertent seepage of liquid or solid stool was present in 75% of patients during the day and 45% of patients at night in the handsewn pouch Mayo series. Nocturnal continence improved over time with 25% having occasional incontinence 4 years after closure of their ileostomy. Similarly, in the Cleveland series which had two-thirds stapled pouch anastomoses, 71% of patients had perfect continence with 82% daytime and 71% night time continence. In the University of Michigan series of straight ERPT, daytime continence was 98% 3 months after ileostomy closure, with 100% continence at 1 year. Nocturnal continence was 96% at 1 year with 100% continence by 2 years.

The volume of fecal output can be decreased by one-third by the use of loperamide hydrochloride, while bulking agents such as kapectate thicken stools but do not decrease output. Up to 44% of patients are on some form of dietary restriction to help limit frequency and incontinence.

The most significant complication of pouch creation was a 23-28% incidence of symptomatic pouchitis, which was completely avoided by straight ERPT. Symptomatic pouchitis is diagnosed by a history of “rectal” cramping, diarrhea and occasionally hematochezia. Malaise, fever, anorexia and extra-intestinal manifestations of UC such as arthritis, uveitis or erythema nodosum may be found. Nicholls and others have reported that 90% of pouch reservoirs showed evidence of chronic and acute inflammation on biopsy. This inflammation is thought to be due to stasis and bacterial overgrowth. Thus, frequent, complete pouch emptying minimizes pouchitis and therapy includes the use of drugs such as metronidazole, ciprofloxacin, pouch washouts and even topical steroids. Rectal dilatation is also helpful.

All of the straight ERPT patients have undergone annual or semiannual biopsy of their pull-through ileum. No patient has had evidence of significant inflammation. Further complications related to pouch creation included a 3.8% incidence of bleeding from the pouch suture line and a 4.2% incidence of pouch-vaginal fistulas, complications avoided by not creating a pouch. However, the straight ERPT series did have a 1.4% rectovaginal fistula rate.

Because of the endorectal pelvic dissection, straight ERPT patients did not develop postoperative major sexual or urinary dysfunction. However, following pouch creation, 3-6% of patients had transient sexual dysfunction, including 1-4% of patients with retrograde ejaculation and 0.1% with impotence. Dyspareunia was noted in 1-7% of female patients. Urinary dysfunction occurred in less than 1% of pouch patients.

The incidence of postoperative small bowel obstruction ranged from 15 to 25.3% for pouch patients with about a third in each series requiring operative intervention. In the straight ERPT group, 8% developed bowel obstruction with 4% requiring surgical intervention.
Anal anastomotic strictures were found in 14% of pouch patients and 6% of straight ERPT patients. All of these patients responded well to periodic anal dilatation, but 0.3% of pouch patients eventually required reoperation for stricture.

A recent trend to avoid a diverting ileostomy in selected patients undergoing restorative proctocolectomy has reduced the expense and hospital time associated with the surgery, but may have slightly higher complication rates. About 10% of the most favorable patients in the Cleveland study had one-stage procedures with a similar complication rate to those having multiple stage procedure. However, this cohort of optimal patients should intuitively have a lower complication rate with multiple stage procedures, therefore it is difficult to assess the true benefits of the single-stage procedure until similar cohorts of patients are compared. We have performed such one-stage ERPT procedures successfully on patients with familial polyposis and total colonic Hirschsprung’s disease without an increased incidence of complications.

A relatively new development in this field of surgery is laparoscopic or laparoscopically-assisted colectomy and endorectal pull-through. We and others have recently begun to use this technique in selected patients, but while preliminary results are promising, it is still too early to make long-term comparisons.

In all studies, the cohort of patients having the highest complication rates from their ileoanal procedures with or without pouch creation, were the 4-8% who subsequently proved to have CD. While the focus of this chapter is inflammatory bowel disease, none of the large series on ileal pouch-anal anastomoses and straight ERPT differentiate between diagnostic subgroups. However, more than 75% of patients in all three series had a diagnosis of UC. and as a group, UC patients did have more complications than patients having either procedure for familial polyposis or Hirschsprung’s disease.

In patients with pancolitis, the observed risk of cancer at 35 years after diagnosis is 30% for all patients, but 40% for those diagnosed before 15 years of age. In a group of Danish patients who underwent surveillance management, the cumulative cancer incidence was 3.1% over 25 years of follow-up, with 32% of patients having a colectomy during that period. The cancer rate in this carefully followed group was not different from that in the general population.

Based on this and other reports, surveillance colonoscopy is recommended beginning 8 years after diagnosis in children with pancolitis.

CONCLUSION

Almost all children with UC should be managed medically until surgery is indicated by worsening disease, medical complications or growth and developmental retardation. Prior to definitive surgery, the diagnosis of CD should be excluded. Surgery (i.e. total proctocolectomy) should be curative for gastrointestinal UC in children.

The major surgical decision is whether to create a reservoir or not. The sole purpose of a reservoir is to increase rectal capacity and thereby decrease stool frequency. We have shown that the neorectum created by the straight ERPT progressively dilates during the first 2 years after operation and develops a normal rectal appearance on barium enema (suggesting normal rectal capacity). This is consistent with the clinical observation that initially the stool frequencies on average are higher with the straight ERPT than pouch procedures, but these differences equilibrate 1-2 years after the procedure.

This chapter mainly deals with hereditary neoplastic polyposes, but some other syndromes involving the colon and rectum are also described.

**NEOPLASTIC POLYPOSES**

Familial adenomatous polyposis (FAP) is the disease associated with the highest risk of development of cancer. Affected individuals are virtually certain to develop a colorectal carcinoma if preventive colectomy is not performed. Furthermore, FAP is the best model to support the hypothesis of the adenoma-carcinoma sequence. Because of its autosomal dominant inheritable characteristics, it has stimulated investigators to look into genetic and molecular biology approaches to elucidate the etiology of the disease (Fig. 70.1).

Numerous adenomas are present primarily in the colon, but polyps may also occur elsewhere in the digestive tract. The most important feature is that one or more of the adenomas in the large bowel will develop into cancer, usually before the age of 40 years. In fact, thousands of polyps are usually present in patients with FAP. Bodmer et al found that FAP is caused by a mutation in the APC gene on the long arm of chromosome.

Despite the inherited nature of the condition, in approximately 20% of patients there is no clear family history.

The size of the polyps varies from case to case, but rarely exceeds 1 cm in diameter. Very occasionally, there is a lack of polyps in the cecum and right colon.

Histologically, the adenomatous polyps seen in FAP are similar to those seen in nonpolyposis patients. They are predominantly tubular adenomas. The coexistence of stomach and duodenal polyps is more frequent than previously realized.

Jagelman et al found that the incidence of malignancy of the Upper 61 tract was 4.5% in 1255 FAP patients. In addition to extracolonic polyps, many other lesions have been described in FAP. The most frequent include the following.

**Eye Lesions**

A total of 75-80% of individuals with FAP have congenital hypertrophy of the retinal pigmented epithelium. These Patchy lesions are due to 1 freckle-like increased content of melanin granules. Hence, ophthalmological examination to detect epithelial lesions may be useful screening technique for FAP.
Skin Lesions
First described by Gardner and Richards. They consist of epidermal cysts, usually multiple and on the face.

Endocrine Gland Lesion
The best-documented association of FAP is with papillary carcinoma of the thyroid.

Desmoid Tumors
Desmoid tumors are rare, and since there is a well-documented association with polyposis. All patients who present with such lesions should be investigated for FAP.

Bone Tumors
The so-called osteomas occurring in FAP are exostoses and endostoses and tend to arise on long bones.

Liver and Biliary Tree Tumors
There is an increased incidence of hepatoblastoma in children of families affected by FAP.

Dental Lesions
Teeth abnormalities, distinct from osteomas of the jaw, have been described in 11-80% of individuals with FAP. As they often appear at an early age, dental anomalies are helpful in the diagnosis of FAP.

DIAGNOSIS
The natural history of FAP is variable. Adenomas usually appear during puberty, with subsequent development of cancer in early childhood. Many subjects with polyposis are asymptomatic and the diagnosis is only made when screening the family of a known patient.

Since the rectum is rarely spared, digital examination, sigmoidoscopy, and biopsy are usually all that is required to confirm the diagnosis of FAP. Sigmoidoscopy and barium enema will usually distinguish between these two conditions. It may as well provide evidence for the diagnosis of FAP. Colonoscopy with histological examination should follow in order to evaluate the extension of the disease. For investigation of manifestations of variants of the disease outside the GI tract, it is worth performing skull and jaw radiography to determine whether osteomata are present and computed tomography (CT) scan to rule out other lesions.

MANAGEMENT
Treatment of FAP is influenced by the natural history of the disease. If patients are left long enough without a colectomy, they will develop carcinoma. The average age at which symptoms develop is about 20 years.

The procedure of choice for FAP is still the subject of much debate. The options are proctocolectomy or colectomy and rectal mucosectomy without restoration of GI continuity, colectomy and ileorectal anastomosis, or restorative proctocolectomy.

Although an ileostomy patient can have a full and active life, it is difficult for a young and active family member, usually asymptomatic, to accept such a procedure.

The advantages of colectomy with ileorectal anastomosis are that GI continuity is restored and bowel function is reasonable.

Furthermore, there is evidence suggesting that carcinoma can develop de novo even in rectal mucosa not occupied by polyps.

The ileum should be divided at approximately 10 cm from the ileocecal junction and its lumen inspected for the presence of polyps (Fig. 70.2).

In patients who develop numerous polyps following ileorectal anastomosis which fulguration fails to control, restorative proctocolectomy should be considered. If this operation is contraindicated because...
of poor anal function or ileal polyposis, the entire rectum should be removed and a permanent ileostomy constructed.

Restorative proctocolectomy is the operation of choice for patients with numerous polyps in the rectum. This procedure is performed in the same manner as for ulcerative colitis. All anal mucosa above the dentate line should be excised.

The approach taken in many units still involves performing colectomy and ileorectal anastomosis in the first instance. Patients with 20-100 polyps are treated by colectomy and ileorectal anastomosis. All others are advised to have an ileoanal pouch.

Desmoid tumors in the abdominal wall should be removed if there is progressive enlargement or if they produce symptoms.

GARDNER'S SYNDROME

Gardner's syndrome was originally described as consisting of cutaneous cysts, osteomata, and fibromata associated with the polyposis. Later, other extracolonic lesions were described. Today, Gardner's syndrome is no longer regarded as a separate entity, but merely as one group of patients in the whole spectrum of FAP.

TURCOT'S SYNDROME

Turcot's syndrome is an eponym given to familial polyposis in association with malignant tumors of the central nervous system. The neurological condition may become apparent before the polyposis. Turcot's syndrome is thought to be a distinct entity from FAP, unlike Gardner's syndrome.

HAMARTOMATOUS POLYPOSIS

Juvenile Polyposis

Originally described in 1964, this rare condition is characterized by multiple polyps, predominantly in the large bowel. Nonfamilial cases may have other associated congenital abnormalities. Although it was initially believed that there was no danger of cancer development, further studies demonstrated that some of the polyps show adenomatous features with malignant potential. Several authors found frank malignancy within polyps from these patients. True juvenile polyposis is now considered to be a premalignant condition akin to adenomatous polyposis, and the current trend is to treat it in the same radical way as FAP, with colectomy and ileorectal anastomosis or restorative proctocolectomy.

Diagnosis

The first office evaluation must include a careful and gentle digital rectal examination, with concomitant stool examinations to rule out the presence of enteric pathogens and the presence of blood. The finding of a firm polypoid mass or an irregular firmness in the rectal mucosa suggests the need for proctosigmoidoscopy.

Juvenile Retention (Inflammatory) Polyps

These lesions are often silent, but they may cause blood-streaking on the stools. Sharp rectal bleeding from the stalk occurs after spontaneous avulsion of the polyp, but exsanguinating hemorrhage and anemia do not occur. Occasionally the polyp appears as a purple colored protruding mass in the anal canal. A prolapsed polyp can descend to the anal canal from the rectosigmoid junction or even higher, and it may not be palpable to digital examination.

Rigid or flexible proctosigmoidoscopy will permit the diagnosis of rectal polyps in over 85 percent of the cases. Because any polyp can contain adenomatous or other malignant elements, it is essential to secure one or more of the lesions for histologic examination (Fig. 70.3).
**Gross and Microscopic**

*Appearance of the Juvenile Polyp*

These common polyps have a smooth, round, oval or slightly lobulated surface and a reddish or reddish-brown appearance. On cut section, large numbers of mucus-filled irregular cysts are seen to be lined by mucin-containing columnar cells.

*Treatment*

Unless multiple large polyps are present, anemia is rarely a problem. The 15 cm pediatric rigid proctosigmoidoscope is adequate for identifying and removing at least 75 percent of juvenile polyps. The stalk can be sectioned by an electrocautery snare or by cutting through it with simple biopsy forceps. There may be brisk bleeding from the vessels in the stalk. All visible polyps should be removed.

Juvenile polyps can be intermixed with true adenomatous polyps. Patients should therefore be followed more carefully than has suggested in the past.

**PEUTZ-JEGHERS SYNDROME**

Peutz-Jeghers syndrome is a very rare, usually familial, syndrome of pigmentation of the mouth and other parts of the body together with GI polyps and was first described by Peutz in 1921.13,14 Jeghers later reported several patients with the disease. Although it is almost invariably a familial disease with an autosomal dominant inheritance, sporadic cases do occur.

The most frequent site for polyps is the upper small bowel, but they may also occur in the stomach and large bowel.

Peutz-Jeghers syndrome occurs equally in both sexes. The age of onset of manifestations is commonly in childhood or adolescence. Cutaneous pigmentation often precedes polyp formation and may disappear after puberty. The most common symptoms are abdominal pain and rectal bleeding. The risk is greater with polyps in the stomach and small bowel, whereas for colonic polyps it seems negligible (Fig. 70.4).

The management of Peutz-Jeghers syndrome is usually conservative. Surgery is sometimes performed for complications such as intussusception or massive hemorrhage.15

**CANADA-CRONKHITE SYNDROME**

Canada-Cronkhite syndrome16 is one of the rare generalized GI polypoid syndromes of which the components have only recently been classified. There are five cardinal features:

1. Presence of multiple hamartomatous polyps of the juvenile variety
2. Ectodermal changes, consisting of alopecia, onychodystrophy, and hyperpigmentation
3. Absence of a family history
4. Adult onset
5. Eventual development of diarrhea and weight loss.

Anemia, edema, and tetany result from malabsorption, and hypokalemia is common. The hyperpigmentation takes the form of brown macular lesions which occur most frequently on the upper and lower extremities and on the face. The nails are dystrophic, fragile, discolored, and sometimes absent. The appearance of multiple, rounded filling defects on barium examination is characteristic.

An aggressive treatment may result in long periods of remission. Patients need fluid and electrolyte correction, nutritional support, treatment of anemia and coagulation defects, and prophylaxis for peptic ulcer.

The risk of developing carcinoma is insufficient to justify prophylactic colectomy.

**CONCLUSION**

Intestinal polyposis encompasses a spectrum of abnormal growths. These syndromes vary from
discrete polyps and cancer to Gardner’s syndrome with its dramatic extracolonic manifestations. FAP and Turcot’s syndrome are both part of a systemic overgrowth pattern, and the associated soft tissue, bony, glandular, and brain tumors illustrate the wide spectrum of this disorder.

Our understanding of the contribution of a genetic susceptibility to the development of GI polyps and cancer is increasing rapidly.

Treatment has also made great strides. Recognition of the familial tendency allows the detection of asymptomatic patients before cancer develops. Prophylactic operations are now well accepted. The choice between colectomy/ileorectal anastomosis, with the remaining risk of rectal cancer, and proctocolectomy/permanent ileostomy has been altered by the appearance of the ileoanal pouch procedure. We should therefore be able to treat every patient with neoplastic polyposis so as to avoid the development of colon cancer.

REFERENCES

A mother, in true sense of the term, can never say 'No' to her child however, serious congenital malformation the child might have. But when the child has fecal (and or urinary) incontinence a day does come when the mother turns her face. Thousands of suns cannot put light to the life of the child. Thus, normal continence has rightly been called "God's greatest gift for mankind". So the surgeon operating upon a child with ARM must have the highest degree of knowledge of anatomy so that the sphincter muscles and nerves are not damaged during operation and thus the prospect of continence is not jeopardized for ever.

Willis Pots wrote in 1959, "In general, the atresia of the rectum is more poorly handled than any other congenital anomaly of the newborn. A properly functioning rectum is an unappreciated gift of greatest price. The child who is so unfortunate as to be born with an imperforate anus may be saved from a lifetime misery and social seclusion by the surgeon, who with skill, diligence and judgement performs the first operation on the malformed rectum."

HISTORY

From Webster's article we get a beautiful description of the way to deal with this common anomaly. Initially the procedure was done by the Byzantine Physician Paul of Aegina. The bowel was opened by plunging a bistoury through the perineum and then dilating the passage with bougies. This method of treatment was followed throughout the next thousand years. In 1787, Benjamin Bell performed perineal dissection and could locate the blind rectal ampulla. Amussat recognized the severe complications of these methods. He opened the rectum and sutured it to the skin margins. Perhaps this was the first definitive anorectoplasty in the history of management of ARM. In 1833, Roux had stressed on the importance of keeping the perineal dissection strictly in the midline. Splitting, dislocating or excising the coccyx were practiced by many surgeons and a few deliberately opened the pelvis to gain extra length of the bowel.

For the low anomalies most of the surgeons used to perform a perineal anoplasty without a colostomy during the first sixty years of the 20th century. For high anomalies a colostomy used to be done in the newborn period and it was later followed by an abdominoperineal pull-through operation. The decision to create the colostomy was based mainly on the radiological information obtained from the invertogram. While doing abdominoperineal pull-through operation surgeons used to keep close to the sacrum in order to avoid trauma to the genitourinary tract. In 1880 Neil Mcleod performed a combined and perineal exploration. It was accepted and modified by many surgeons. As early as 1948 Rhoades et al successfully ventured one stage abdominoperineal procedure in the newborn.

First objective anatomic studies on human specimens were done by Stephens. In 1953, he proposed an initial sacral approach, followed by an abdominoperineal operation when necessary. His main idea was to avoid injury to the puborectal sling which was considered to be the most important factor in maintaining fecal continence. Since then various modifications have been done by many surgeons.

Submucosal resection was done independently by Rehbein and Kiesewetter. Advantage of this procedure is that it can avoid damage to the pararectal nerves and muscles. Mollard’s anterior dissection to
define the puborectalis muscles just adjacent to the urethra has proved another milestone in the operation of ARM. It is considered to be a good approach when the standard approaches have failed and the surgeon wants to go through a virgin field.

Posterior Sagittal Anorectoplasty (PSARP) for the treatment of ARM was first performed by de Vries and Pena in September, 1980. They published it in 1982. This approach allowed good exposure of this complex anatomic area. Since the advent of this approach pull-through operation for ARM is no more a blind procedure, and the clinical results have become more predictable. So with due reasons PSARP is now the standard operation done throughout the world.

EMBRYOLOGY

The exact mechanism of development of anorectum is still mysterious and controversial. Two main events are thought to be important for the differentiation of the cloaca. The conventional view is that downgrowth of the urorectal septum divides cloaca into urogenital (anterior) and anorectal (posterior) parts (Fig. 71.1). Controversy does still persist whether the division takes place by downward frontal septum (Tourneux fold), median fusion of lateral folds of Rathke or a combination of both. The cloacal membrane is divided into anal and urogenital membranes.

Three theories are there:
1. Conventional
2. Chatterjee and Roy (1978)

Conventional Theory

The foregut has a ventral diverticulum which develops into a completely different system, i.e. respiratory system. Similarly the hindgut has a ventral diverticulum that too develops into a separate system. This diverticulum is called ‘Allantois’. In stage 10 of the developmental process there is reorganization of the caudal region of the embryo. As a result a part of the allantois is drawn into the body cavity.

Now the hindgut has a dorsal part extending from the caudal intestinal portal to the cloacal membrane, and a ventral part, i.e. the allantois.

The dilated cavity receiving the hindgut proper and allantois is lined by endoderm and is called endodermal cloaca. Ventrally endodermal cloaca is closed by cloacal membrane. Endodermal cloaca with hindgut proper and allantois are together surrounded by mesenchyme. At the junction of the hindgut and allantois there is proliferation of the mesenchyme and endoderm, and as a result a septum develops called the urorectal septum. Classically the urorectal septum is formed by the downgrowth of the Tourneux’s fold.
and ingrowth of the lateral folds of Rathke that fuse in the midline. This septum grows further to divide the endodermal cloaca into a dorsal part and a ventral part. The dorsal part develops into rectum and anal canal. The ventral part develops into vesicourethral part and urogenital sinus. The vesicourethral part gives rise to the bladder and the proximal part of prostatic urethra in male, and bladder and the whole of the urethra in female. The urogenital sinus develops into the rest of the urethra in male, and caudal five-sixths of vagina in female.

The urorectal septum also divides the cloacal membrane. The posterior part is called the anal membrane and the anterior part is called the urogenital membrane. Perineal body develops at the junction of these two membranes.

**Theory of Chatterjee and Roy**

As the conventional theory fails to explain all the anomalies Chatterjee and Roy put forward a different hypothesis.

a. **Internal cloaca with allantois and hindgut opening into it:** It is separated from external cloaca by cloacal membrane. Arrow is in the mesodermal urorectal septum (Fig. 71.2).

b. **Descent of the urorectal septum and cloacal duct and growth of hindgut (Fig. 71.3):** The internal cloaca is now the urogenital sinus and Wolffian duct opens into it. A ureteric bud grows from the terminal end of each Wolffian duct.

Wolffian duct opens into it. A ureteric bud grows from the terminal end of each Wolffian duct.

c. **The growing tip of the hindgut reaches the posterior margin of the cloacal membrane and thus opens into the external cloaca (Fig. 71.4).**

d. **The cloacal duct has closed and the mesoderm fills the space between the hindgut and the urogenital sinus (Fig. 71.5).**
e. The surface ectoderm around the opening of the hindgut is drawn in to form the lining of the lower half of the anal canal (Fig. 71.6).

f. The anal opening migrates backwards to reach the posterior perineum (Fig. 71.7).

They agreed that hindgut developed by growth and caudal migration. The growing tip was not at the cloacal opening, but distal to the opening. When it reaches the normal anal site the cloacal opening closed. This closure was brought about by the frontal and lateral septa described earlier.

The majority of the malformations are due to the growth failure of the hindgut or agenesis. Arrest of growth takes place at varying distances from the cloacal membrane giving rise to high, intermediate or low malformations. In these anomalies, the whole of the cloacal membrane is taken up by urogenital sinus. Surface ectoderm at the normal anal site forms the normal skin without any dimple. Mesoderm intervenes between the endoderm and surface ectoderm. It differentiates normally to form the pelvic diaphragm, the levator sling around the urogenital tubes and striated muscle complex at the normal anal site.

Abnormal Development due to Anorectal Agenesis (Figs 71.8A to D)

a. The connection between the hindgut and the urogenital sinus may remain patent as a fistulous opening into the urinary bladder, prostatic or bulbar urethra in male or unsplit rectovaginal passage, the vagina or the vestibule in the female.
b. Cloacal duct closes and leaves a blind terminal bowel.
c. Original connection may close and a new connection can develop.
d. New connection may persist with non-obliteration of the cloacal duct leading to formation of two openings.

Abnormal Development without Anorectal Agenesis (Figs 71.9A to D)

a. Persistence of the cloacal duct leading to a fistula with normal anorectum.
b. Anterior perineal anus—failure of posterior migration
c. Covered anus—anus covered by genital folds.
d. Normal anus with atresia.

Theory of Van der Putte

After working on pig embryos he has shown that previous theories are not acceptable. He showed that future urinary passage, future anorectum and tail gut open into the cloaca. Cloacal plate, made of multilayered solid epithelium, separates cloaca from the amniotic cavity. The cloacal plate extends dorsally to the tail groove and ventrally to the tip of the genital tubercle. The urorectal septum is not a true septum, but a large mesenchymal mass with two tubular structures which are the future urinary and anorectal...
Figs 71.8A to D: A. Connection between hindgut and urogenital sinus B. Blind terminal bowel C. New connection between terminal bowel and exterior D. New connection with non-obliteration of cloacal duct

Figs 71.9A to D: A. Persistence of cloacal duct B. Anterior perineal anus C. Covered anus D. Rectal atresia
passages. He suggested ‘uroenteric region’ to be a more appropriate term for the urorectal septum. In the older embryo (15 -18 mm.) the urorectal septum was never to fuse with the cloacal plate. The classically described downgrowth of the urorectal septum was brought about by the changes that occur in the dorsal part of the cloacal membrane. When the dorsal part of the cloacal membrane breaks, the future urinary tract and the anorectum are simultaneously exposed. The urorectal septum broadens and the distance between the urogenital sinus and the anorectum increases.

He postulated the followings:

a. Agenesis of the whole cloacal membrane gave rise to absence of both urethral and anorectal orifices.

b. Agenesis of the dorsal part of the cloacal membrane gave rise to the anorectal agenesis, stenosis and ectopia. Superficial defects were thought to give rise to low malformations like simple stenotic anus, complete and incomplete covered anus and anterior perineal anus in male and female, and vestibular anus or rectovaginal fistula in the female. Defects extending deeper were responsible for anal or anorectal agenesis with rectobulbar, rectoprostatic, rectovesical fistulae in the male, and rectovesical and rectovestibular fistulae in the female. In the same way anorectal agenesis without communication and regressive changes in the epithelium of these communications were found in a number of embryos he studied.

c. Agenesis of the ventral part of the cloacal membrane gave rise to stenosis and ectopia of the urethral orifice, hypospadias or urethral agenesis with communications to the anorectum.

d. Interruption of the dorsal part by an isolated defect produced a double anus or a combination of an ectopic anus and a fistula with the urogenital system.

e. Interruption of the ventral part by an isolated defect produced a double urethral orifice.

f. Excessive formation of the cloacal membrane with extension too far ventrallywards gave rise to epispadias and extrophiies.

**ANATOMY**

Structures responsible for anorectal continence are gut, muscles, nerves and higher centers.

**Gut**

Sensory elements:

a. Rectal wall nerve endings and stretch receptors

b. Puborectalis

c. Striated muscle complex

d. Anal mucosa

Motor elements:

a. Rectal wall

b. Levator ani

c. Puborectalis

d. Striated muscle complex

e. Internal sphincter

f. External sphincter: Superficial, deep and subcutaneous.

**Muscles**

Important muscles for anorectal continence are internal sphincter, external sphincter, puborectalis and striated muscle complex. Levator ani, except its puborectalis part, has a less important role.

i. **Internal anal sphincter**: Classically it is described as a condensation of circular smooth muscle around the upper three-fourths of the anal canal. It starts at the anorectal junction and ends at white line. Normally it remains tonically contracted. When feces enters the rectum the internal sphincter gets dilated reflexly. About 80% of the resting anal pressure is due to the internal anal sphincter.

Sympathetic nerve supply comes from plexuses around superior rectal artery and hypogastric plexus. Parasympathetic nerve supply comes from pelvic splanchnic nerves (S₂, 3, 4).

ii. **External anal sphincter**: Classically it has three parts—deep, superficial and subcutaneous (Fig. 71.10).

a. Deep part: It is a thick band of muscle encircling the upper part of the internal sphincter. It has no bony attachments. Its proximal and deeper fibers blend with puborectalis, a part of levator ani. Anteriorly after encircling the anal canal some fibers decussate into superficial transverse perineal muscles (Fig. 71.11).

b. Superficial part: Only this part of the external sphincter has bony attachment. It is attached
posteriorly to the last piece of coccyx through the anococcygeal raphe. Anteriorly it is attached to the perineal body. This part encircles the lower part of the internal sphincter.

c. **Subcutaneous part:** It encircles the lower end of anal canal. Motor supply of external sphincter comes from the inferior rectal branch of the pudendal nerve (S2,3) and from the perineal branch of the 4th sacral nerve.

**iii. Levator Ani:** Levator ani of both sides form the major part of the pelvic floor. So far as the multiple parts and functions are concerned it is the most complex muscle of the body. It has the following parts.

a. **Pubococcygeus:** Anteriorly it is attached to the posterior surface of the body of the pubic bone of the same side. Posteriorly it is attached to the anterior surface of the coccyx. Medial part of pubococcygeus has the following subdivisions:
   - Fibers related to sphincter urethrae in both sexes and levator prostatae in male.
   - Some fibers are attached to vaginal wall, called pubovaginalis.
   - Some fibers are attached to the perineal body and anal canal, called puboanalis.
   - **Puborectalis:** It forms a sling around the anorectal junction (Described below in details).

b. **Iliococcygeus:** It is thinner than pubococcygeus. Anterolaterally it arises from obturator fascia and ischial spine. Posteriorly it forms the anococcygeal ligament and is attached to the sides of the last two pieces of coccyx.

   Medial fibers of levator ani have important role in fecal continence. During PSARP operation the surgeon deals with these fibers. The puborectalis part of levator ani increases the strength of external sphincter.

iv. **Puborectalis:** Histologically it is a skeletal muscle. It is the medial most part of levator ani. Puborectalis of both sides form a muscular sling around the posterior aspect of the anorectal junction. Anteriorly each puborectalis is attached as a band to the pubic bone of the same side. Anterior to the anorectal junction only a few fibers of each side unite with each other—thus forming some sort of a complete ring. Puborectal sling causes an acute angle at the anorectal junction.

Arrangement of the muscle fibers of the puborectalis and the different parts of the external sphincter is complex. Muscle tone of both external and internal sphincters keeps the anal canal and anus closed except during defecation. Their contractions increase when the intra-abdominal pressure rises during forced expiration, straining, coughing, etc. The purpose is to prevent soiling. The external sphincter, being a striated muscle, can also be voluntarily contracted to occlude the anus more firmly. The external sphincter is more effective than the internal sphincter. The latter is unable to close the anal canal.
completely. Puborectalis forming a sling round the posterior aspect anorectal junction pulls the upper part of the canal forwards to form an acute angle at the anorectal junction, thus assisting its closure.

In resting conditions the anal sphincters undergo periodic increased contractions at the rate of about 15/min with some reversal of peristaltic action, presumably helping to prevent leakage and returning the fecal debris to rectum and upwards.

vi. **Striated Muscle Complex:** Puborectalis and the deep part of the external anal sphincter fuse together to form striated muscle complex.

**Nerves (Figs 71.12A and B)**

i. **Parasympathetic:** Sacral3,4 are motor to the bowel and inhibitor to the sphincters and carries sensation for rectal distension.

ii. **Sympathetic:** Arises from the lumbar2,3,4 ganglia, and they form preaortic plexus. These are inhibitor to the bowel and motor to the internal sphincter.

iii. **Somatic:** Anterior roots of S2,3,4 via pudendal nerve, then through the perineal branch of the 4th sacral nerve. These fibers supply puborectalis and external sphincter.

iv. **Sensory:**
1. Pain is carried by free nerve endings.
2. Touch sensation is carried by Meissner’s corpuscles.
3. Cold sensation is carried by end bulb of Krause.
4. Sensation of Tension is carried by Pacinian corpuscles and Golgi Mazzini.
5. Sensation of friction is carried by genital corpuscles.

Muscular coordination required for the complex activities depends on reflex control involving the smooth muscles of the internal sphincter, enteric plexuses and associated autonomic and visceral sensory nerves. For the skeletal muscle of the external sphincter, puborectalis and associated perineal muscles, regulation is partly reflex and partly voluntary through the visceral and somatic afferent nerves.

Rich sensory innervation of the rectal and anal canal linings and proprioceptive fibers in the muscles and surrounding tissues is essential for normal anorectal continence. Neural integration of these sensory inputs and appropriate motor control are performed at many levels in the nervous system including the spinal cord, brain stem, thalamus and the cortex. Process of defecation is regulated by these operations. Moreover, the integrity of the sensory nerves and the higher center enables the child to differentiate between flatus and feces, and between solid and liquid stool. This differentiation is essential for normal anorectal continence.

**CONCEPT OF DE VRIES AND PENA**

The knowledge of anatomy of the pelvic floor muscles and anorectal sphincters, and their role in the maintenance of continence was standing more or less in the same place for a long time. Two decades ago Alberto Pena the Mexican Pediatric surgeon introduced the revolutionary operation, i.e. Posterior Sagittal Anorectoplasty (PSARP) for the management of ARM.18,19
Several authors studied levator ani muscles for the presence of puborectal sling and formation of the rectal sphincters. Their views were accepted without modification. Pena performed anatomical dissection and electrical dissection of the pelvic muscles and CT scan for the pelvic musculature. He found that the levator ani of both sides constituted a funnel shaped structure around the rectum and anal canal. On each side of the rectum and anal canal there is a sheet of parasagittal fibers. He also stated that these muscle fibers run parallel to each other on either side of the mid sagittal plane. His concept not only challenged the various components (e.g. subcutaneous, superficial and deep) of external sphincter, but also questioned the very existence of the puborectal sling, which was once considered as the key factor in maintaining anorectal continence.

So it can be concluded that:
1. External anal sphincter is represented by two sets of fibers:
   a. Parasagittal fibers running from the tip of the coccyx to the anal skin parallel to the midline in the sagittal plane.
   b. Vertical fibers running medial and perpendicular to the parasagittal fibers.
2. The levator ani fibers are continuous below with the upper part of the vertical part of the external sphincter and they are inseparable from each other.
3. Separate existence of the puborectal sling cannot be ascertained.

Pena says that the most of the muscle fibers run in a cephalocaudal direction. The muscles have their nerve supply from the respective sides. So if the muscles are divided exactly in the midline, no damage is done because the parallel muscle fibers are actually separated, not divided.

Pena and his associates showed that their views were proposed by Amussat (1835) long ago. But no detail descriptions were given.

Pena's views have been challenged by Prof Durham Smith (1987), the father figure of Pediatric Surgery with a mammoth contribution in the field of ARM. He criticized the deliberate division of the muscle complex and considered that the deep portions (deep external sphincter and puborectalis) were essential muscles for continence and the patient would never gain continence since the puborectalis has been considered a key structure for fecal continence (Konar H). Direct exposure of the anatomy allows one to recognize that the divided muscle do not retract, as expected. Although there are some horizontal fibers, most of the muscle fibers run in a cephalocaudal direction, so one is separating parallel muscle fibers. In addition, there is a very thin midline fascia and raphe hat requires a meticulous technique to be identified and posterior sagittal approach is based on the fact that the nerves do not cross the midline. So keeping exactly in the midline ensures preservation of nerves of all important pelvic structures. Moreover, suturing all the muscles behind the pulled-through rectum will restore the functional efficacy of these muscles.

Good results of PSARP operation done by most of the surgeons all over the world support the golden concept of Pena.

ANATOMIC CONSIDERATIONS

Poor Continence in High ARM

a. In high ARM the whole of the anal canal may be absent. As the sensory receptors are present in the distal half of the anal canal, and as sensory receptors have a very important role in normal continence, in high ARM often there is poor continence.

b. In high ARM extensive dissection becomes necessary, during which small blood vessels supplying the rectum have to divided. The nerves accompany the blood vessels. So during this procedure fine nerves are also injured. So there is poor continence.

c. Associated anomalies of the sacrum and vertebral column in high ARM is an important factor for poor continence.

d. Sphincter muscles are often poorly developed in high ARM.

ARM and Sacral Agenesis

Important points are:
1. Development of sacrum, levator muscles and sacral nerves are closely related. At least three sacral segments are necessary for normal continence.
2. 30% of ARM cases have spinal or sacral anomalies. About 50% of high ARM cases have vertebral anomalies. So at least a straight X-ray of the spine must be done in all cases of ARM.
3. In caudal regression syndrome vertebral anomalies are associated with urinary and gastrointestinal anomalies.
4. Sacral anomalies may be symmetric or asymmetric. Types of sacral deformities are butterfly, dysplastic and hemivertebra.

5. 1% of the diabetic mothers have offspring with sacral agenesis. 16% of children with sacral agenesis have insulin-dependent diabetes mellitus.

6. Clinical diagnosis can be made by the absence of bony prominence just behind the normal anal site. Gluteal cleft is usually absent and the buttocks are flat.

7. Degree of neurologic deficit cannot be predicted from the number of absent sacral segments. Motor involvement is more common than sensory involvement. In 75% cases of sacral agenesis perianal sensation does persist.

**Problems of Common Wall in ARM**

The problems are:

1. In rectourethral fistula in male invariably there is a common wall. The lower the level of rectourethral fistula, the more is the length of the common wall. Common wall between the rectum and the urethra makes the dissection difficult, and there is risk of injury to the urethra. Persistence of cloacal duct explains blind ending rectum, rectourinary fistula and a common wall.

2. In anovestibular or rectovestibular fistula in female there is a common wall between the rectum and the vagina.

**Anatomic Abnormalities and Urinary Tract Injuries in ARM**

Problems are:

1. As there is failure of complete separation between the anorectum and the urinary tract, they are in more close proximity than in normal children. So during dissection of the blind anorectum there is risk of injury to the bladder and urethra. Placing a urethral dilator in the urethra helps identification of the urethra better than placing a Foley’s catheter. Before opening up the bowel it is a good practice to aspirate with a syringe-needle. Of course a catheter introduced through the distal colostomy opening helps identification of the blind rectal end.

2. Rarely an ectopic ureter may get injured during dissection of the rectum.

3. Sometimes the most distal structure is the bladder (or urethra) and not the rectum. So it is better to open the bowel 1 cm proximal to the end of the blind rectum.

**PHYSIOLOGY**

Anorectal continence depends on:

A. *Propulsive force*: It depends on the volume of feces, voluntary contraction of the striated muscles (abdominal and diaphragm) and contraction of the smooth muscles of the colon and rectum.

B. *Resistance at the outlet*: Resistance at rest is offered by anorectal angulation, tonicity of the internal sphincter, contraction of striated muscle complex and congested veins of the pelvic floor.

C. *Sensation*: Exquisite sensation in the normal individual resides in the anal canal. Except for the patients for rectal atresia most patients with ARM are born without an anal canal, therefore the sensation does not exist or is rudimentary. Still the distension of the rectum is felt in many of these patients, provided the rectum has been placed properly within the muscles. This sensation appears to be due to stretching of the voluntary muscle (proprioceptive). The most important clinical problem is that liquid stool or soft fecal material may not be perceived by the patients with anorectal malformations as the rectum is not distended. Thus, to achieve some degree of sensation and bowel control, the patient must have the capacity to form solid stool.

D. *Bowel motility*: Perhaps the most important factor in fecal continence is bowel motility. However, motility has been largely underestimated. In a normal individual the rectosigmoid remains quiet for periods of 12 hours to several days. So if there is motility disorder that has to be corrected.

**CONCLUSION**

If anorectal reconstruction is done early in ARM it is perhaps true that new nerves do develop in the pulled-down bowel. As in other cases perhaps locally acting growth factor is responsible for this neural advancement.

*After all these detailed discussions it boils down like this:*

1. Pena has not shown any new anatomical concept of the muscles of the anorectal region. If it would have been so, his concept would have been included in all the current text books of Anatomy. A thorough search was made in all the recent text books free.com
books of Anatomy as also on the internet, but there is no reference of Pena’s article.

2. Discussions with the anatomists about the concept of Pena revealed that if we go down from above—levator ani, puborectal sling, deep part of the external sphincter, superficial part of the external sphincter—it will look like a funnel. Parasagittal fibers are nothing but superficial part of the external sphincter.

What Pena has impressed us all?
Previously we were afraid of cutting the puborectal sling and the vertical component of the muscle in the pre-Pena era with a mental block that if we cut the puborectal sling and vertical component it will lead to incontinence. In order to avoid cutting the puborectal sling people had to operate on an area where there was so little space to work in sacroperineal or sacroabdominoperineal approach. In this approach there was unnecessary overstretching of the puborectal sling and in some of the cases one could not place the bowel within this sling and thereby compromising with the continence.

What Pena has shown to all of us?
If we stay exactly in the midline and cut all the muscles from the sacrum down to the anus:
1. There is no chance of damaging the nerves.
2. Excellent operative visualization.
3. If we suture all the components in the midline after bringing the bowel down to the anus—there is no compromise with the continence. Pena has demonstrated this by his operation and postoperative results.

Many ill-treated cases of ARM are leading a miserable life with fecal incontinence. As ARM is a common anomaly, and as fecal incontinence is a serious hindrance for a child to live meaningfully in a society, and as failure cases are very difficult to manage, it is perhaps well justified to build up a separate discipline to deal with ARM only.

REFERENCES
Whenever a baby is born with absence of anal opening in perineum, the condition has been traditionally named as "imperforate anus". It is actually an overt clinical presentation of a wide spectrum of malformations involving the agenesis of anal canal and/or rectum with variable development of sphincteric muscles of continence. It is more often associated with fistula and possibilities of associated visceral and skeletal anomalies. These anomalies of imperforate anus are more accurately termed as anorectal malformations (ARM). Wide spectrum of defects ranges from non-complex low malformations to very complex high malformations of anorectum. Low anorectal malformations are associated with well developed rectum, anal canal, sphincters and sensory receptors with prospects of good prognosis whereas high malformations are complicated due to poor development of sphincters and its innervation with associated genitourinary anomalies which are difficult to treat and associated with prospects of poor prognosis.

Precise diagnosis of pathological anatomy, effective and efficient therapeutic approach and meticulous technique of repair in planned manner by an expert, is the only hope to save these babies from life time misery and offer the control of defecation. In 1959, Potts, then Surgeon in Chief at Children's Memorial Hospital in Chicago wrote "In general, atresia of the rectum is more poorly handled than any other congenital anomaly of the newborn. A properly functioning rectum is an unappreciated gift of greatest price. The child who is so unfortunate as to be born with an imperforate anus can be saved a life time of misery and social seclusion by the surgeon who with skill, diligence and judgement performs the first operation on the malformed rectum.

More than forty years later despite enormous advancement in understanding of abnormal anatomy, advances in imaging and plethora of technical breakthrough above statement stands true even today. Approximately 50% of babies with high ARM fail to achieve normal continence despite being treated with perfection in best hands and the figure will swiftly go up with inappropriate decision and wrong technique forcing more children towards life long misery and permanent colostomy. Therefore, surgeons carry great responsibility in management of this problem and cannot afford a casual approach. This chapter will review the diagnosis and current management of ARM.

MAGNITUDE OF THE PROBLEM

Average worldwide incidence of ARM is reported to be 1 in 5000 live births. However, in India Chatterjee reported incidence of 1 in 1862 births in Calcutta and approximately 13,223 babies with anorectal malformations are born every year in India. Even this may be an underestimate. Firstly because some cases may never reach the hospital and low anomalies with fistula may not attend the hospital in neonatal period.

CLASSIFICATION

Importance of determination of exact type of malformation and level of patent rectum cannot be overemphasized (Figs 72.1 to 72.5). It will not only guide the management strategy but also help in comparing the clinical results of one technique with those of another.
In addition to records of earlier classification first modern classification of ARM was described by Ladd and Gross in 1934. Denis Browne first conceived the necessity of classifying the Ladd-3 type of anorectal malformations into "High" and "low" depending upon whether the gut terminated above or below the pelvic floor. Douglas Stephens recognized the importance of puborectalis sling in defecation and fecal continence and divided these lesions into high or supralevator where bowel terminates on cranial side of the levator muscle and low or infralevator anomalies in whom the bowel extends through most of the levator and sphincter muscles.

The International Classification of 1970 was proposed in an attempt to ensure that surgeons were describing the same condition and Intermediate or translevator group of anomalies were added with other diverse anomalies. In practice, it proved unwieldy and complex. The Wingspread classification of 1984 is a simpler version that combines anatomic details with what is known of the embryology (Table 72.1).
A descriptive classification based on initial management decision more related to surgical imperatives was proposed by Alberto Pena to decide whether a colostomy is required or not (Table 72.2) which was subsequently modified by Rintala.9,10

Irrespective of the method used for classification basic essential features remain unchanged which are:

1. Most female babies with ARM are intermediate and low anomalies while majority of malformation in male are high or intermediate anomalies.

2. In female baby with ARM rectum or anal canal almost always opens as fistula either in vagina, vestibule or perineum, wide enough to permit passage of gas and stool, therefore, these patients may not present as intestinal obstruction.

3. In male baby with ARM rectum may open in bladder neck, prostatic urethra or bulbar urethra with narrow fistula insufficient to decompress the colon or a fistula may not be present at all and these patients present with intestinal obstruction.
**DIAGNOSIS AND INVESTIGATIONS**

**Antenatal Diagnosis**

The normal anal canal in the fetus can be appreciated on ultrasound as circular rim of hypoechoic tissue in the perineum with central linear echogenic stripe (Guzman et al).\(^1\) The sonographic evidence of ARM is non-specific in the form of dilated fetal bowel and abnormal appearance which is suggestive but not diagnostic of ARM. Associated anomalies like esophageal atresia, caudal regression syndrome, hydrometrocolpos and renal anomalies are readily identified by antenatal sonography.

**Neonatal Assessment**

Diagnosis of absence of anal opening is usually straightforward, it is surprising but not uncommon that such obvious anomaly is often missed and discovered at second look when abdominal distension begins or baby does not pass stool for 24 hours.\(^4\)

*Fig. 72.3:* Anatomy of Low ARM showing level of rectum, site of fistula and relation to sphincter muscle.
Fig. 72.4: Anatomy of cloacal malformations showing level of fistula and relation to sphincter muscle

Fig. 72.5: Rare ARM showing level of fistula and relation to sphincter muscle
C. What is the integrity of neuromuscular component?

Assessment of level of malformation, and fistula in relation to sphincters can be done by: 12

1. Clinical examination of baby and examination of urine in males
2. Invertogram
3. Plan X-ray showing presence of gas in other viscera
4. Dye study of fistula
5. Ultrasound
6. CT scan
7. Endoscopy and Electromyography.

In neonatal period sufficient information can be obtained with careful clinical examination alone and combined with findings of invertogram, correct decision regarding initial operative management can be made in almost all cases.

Clinical Evaluation in Male

Mother of the baby may give information about passage of meconium per urethra (meconuria), passage of air per urethra (pneumaturia) or history of staining of clothing with meconium coming out from unidentified orifice. Occasionally, baby is brought to hospital with history of abdominal distension and absolute constipation since birth absolutely unaware of absence of anal orifice. In India, it is not rare to see patients with ARM reaching hospital with perforation-peritonitis, severe respiratory distress and septicemia.

Initial assessment of a neonate with absence of anal opening is aimed at answering the following questions:

A. What is the level of rectum, in relation to sphincters and where is fistula. This information will help in deciding.

1. Can the anomaly be corrected without colostomy by single stage perineal surgery?
2. Whether colostomy is required and definitive surgery is to be done later on?

B. Is there any other associated anomaly which needs immediate or subsequent correction?
History of regurgitation of feeds with drooling of saliva may be present if the patient of ARM has associated esophageal atresia.

In addition to general examination and assessment of associated anomalies local inspection of perineum may reveal valuable information regarding the type of anomaly and level of rectum. Perineal inspection should always be done under good shadowless light with baby held in lithotomy position and if needed magnifying glass may be used for inspection of median raphe.

Inspection starts at the point where normal anal opening should have been present and proceeds anteriorly along the median raphe. Appearance of perineum, natal cleft, and presence of skin fold or pigmentation at anal dimple, configuration of genitalia and presence of an orifice on medium raphe from frenulum to anal dimple are noted. Careful inspection of perineum will reveal either of the three possibilities

1. Absent anal orifice with clinical evidence of perineal or urethral fistula.
2. Normal looking anal orifice with anorectal malformation.
3. Absent anal orifice with no external evidence to indicate the level of rectum and fistula. In this group presence of meconeum or squamous epithelial cells in voided urine sample may provide the clue. If urine examination is also normal, invertogram is must for decision making.

Description of physical sign and diagnosis by inspection of perineum with management decision in male ARM is given in Table 72.3.

Pena has described a decision making algorithm for ARM in male.13 It essentially gives three options.

i. A perineal fistula indicates low malformation and baby can be managed with anoplasty without colostomy.
ii. Meconeum in urine indicates recto-urethral fistula and initial colostomy is needed followed by definitive surgery.

In case no perineal fistula and no meconeum in urine is discovered further decision making is based on Invertogram/prone cross table X-ray findings.

**Clinical Evaluation in Female**

In female patients with ARM, almost always mother will complain that baby passes stool through genital orifice with absence of anal opening.

Rare anomaly like anorectal agenesis without fistula and rectal atresia will present with abdominal distension. Patients with perineal canal will present with history of passage of stool through normal anal orifice and genital orifice as well.

Decision-making involving opening of colostomy in female is an easier process and rarely radiological investigations are needed. By and large female ARM will have a fistulous communication through which they pass meconeum and diagnosis can nearly always be predicted by examination of genitalia and perineum.

For perineal inspection, importance of good shadowless light, adequate prior cleaning of genitalia and vestibule which may be full of stool or meconeum and identification of abnormal orifice in vestibule by probing with lubricated red rubber catheter or hegar’s dilator cannot be overemphasized.

In cases of closed vulva repeat examination under general anesthesia and midline division of fused labial folds may be needed.12 Description of findings of perineal inspection, diagnosis and decision-making is given in Table 72.4.

In malformations without fistula which is very rare, help of invertogram or prone cross table X-ray is sought for decision-making process.

**Invertogram**

Invertogram is the single most important investigation that helps in deciding the level of rectum in relation to sphincters. The use of plain radiograph for determination of level of rectal pouch was first described by Wangensteen and Rice in 1930 and subsequently modified by Stephen in 1953, Kelly in 1969.14-16

**Basic Principle**

Soon after birth, with each breath, baby starts swallowing air which traverses through the gastrointestinal tract to reach the rectum in 4 to 12 hours and by 18 hours rectum is well distended. X-ray, true lateral view of the pelvis at birth shows following relevant bony landmarks.

1. Anterior most boomerang shaped shadow is casted by superior pubic ramii and ospubis. The angle of junction of the boomerang corresponds to upper border of pubic symphysis which forms the p point (The ossification of the pubis
begins at second fetal month under the acetabulum and extends along the superior ramus to body.

2. Posterior most bony shadows are five ossified segments of sacrum, fifth sacral segment at birth appears as small ossific ring (ossification begins at 4th mouth of gestation) coccyx is not ossified at birth hence not visible, but a point just caudal (5 mm) to fifth ossific center of sacrum corresponds to coccyx and is marked as C point. Line drawn between P and C point is called pubococygeal line (PC line).

Contd...
Ill. Third orifice seen as normal anal orifice (No intestinal obstruction)

i. Stool coming out from anal orifice as well as vestibular fistula
   Perineal canal (Fig. 72.14)          ASARP
   No colostomy

ii. Normal anal orifice with red moist groove between anus and fourchette
    Perineal groove          Anoplasty
    No colostomy

Illb- Third orifice seen as normal anal orifice (with intestinal obstruction)

i. Anal orifice present but with intestinal obstruction.
   Red rubber catheter can not be passed beyond 2 cm
   Rectal atresia          Colostomy

ii. Anal orifice present but with intestinal obstruction.
    Red rubber catheter can not be passed beyond 1 cm
    Imperforate anal membrane          Anoplasty

iii. Anal orifice present but with intestinal obstruction. Red rubber catheter can not be passed beyond 1 cm with ribbon stool.
     Anal membrane stenosis (rarely anorectal stenosis)          Anoplasty

iv. Third orifice seen as stenotic anal orifice
    Covered anal stenosis          Anoplasty

IV- No external orifice or fistula seen (rare)

i. No orifice discovered with absence of anus (rare) (Fig. 72.15)
   Diagnosis can not be predicted          Investogram

---

Figs 72.10A to C: A. Appearance of perineum in a case of cloaca; only one orifice is seen. B. Perineal appearance in rectovaginal fistula. Urethral meatus (U) is seen separate from vaginal orifice. Stool is coming out from vaginal orifice. C. Perineal appearance in a case of rectovestibular fistula with vaginal atresia; urethral and vestibular orifices are seen.

Figs 72.11A and B: A. Rectovestibular fistula. Examination reveals urethral meatus (U), vaginal orifice (V) and third vestibular orifice (R) from which stool is coming out. B. Hegar’s dilator passed through vestibular fistula goes cranially parallel to vagina and its tip is not palpable at anal dimple.
Figs 72.12A and B: A. Anovestibular fistula, urthral orifice (U), vaginal orifice (V) and third vestibular (R) orifice seen, B. Hegar's dilator in vestibular fistula goes posteriorly and its tip can be palpated at anal dimple

Figs 72.13A to C: A. Perineal appearance in case of anovestibular fistula with septate vagina. Urethral orifice (U), two vaginal orifices (V) and fourth vestibular orifice (A) is seen, B. Anterior perineal anus; normal calibre anus sited forward in perineum near the vulva, C. Anocutaneous fistula; stenotic and anteriorly placed anal orifice

Fig. 72.14: Perineal canal; Hegar's dilator can be passed through fistula between vestibule and anal canal

Fig. 72.15: A case of female ARM with no fistula, invertogram revealed intermediate malformation
3. In between P point and C point comma shaped shadow of ossified ischium is seen and PC line crosses it through the junction of caudal 3/4 and cranial 1/4 of ischial shadow. Anterior and inferior end of ischial comma is marked as I point. In cases of sacral agenesis PC line can be drawn between P point and the points at the junction of caudal 3/4 and cranial 1/4 of ischial comma (Fig. 72.16).

Stephens has demonstrated that PC line crosses through bladder neck, verumontanum, peritoneal reflection from prostate to rectum in male (Fig. 72.17). In female PC line crosses through bladder neck, external os of cervix and peritoneal reflection from vagina to rectum. Puborectalis and diaphragm part of levator lie caudal to PC line (Fig. 72.18).

**Technique**

For correct interpretation, invertogram should not be done before 18 hours of birth and relevant points in technique should be adhered to.

A true lateral view with accurate centering on greater trochanter is essential to ensure that two shadows of faintly ossified centers of pubes are superimposed with superimposition of shadows of two ischial bones.

The baby should be held upside-down for 3 minutes to allow displacement of meconium and accumulation of gas in terminal rectal pouch. A marker or thin barium smear accurately applied at natal cleft on anal dimple helps in measurement of skin bowel distance in invertogram film.

Repeat films may be taken if gas shadow remains proximal to ischial line and abdominal distension is minimal.
If X-ray is taken earlier than 18 hours, time allowed after inversion is less than 3 minutes, meconium remains stuck to terminal rectum, active contraction of pulsorectalis occurs or gas escapes through fistula an intermediate or low ARM may be wrongly interpreted as high anomaly.

**Prone Cross-table Lateral X-ray**

An alternative to invertogram is prone cross table lateral X-ray described by Narasimha Rao et al. Baby is placed in prone genu pectoral position for 3 minutes and a true lateral radiograph is taken centered over greater trochanter. Interpretation is similar to invertogram but following advantages are reported:

1. Positioning in genu pectoral position is easier as compared to inverted position.
2. Baby remains comfortable in this position, fallacy in interpretation of invertogram due to contraction of puborectalis while baby is crying in inverted position is less likely to occur with prone position.
3. Rectum may be pulled in cephalic direction due to gravity with invertogram but not in prone position.
4. In tracheo-esophageal fistula prone position will be preferred as compared to inverted position.

**Interpretation**

I. Gas shadow ends proximal to PC line → High anomaly → Colostomy is required (Fig. 72.19).

II. Gas shadow ends in between two lines → intermediate anomaly → Colostomy is required (Fig. 72.20).

III. Gas shadow crossing the I point → Low anomaly → Perineal proctoplasty is required - no colostomy (Fig. 72.21).

In place of anatomical landmarks, Pena prefers to measure skin bowel distance which if shorter than 1 cm, anomaly is treated as low and if skin bowel
distance is more than 1 cm, colostomy is recommended, however, author finds use of anatomical landmarks a more reliable method in decision making (Fig. 72.22). It may not be possible to accurately identify the 'P' point if the centering of patient is inaccurate. If identification of 'P' point becomes difficult, even in repeated films either because of inaccurate centering or due to superimposition of shadow of femur specially in prone cross table lateral films, decision regarding creation of colostomy versus anoplasty can be made by observing the rectal gas shadow in relation to 'I' point.

Apart from rectal gas shadow, study of distribution of gas in other viscera in anteroposterior and lateral films may provide valuable information. Presence of congenital short colon is diagnosed if single large gas shadow occupies half of the abdominal width in anteroposterior film (Fig. 72.23). Presence of gas in bladder may indicate rectovesical fistula (Fig. 72.24).

**Ultrasound Examination**

Abdominal ultrasound will help in assessing genitourinary anomalies while perineal ultrasound can help to decide the distance between skin and rectal pouch as an alternative or supplement to information provided by invertogram.18,19

**Dye Study of Fistula (Figs 72.25A and B)**

It is not an essential investigation because site of external visible orifice mostly indicates the pattern of internal anatomy. However, in female ARM it may be helpful in distinguishing rectovestibular from anovestibular fistula and the investigation can be used for assessment of length of fistula specially in cases of anorectal stenosis.

---

**Fig. 72.22:** Invertogram of a case of low ARM; skin bowel distance is less than 1 cm

**Fig. 72.23:** Congenital short colon; inverted X-ray AP view shows single large gas shadow occupying half of the width of abdomen

**Fig. 72.24:** Invertogram showing presence of air in urinary bladder. Patient had rectovesical fistula
Direct percutaneous needle aspiration and injection of contrast in the rectal pouch have been described but in practice we do not prefer it because of invasiveness of the procedure while other non-invasive methods are quite satisfactory.

Finally, it cannot be overemphasized that in case level of rectum is not certain and doubt persists after investigations, a colostomy is done to leave the sphincters intact for subsequent planning and appropriate surgery. Currently, it is inexcusable to explore the perineum blindly and cause irreversible damage to continence mechanism.

**Preliminary Assessment of Associated Anomalies in Neonatal Period**

In addition to examination of a neonate, as a whole; recording gestational age, weight, temperature, color, cry, respiration, jaundice, abdominal distension, signs of respiratory distress, septicemia and dehydration, one should look for any other associated occult congenital malformation in general, and VACTERL syndrome in particular [V = Vertebral; A = Anorectal; C = Cardiac; TE = Tracheo-esophageal fistula with esophageal atresia; R = Radial and Renal, and L = Limb or skeletal anomalies]. Some of these anomalies are life threatening and need immediate correction. Esophageal atresia should be ruled out by passage of no. 8 red rubber catheter down to stomach. Plain X-ray of baby on a large plate will quickly reveal condition of chest, abdomen, short colon, presence of gas in other viscera and an overview of spine and skeletal anomaly. If general condition of baby permits and facility is available, emergency ultrasound and echocardiography may be included in part of neonatal assessment.

**Assessment after Colostomy**

Patients with high or intermediate ARM with colostomy are subjected to further investigations before planning definitive reconstruction. Purpose of the investigations are following:

Once acute emergency is over and intestinal obstruction is relieved detailed assessment of baby with colostomy is aimed at obtaining maximum possible information regarding:

1. Configuration, size and level of rectum and information regarding presence or absence of fistula.
2. Integrity of neuromuscular component and development of sphincters.
3. Detailed evaluation of urogenital system, spine, heart and other associated anomalies.

The most important investigation after colostomy is distal cologram which provides excellent infor-
Information about the level of rectum and presence or absence of fistula.

**Distal cologram:** Keiller was first to use barium suspension into the distal limb of colostomy to demonstrate the site of fistula but in current practice a water soluble contrast medium is used in place of barium.20

Before performing this valuable investigation distal loop of colostomy should be thoroughly washed with saline ensuring complete evacuation of any residual fecal matter in the rectum. Cologram performed with residual meconium or feces in the rectum will give inaccurate information regarding level of rectum and fistula will not be demonstrated even if it is present.

A Foley catheter is passed in distal stoma of colostomy and balloon is sufficiently inflated to block the distal lumen, purpose is to prevent reflux of contrast outside the distal stoma while injecting the contrast medium under pressure.

Patient is positioned to obtain true lateral view of the pelvis.

Organic iodine solution (we prefer urografin 76% diluted with equal volume of saline) is pushed in distal lumen under pressure through Foley’s catheter.

Volume of contrast instilled in distal lumen should be sufficient enough to distend the rectum under pressure for demonstration of exact level of rectum and fistula is opened up under pressure even if it is narrow.

Inadequate volume of contrast not injected under pressure will give false information regarding the level of rectum and presence of fistula.

Cologram, performed with precision, provides excellent information regarding shape, size and level of rectum with delineation of size and site of fistula, which is of immense value while performing the definitive repair (Figs 72.26A to 72.27B).

**Micturating cystourethrography and retrograde urethrogram (MCU and RGU):** Combined with cologram (MCU and RGU), can provide better information regarding the site of fistula. It will also provide information regarding vesicoureteric reflux and other associated anomaly in bladder and urethra.

**Assessment of Sphincters and its Nerve Supply**

Radiograph of the sacrum and lumbar spine are obtained for assessment of levator muscle. Smith has described a closed relationship between development of sacrum and extent of formation of levator muscle.12

i. Normal spine and well developed all segments of sacrum are the indicators of normal levator function and innervation.

ii. Deficiency of fourth and fifth sacral vertebrae usually allow normal innervation of bladder and levator.

iii. Deficiency of third, fourth and fifth sacral vertebrae is associated with variable innervation

---

**Figs 72.26A and B:**
- **A.** Distal cologram; rectovesical fistula
- **B.** Distal cologram; rectoprostatic urethral fistula is present, contrast has gone into bladder and urethra

**Figs 72.27A and B:**
- **A.** Distal cologram performed with insufficient volume and pressure fails to demonstrate the fistula
- **B.** Repeat film with adequate volume of contrast and pressure has demonstrated recto bulbar-urethral fistula
and muscle development, most patients are incontinent.

iv. Deficiency of first and second sacral segment is always associated with incontinence.

v. Presence of lumbosacral myelomeningocele is almost always associated with serious defect in innervation.

vi. Presence of hemisacral defects is associated with variable innervation and muscle development.

In order to improve the prognostic accuracy Pena has devised a sacral ratio based on sacral abnormalities. One ratio calculated from anteroposterior and lateral radiograph of sacrum in children with good prognosis is about 0.7-0.8 but those with a ratio of less than 0.4 tend to have high malformation with poor functional prognosis (Fig. 72.28).

**Assessment of Sphincters with Magnetic Resonance Imaging (MRI)/Computerized Tomography (CT) Scan**

With use of MRI and CT scans, components of sphincter can be visualized and their quality can be assessed before surgery. Level of rectum in relation to sphincter can be visualized in sagittal cut MRI (Figs 72.29A and B). The value of CT scan for patients

---

**Fig. 72.28:** Diagram to show calculation of sacral ratio. Line A drawn through highest point of iliac crest, line B through lowermost point of sacroiliac joint and line C passes through coccyx. Ratio of AB/BC should be 0.7 to 0.8. Ratio of less than 0.4 indicates poor prognosis (from Pena)

**Figs 72.29A and B:** A. MRI: Sagittal cut study in case of recto prostatic urethral fistula patient presented at the age of 20 year for definitive repair B. MRI: Sagittal cut study in a case of rectal atresia. Distance between proximal rectum, distal and canal is well demonstrated
with anorectal malformation was first reported by Ikawa in 1985. Pringle in 1987 reported use of MRI in delineating the anatomy of sphincters before and after corrective surgery. Since then numerous reports on role of CT/MRI scan have come up describing the morphology of sphincters. Before performing the definitive surgery, CT/MRI imaging of sphincters helps in better planning of definitive surgery. After surgery objective demonstration of deviation or placement of the rectum in the muscle complex is best possible with CT and MRI.

**Sacral Outflow Tests for Sphincter Innervations**

Second, third and fourth sacral segments innervate levator ani, sphincters, bladder parasympathetics and perineal dermatomes. Therefore, analysis of bladder and perineal sensation may provide important information about hidden pelvic floor innervation. History of voiding pattern may reveal almost continuous dribbling or overflow leakage. Bladder expressibility is most constant sign of paretic bladder. Presence of expressible bladder with or without bladder lamp heralds poor innervation of pelvic musculature.

*Perineal sensations:* Absence of response to pin prick sensation indicates defective innervation, however, normal perineal sensation does not mean normal sphincters.

**Detailed Assessment of Genitourinary System, Spine and Heart**

Children with ARM have a high incidence of genitourinary and lumbosacral spine anomalies. Some genitourinary anomalies are associated in approximately 66-71% in high ARM and 25% in low ARM. Vesicoureteric reflux, voiding dysfunction and sacral agenesis being more common. Therefore, ultrasound examination or IVP, micturating cystourethrogram and urodynamic studies are desirable. Cardiac anomalies most commonly encountered are ventricular septal defect, patent ductus arteriosus, atrial septal defect and tetralogy of Fallot’s should be identified and will effect the survival.

**Associated Defects**

These have been dealt with in a chapter 74.

**OPERATIVE MANAGEMENT OF LOW ANORECTAL MALFORMATIONS AND SINGLE STAGE PERINEAL REPAIR**

Low anorectal malformations are easier to correct because rectum and anal canal are well developed with its sensory receptors and is embraced by the striated muscle complex for control of defecation. The muscles are mostly well developed without loss of innervation or sacral vertebral segments. The surgical procedure is basically aimed at re-establishing a satisfactory anal orifice at normal site by simple perineal anoplasty. If low malformation presents with anterior ectopic fistula the orifice is transferred back to normal site. Results with all the techniques are good provided there is no stenosis of stoma, residual persistent posterior ledge or there is no infection and scarring. In emergency anal stenosis can be relieved by dilatation only and anoplasty be planned subsequently. The common surgical procedures in practice are:

**Anal Cutback**

This procedure was first described by Denis Browne in 1951. It was initially favoured because of simple technique and low complications. Cutback was described as a life saving procedure for a surgeon with limited experience and facility.

One blade of a pair of straight scissors is placed along the horizontal fistula and perineal tissue is cut exactly in midline to the site of neoanal orifice. Mucosa is sutured to the skin. Alternatively, Hegar’s dilator is passed in the fistula and midline division of all structures from fistula to anal site can be completed with a knife followed by mucocutaneous anastomosis (Figs 72.30A and B). It has been used as first aid procedure in patient with anovestibular fistula with severe stenosis having low birth weight and poor general condition to relieve the obstruction. Anocutaneous fistula, covered anus, anterior ectopic anus and anal stenosis have been managed with this technique with quite satisfactory results.

Presently, it has gone into disrepute due to nonscientific basis and resulting severe incontinence.

**YV Anoplasty**

An alternative procedure for low ARM with or without perineal fistula in YV anoplasty also known as...
Barrow’s flap anoplasty. A V-shaped skin flap is raised posteriorly with apex at posterior margin of fistula. Vertical incision through full thickness of bowel is made on posterior wall of anal canal which opens the bowel and creates a defect for advancement of skin flap into anal canal.

**Anal Transposition**

The anovestibular fistula is dissected all around and brought out through a separate incision given only above the proposed anal site.

**Limited Posterior Sagittal Anoplasty (PSAP)**

Pena has described minimal posterior mobilisation of fistula within the limits of external sphincter and anoplasty in prone position but author prefers to use the technique of anterior sagittal anorectoplasty for reconstruction of low malformations.

**Anterior Sagittal Anorectoplasty (ASARP)**

Anovestibular fistula and rectovestibular fistula in girls and anocutaneous or rectocutaneous fistula in boys are best managed with this technique as single stage perineal surgery. This procedure demands greater surgical skill and meticulous dissection because from anterior fistula to the proposed site of normal anal opening skin, and muscles are divided exactly in midline. The anus and rectum are dissected free from vagina or urethra and mobilized to be transposed posteriorly. Perineal body is reconstructed anterior to rectum and anoplasty is performed at proposed normal site well embraced by sphincter. The procedure reported by Okada and Wakhlu et al offers excellent results in anovestibular fistula and rectovestibular fistula in female. It can also be used for anocutaneous fistula in males. Author prefers single stage correction of all cases of anovestibular and rectovestibular fistula without colostomy.

**Anatomical Basis**

In anovestibular fistula and rectovestibular fistula levator muscle and adjacent part of muscle complex embraces the bowel at the cranial end, but downwards muscle complex runs posteriorly to terminate at anal dimple while anorectum courses anteriorly out of muscle complex to terminate in vestibule. Mid line incision from fistula to anal dimple will divide the caudal end of muscle complex and anterior segment of parasagittal fibers in two half without damaging its nerve supply exposing the posterior wall of rectum. Wide anatomic exposure allows separation of bowel from vagina under vision. Bowel is placed in the centre of bisected muscle complex with midline reconstruction of perineal body, muscles, vestibule and neoanal orifice.

**Indications**

The procedures can be used for single stage correction of anovestibular fistula, vulvar anus, anterior ectopic
Vestibular fistula is now to be separated from posterior wall of vagina which is technically the most important and difficult part of dissection but usually completed without complications, provided meticulous technical details are adhered to. It is elaborated herewith. For uniform traction, 3-5 stay sutures are placed on posterior edge of vestibular orifice which is retracted downward and posteriorly, inspecting vaginal orifice hymen and posterior vaginal wall (Fig. 72.32C).

Separation of initial 1-1.5 cm of posterior wall of vagina adherent to anterior wall of rectum and vestibular fistula is started with sharp dissection. Infiltration of 1:150000 adrenaline in posterior wall of vagina makes dissection easier. Initial sharp dissection proceeds from lateral to midline in a plane just outside the longitudinal muscle coat of the bowel taking great care not to open the bowel. The plane of dissection is kept very close to vaginal wall even if accidental hole is made in vagina. It is acceptable at the cost of separating the intact bowel. Commonest site of vaginal wall injury is at a recess present at the junction of posterior vaginal wall and hymen at 8'o clock and 4'o clock position. This injury can be prevented if dissection proceeds just outside the longitudinal muscle coat of bowel but at the same time very thin vaginal wall remains all the time identified by placing the tip of a forceps, through vaginal orifice. Its tip can be seen through intact but thin vaginal wall. Once initial 1-1.5 cm of vagina is separated in correct plane remaining part can be easily and quickly separated with by sweeping it off the rectum with help of a pledget and sharp dissection.

Higher up, two constant vessels (branches of middle rectal artery) running on lateral wall of rectum are to be coagulated for hemostasis. If the bowel is sufficiently mobilised, vestibular fistula should lie at neoanal orifice site without tension, and without tendency for upward retraction.

If it is not so, bowel is further mobilised and lengthened by dividing fascial bands. Once dissection is complete rectum is placed in between bisected muscle complex, muscle complex is reapproximated posterior and anterior to rectum. Anoplasty is completed by suturing the vestibular fistula to neoanal orifice. Anterior midline cut in bowel may be made if orifice is narrow.
Between vagina and rectum, perineal muscles are reapproximated in midline, perineal body is reconstructed with interrupted vicryl sutures. After anoplasty, the procedure is completed by reconstruction of vestibule, fourchette and midline raphe (Fig. 72.32D).

**Postoperative Care**

Patient may be orally allowed as soon as recovery from general anesthesia occurs. Perineal dressing applied in OT can be removed when patient passes urine and wound is best managed with open care without dressing. Sitz bath or local warm saline compresses without rubbing at stitches after each bowel movement will keep the perineum clean. Three weeks after surgery assessment is made regarding the need for dilatation. Most patients are not constipated and anal orifice admits no. 16 Hegars. In case orifice is narrow, dilatation may be continued for three months.

**Complications**

Two major complications associated with this technique are related to technical difficulty which are entirely preventable.

i. **Complete wound dehiscence and anterior migration of anus** is almost always secondary to inadequate mobilisation of bowel and anoplasty performed under tension. Intact bowel mobilised adequately to lie at neoanal orifice even without suturing is the only and surest way to prevent this complication.

ii. **Recurrent fistula:** Occurs if during separation of bowel from vagina, a hole in anterior wall of rectum is made. This complication will never
occur if bowel is mobilised off the vagina without injuring its anterior wall. Adherence to meticulous technique will prevent this complication. If you have opened the anterior rectal wall during mobilisation the best option is to repair it and perform a protective colostomy.

iii. Persistent posterior ledge: If incision is not extended little beyond the posterior limit of anal dimple, residual posterior ledge can be troublesome and persistent constipation may necessitate secondary procedure like cutback, anoplasty.

Other complications recorded with the technique include postoperative retention of urine, bleeding, wound infection, edema and perianal excoriation.

Advantages

Though the basic principle and approach is eventually the same as described in procedure of limited PSARP for vestibular fistula by Pena but anterior sagittal anorectoplasty allows far better exposure. Direct vision of vaginal orifice as well as vestibular fistula is of great help in mobilisation of intact full thickness bowel from vagina. Mobilized full thickness bowel placed in sphincter muscle obviates the need for colostomy.

There is no need to perform colostomy because bowel is mobilised full thickness and placed in muscle complex which is split from anterior to posterior in lower part only leaving intact levator muscle and upper segment of muscle complex.

Superficial muscles of perineum and reconstruction of perineal body prevents anterior migration of anus. Overall appearance of the perineum becomes identical to normal.

Results

Till date we have successfully treated more than 528 cases of vestibular fistula, 58 perineal canal, and 31 cases of perineal ectopic anus with this technique without significant complications. Follow-up analysis of 326 patients revealed normal looking perineum and normal defecation in 291. Constipation was present in 35 patients. Persistent posterior ledge was found responsible in 25 and treated with cut back anoplasty. Anal stenosis was present in 6 (Barrow flap anoplasty done in 4) while 4 patients had functional constipation.

OPERATIVE MANAGEMENT OF HIGH ANORECTAL MALFORMATIONS

Colostomy

A divided and separated proximal sigmoid colostomy is recommended by Pena to achieve complete defunctioning of the distal loop. We have found that simple loop colostomy done at the junction of descending and sigmoid colon with adequate spur works very well to relieve the obstruction in emergency and defunctioning of distal loop is also obtained provided that loop is adequately exteriorized with no tendency of recession.

Transverse colostomy is not preferred because of the disadvantages which are:

1. Colostomy diarrhea is poorly tolerated with transverse colostomy as compared to sigmoid colostomy.
2. Stagnation of urine and severe metabolic acidosis may occur with transverse colostomy if wide rectourethral fistula is present and there is reflux of urine in colon through fistula.
3. Distal loop wash outs are difficult and it is difficult to obtain good quality of cologram with transverse colostomy.

However, in cases of type IV congenital short colon, bladder neck fistula and complex malformations of cloaca, sigmoid colostomy may not be preferred because it is necessary to preserve the blood supply of rectum during colostomy and its subsequent closure. With sigmoid colostomy in these conditions, firstly, it may be difficult to mobilise rectum to gain sufficient length during abdominal exploration for a definitive repair. Secondly during colostomy closure blood supply of the pulled through rectum may be damaged leading to ischemia of the rectum. In these cases transverse colostomy may be preferred alternative to obviate these problems.

Overview of Operative Procedure

The ultimate cherished goal to be attained is provision of anal opening with perfect fecal continence. With endeavour to utilize the functional contribution of available sphincter muscle and avoid damage to innervation of already existing sphincters yet providing anal orifice has led to innovation of
numerous techniques and advancement concomitant with advancement in understanding of pathological anatomy and physiology.

Norris in 1943 and Rhoads in 1944, reported one stage abdominoperineal rectoplasty in neonate describing abdominal exploration, disconnection of fistula and pull through anterior to sacrum with perineal anoplasty. At that time concept of the puborectalis sling was non-existent.

Stephens by the early 1960s described the importance of puborectalis sling, a principal muscle of continence which hugs the urethra in male and vagina in female. He emphasized that by sacroperineal route, a narrow plane anterior to but within the sling of muscle can be defined and rectum must be routed through it for continence.

Based on this information, Swenson and Donnellan modified the abdominoperineal approach. After disconnection of fistula through abdominal route; puborectalis sling was identified, space was created between the sling and posterior urethra and the rectum was pulled through the space and sutured in perineum creating a neoanus. No importance was given to striated muscles of external sphincter.

Retbein who earlier proposed submucosal resection of rectum and abdominoperineal rectoplasty to minimize injury to the nerves and blood vessels; modified the procedure to palpate the levator with a finger above and below to define a plane anterior to puborectalis and passed rectum through it. It was Stephens contention that the entrance to the tunnel can never be seen by an abdominal approach nor can it be palpated; only gentle blunt probing with a right angle clamp can actually open the plane in front of sphincter muscle against urethra or vagina and for this reason he favored sacroperineal approach. However, when fistula was higher up, in addition laparotomy was performed (Sacro-abdominoperineal pull-through).

Kieswester’s sacro-abdomino perineal pull through was essentially a combination of Stephen’s sacro-perineal approach and Rehbein’s submucosal dissection.

Mollard’s operation reported in 1975 is essentially a Rehbein’s technique with identification of puborectalis sling via anterior sagittal perineal approach in anterior sagittal plane just behind the urethra.

**Congenital Pouch Colon and ARM**

This is described in detail in chapter 76.

**Posterior Sagittal Anorectoplasty**

Posterior sagittal approach (PSARP) since its introduction by Pena and de Vries has practically replaced all earlier techniques because of obvious advantages. In this technique via midline perineal approach all striated sphincter muscles are divided exactly in midline aided by electrostimulation (Fig. 72.33). After splitting the coccyx in midline and levator ani muscle posterior aspect of rectum is exposed (Figs 72.34A to F). Its distal most segment is opened in midline and through lumen of the rectum fistula is directly visualized. Fistula, is disconnected and closed under vision and mobilised rectum is placed exactly in the center of sphincter muscles which are meticulously, reapproximated around rectum.

In this overview of operative procedures it is intriguing to see history moving in a full circle from perineal exposure of the nineteenth century through numerous modifications away from perineum and now back to the perineum again. Smith ED in 1987 has excellently described an overview of surgery of anorectal anomalies.

The PSARP procedure has been discussed in chapter 73.

**Postoperative Management**

Posterior sagittal incision is relatively painless and the course is usually smooth. If repair is not combined with laparotomy patient is orally allowed after recovery from anesthesia.

We remove urethral catheter after 5 days in repair of rectourethral fistula but if catheter was accidentally dislodged earlier, all patients passed urine and no recurrent fistula was noted.

**Fig. 72.33:** Position of the patient for PSARP. Lateral view showing placement of paddings and free abdomen wall.
Dressing is removed after 48 hours, open care of the wound with application of antibiotic ointment is preferred.

Intravenous antibiotics are administered for 48 hours followed by oral antibiotics for 7 days. Patient can be discharged as soon as urethral catheter is removed and patient had spontaneous voiding.

Hospital stay is longer in patients of bladder neck fistula, congenital short colon and cloaca with abdominal exploration.

Pena recommends anal dilatation 2 weeks after surgery but we find if dilatation is started at 3 weeks after surgery, chances of minor bleeding are minimized occurring at the time of first dilatation by parents.

Parents are trained to dilate the orifice twice a day with size of dilator which goes in neoanus without resistance and without causing undue stretching.

Every week parents are called and given progressively increasing size of dilator until the desired size of anal orifice is achieved (Table 72.5).
In the Department of Pediatric Surgery, K.G. Medical College, Lucknow, 1088 patients (749 male, 339 females) of ARM were admitted from 1990 to 2001. Out of 741 patients of high or intermediate malformations, colostomy was done in 700 patients (601 male, 99 male). Type of anomalies in male patients were: congenital short colon 60, rectal atresia 7, rectovesical fistula 25 and 501 patients of rectoprostatic, rectobulbar urethral fistula and without fistula. Among 99 females type of malformations were: cloaca 41, pouch colon with cloaca 8, rectovaginal fistula 30, rectal atresia 1 and in 19 patients type of anomaly was not clear as per records. PSARP was done in 291 patients (243 males and 48 females). Colostomy closure was completed in 204 patients. Follow-up assessment was completed in 106 patients (78 males 28 females). Using Wing Spread criteria good results were noted in 50 (47%), fair in 30 (28%) and poor in 26 (25%) patients. Complications noted during PSARP are given in Tables 72.7 and 72.8.

Steps and Smith concluded that "discussion is not required in the translevator deformities as most authors agree on good results or 70-95%." Recent long-term studies suggest that good bowel control is usually achieved after correction of anomalies in 90% of patients. However, long-term bowel dysfunction especially in the form of constipations has often been troublesome.

The rate of continence after correction of high anomalies by older techniques has been reported as disappointing. Older procedure such as abdomino-perineal, sacroperineal or sacroabdominoperineal procedures are not associated with good results but improvement in continence is reported because most patients organize their lives to minimize the occurrence and effects of soiling. Improved continence has also been reported with procedures where terminal bowel was preserved and used for anorectoplasty.

Experience with posterior sagittal anorectoplasty is clearly encouraging than previous procedures but more time is needed to permit evaluation of long-term result and quality of life in adulthood.

Some careful follow-up studies on results of PSARP indicate that achievement of continence is possible in 50% cases of high ARM.
Data by Bliss et al and Templeton indicate that continence results of PSARP are no different form those obtained with other operations currently in use while Rintala showed that 35% of these patients had apparently normal continence with PSARP\textsuperscript{2,43,49}.

Rintala et al has reported improvement in continence at adolescence in patients having undergone PSARP procedure for high ARM because severity of constipation diminishes with passage of time.\textsuperscript{50}

Follow-up study with comparison of results of PSARP and conventional methods has been reported by Tsuji et al using Kelly’s clinical scoring system.\textsuperscript{51} Overall results were found to be better in PSARP but long-term bowel management was needed in all patients of high and intermediate malformations.

Long term follow-up result in 48 patient, with modified technique of PSARP was reported by Lien NT et al revealing very good function in 4%, good function in 54%, fair in 38% and poor results in 4%.\textsuperscript{52}

Obviously it is apparent that more careful long-term follow-up studies are needed to determine the place of this technique and identify patients who are likely to achieve total continence and those going to remain incontinent.

**PRIMARY NEONATAL PULL-THROUGH**

There has been a recent interest again in primary neonatal PSARP or neonatal laparoscopic pull-through without colostomy. Moore has recommendedoperative repair within the first 7 days without a prior colostomy because activity driven anocortical neurocircuitry develops in perinatal period and within few days after birth.\textsuperscript{53} If act of defecation is not initiated soon after birth by primary repair, the advantage is lost. One stage PSARP has been reported by Goo, Albanse and S Chooramani Gopal.\textsuperscript{54-56} Laparoscopic primary neonatal pull-through is also reported.\textsuperscript{57}

**SUMMARY**

Reconstruction of normal anatomical anal opening and provision of normal continence remains the cherished goal to be achieved in cases of ARM. Correction of associated anomalies is also mandatory. In cases of low ARM with good available sphincters not associated with loss of sacral segment and loss of innervation, it is possible to achieve good results in 95% of cases. Procedure of choice is single stage perineal proctoplasty by various techniques but anterior sagittal anorectoplasty is currently the

procedure of choice. High ARM is best managed with staged procedure, i.e. colostomy, definitive reconstruction and colostomy closure. PSARP is the technique of choice today for definitive reconstruction of high ARM after colostomy. It has to be combined with abdominal exploration in cases of rectovesical fistula, congenital short colon and some cases of cloaca. Results are dependent firstly on meticulous repair with perfect technique, placing the bowel with its preserved sensory receptors and internal sphincter in the centre of muscle complex and secondly on quality of available sphincter muscle complex which can be judged with CT and MRI. Early neonatal surgery may help to establish the normal activity driven anocortical neurocircuitry. Patients of ARM with poorly developed sphincters are helped by medical bowel management program, biofeedback therapy, Malon’s antigrade continent enema or permanent colostomy.

ACKNOWLEDGEMENTS

Author is grateful to Mr Varun for secretarial assistance and Dr Ravi Kanojia for organizing the figures.

REFERENCES

The management of anorectal malformation (ARM) has seen a major change in the surgical approach with the introduction of the Posterior Sagittal Anorectoplasty (PSARP) by Alberto Pena, popularly known as the PSARP approach. Anorectal malformations represent a spectrum of defects. Of the many available techniques, the best is the one that could be performed easily and with least postoperative complications. The surgeon should use the technique with dedication, perseverance and inclination to adopt changes as and when required. This includes evolving toward less aggressive approaches, less number of operations and minimal invasive procedures. The crux of treatment lies in proper identification of the anomaly, so that the child is benefited with a well planned surgery to get the best possible outcome.

If a particular operation is done for a particular anomaly over a long time, sufficient expertise is acquired to handle complicated cases and even those treated earlier by other surgeons. The results of reoperations in good hands are thus far superior to primary operations in inexperienced hands.

Management of anorectal malformations requires an accurate clinical diagnosis, proper newborn treatment, meticulous anatomic reconstruction, and comprehensive postoperative care with the goal of having a child who is clean and dry, with an excellent quality of life, because they either have the capacity for continence or can be kept artificially clean with a comprehensive bowel management program. The surgical treatment has evolved to proper reconstruction, avoid complications and understand mechanisms of incontinence, ultimately leading to improved quality of life for patients. Figures 73.1 and 73.2 outline the algorithm suggested for management.

**COLOSTOMY**

Colostomy is still a widely accepted procedure for high and complex malformations. The circumstances vary from one institution to another and from one country to another. Experienced pediatric surgeons are now managing some of the newborns even without a protective colostomy. A colostomy is mandatory in premature and very sick babies, when they suffer from severe associated defects, or in case of complex malformations, e.g. cloacal anomalies.

A descending colostomy is recommended as all colostomies performed in a mobile portion of colon have a tendency to prolapse. Fixation of the distal mucus fistula to the anterior abdominal wall or making the mucus fistula small (around 5 mm in diameter) is recommended as the purpose of creation of such a mucus fistula is to use the same for chronic irrigation or high pressure distal colostogram. A divided colostomy is still a widely accepted procedure for high and complex malformations. The circumstances vary from one institution to another and from one country to another. Experienced pediatric surgeons are now managing some of the newborns even without a protective colostomy. A colostomy is mandatory in premature and very sick babies, when they suffer from severe associated defects, or in case of complex malformations, e.g. cloacal anomalies.

colostomy is preferred. The loop colostomy has a tendency to prolapse and it does not provide complete diversion of stool. Also fecal impaction in the distal rectum may also contaminate the urinary tract with feces.

The incision is placed in the left lower quadrant long enough to place both stomas sufficiently separated with a skin bridge so as to accommodate the stoma bag only over the proximal stoma. On abdominal exploration the surgeon should select the first portion of the mobile sigmoid just distal to the descending colon. One can place a purse string suture over the distended colon and make an orifice in the center, pass a catheter to irrigate the colon until all the meconium has been removed. This helps to create a better colostomy, without contaminating the field.

Many surgeons still continue performing a loop colostomy. This is only justified provided the colostomy is completely diverting with the help of spur formation between both the loops.

**TIMING OF THE DEFINITIVE REPAIR**

The timing of the definitive surgery depends upon the expertise of the surgeon. Primary repair is feasible for perineal fistula and vestibular fistula. PSARP can be performed by 3-6 weeks when baby is investigated and thriving well. In cases of cloaca, the surgery may be delayed upto 3-6 months after birth.

**UTILITY OF PSARP**

The posterior sagittal approach was also used for the treatment of acquired conditions including tumors, post-trauma and post-radiation fistulae and other postoperative complications. A historic review of the posterior approach disclosed that Cripps, a British surgeon, published his experience with a posterior trans-sphincteric approach to the rectum nine years before Kraske, a German surgeon, whose name has been traditionally associated with the leadership in this approach. Kraske actually approached the rectum through a paramedian incision and never performed a real trans-sphincteric incision. An experimental study done in dogs by the senior author demonstrated that it is not harmful to divide the sphincteric mechanism.13

The posterior sagittal approach represents a useful alternative to treat many pelvic conditions and, therefore, it must be a part of the armamentarium of the colorectal surgeons. Co-ordinated rectosigmoid motility is the most important single factor in fecal continence and, thus, our efforts to help patients suffering from fecal incontinence must be aimed at the
Manipulation of bowel motility. \(^{14}\) PSARP approach is beneficial in redo cases also. It is also helpful for cases of excision of megarectum.

**SCIENTIFIC BASIS OF PSARP**

The PSARP approach is based on the fact that nerves do not cross midline therefore staying exactly in midline guarantees preservation of innervation of all important pelvic structures and sphincters. In the earlier technique, the most important step of placing the bowel in sphincter was blind while with the PSARP approach, one remains exactly in midline. The bowel is placed in the sphincter complex, and under direct vision. The fistula is also disconnected and repaired under vision.

Posterior sagittal anorectoplasty is based upon complete exposure of the anorectal region by means of a median sagittal incision that runs from the sacrum to the anal dimple, cutting through all muscle structures behind the rectum. It was learned through this procedure that the external sphincter is a functionally useful prominent structure. No puborectalis sling, as such, could be identified. However, it was possible to recognize a muscle continuity from the skin to the sacral insertion of the levator ani. \(^{1}\) In the PSARP approach, as the skin incision extends from the sacrum to the perineum (ventral aspect of the anal dimple), it provides an excellent exposure for evaluation and mobilization of the terminal bowel. It also enables one to construct an anal canal, suture the bowel wall to the striated musculature and the mucosa to the skin, thereby reducing or avoiding the complications of prolapse and stenosis. \(^{2}\)

In males, with a rectourethral fistula, a transrectal closure of the mucosa at the fistula site, leaving the rectal longitudinal smooth muscle insertions on the prostatic capsule, avoids the possibility of any damage to the nerves and genital structures. \(^{2}\)

Through PSARP approach, the full understanding of the anatomic damage is obtained and consequently a rational reconstructive plan can be designed in each case. \(^{3}\) Tapering that was done in the past was possible only by this approach. \(^{3}\) It is now required only in cases of megarectum. \(^{3}\)

**LIMITED PSARP**

**Indications**

1. Perineal fistula in males
2. Imperforate anus without fistula
3. Vestibular fistula.

**Procedure**

The patient is catheterized to avoid urethral injury, especially in males. The patient is put in a prone position with a roll under the pelvis and folded towel under the chest to keep the abdomen free from any compression. The incision is given in the midsagittal plane from about 2 cm posterior to the proposed anal opening, dividing the entire sphincter exactly in the midline. The posterior rectal wall is identified with a characteristic whitish appearance. Stay sutures may be applied on the either side of the incision to provide uniform traction to facilitate dissection. The dissection is preceded towards both the lateral walls turn by turn to maintain symmetry and eventually towards the anterior rectal wall. Special care should be taken during anterior dissection to remain very close to the rectal wall to avoid urethral injury in males, as there is no plane of separation between the rectum and the urethra. Moreover, it should be taken into consideration that the anomaly is a spectrum with possibility of the rectum lying very close to the urethra. The dissection should be based on clinical experience to identify the correct plane and proceed slowly especially during anterior dissection. The rectum is mobilized sufficient enough to be placed within the limits of the sphincter complex without any tension and at the same time avoiding any prolapse. The sphincter at the proposed anal site is identified with the help of an electrical stimulator. This usually coincides well with the visual pigmentation of the sphincter at the proposed anal site. The perineal body is reconstructed with long-term absorbable sutures. In case the rectal pouch is a little higher and the dissection has proceeded above the upper limits of the sphincter, it is beneficial to place a stitch high up anteriorly also to approximate both the sides of the incised sphincter, so as to construct a funnel of the sphincter mechanism all around the rectum.

In cases of imperforate anus without fistula, the rectum is usually located at approximately 1-2 cms
above the perineal skin, at the level of the bulbar urethra. This is seen in 5% of all cases of ARM and half of these have Down’s syndrome. This defect has a good prognosis, the rectum is located about 2 cm above the perineal skin, the sacrum is normal, and the sphincter mechanism is good. Almost 95% of patients who have associated Down’s syndrome have this type of anomaly. Care should be taken in these cases as the rectum is intimately attached to the posterior urethra. The surgeon must open the posterior wall and create a place of dissection between the anterior rectal wall and the urethra. All these patients have urinary continence.

The anoplasty is performed within the limits of the sphincter with 16, 6/0 circumferential long-term absorbable sutures.

The baby is kept nil orally for 24-48 hrs with intravenous antibiotics. The duration of the total parental nutrition, if given, depends upon the type of anomaly, the degree of mobilization and the presence or absence of diverting colostomy.

There is a controversy whether or not to operate cases of perineal fistula. The repair of a perineal fistula in females is not only for esthetic reasons but it also potentiates the protection against rectal injury during the vaginal delivery and improves the sexual function. These patients have a good prognosis, good sacrum and good sphincters. About 90% of these without Down’s syndrome have a good bowel control, while 80% of those with Down’s syndrome have a good bowel control.

POSTERIOR SAGITTAL ANORECTOPLASTY (PSARP)

The patient is catheterized to avoid urethral injury, especially in males.

Position

Patient is placed in prone jack knife position with foam bolsters or soft cotton rolls placed under the chest and groin ensuring that the abdomen is not compressed and there is adequate space for abdominal wall movement with respiration. The level of pelvis is little higher than thorax. The lower limbs are positioned on frog-leg fashion symmetrically to avoid any distortion of natal cleft.

Incision and Midline Division of Sphincteric Muscles

The site of the neoanus is identified with electro-stimulation which usually corresponds, to midline pigmented skin fold or anal dimple and the limits are marked with back of knife or the silk sutures. The incision is given in the midsagittal plane, from the middle of the sacrum to the anterior limit of the anal dimple that is identified with electrical stimulation. A fine needle tip cutting diathermy with current of 700-800 mA is used.

The incision is given exactly in the midline dividing the entire sphincter mechanism. The incision goes through the skin, subcutaneous tissue, parasagittal fibers, muscle complex and levator muscle. Stay sutures may be applied on the either side of the incision to provide uniform traction to facilitate dissection. In the region of anal dimple mass of vertically oriented sphincter muscle complex, the fibers are present running from levator mechanism to the skin at anal dimple crossing the parasagittal fibers. In this region, the incision is deepened taking utmost care to stay in midline. As the lateral limits of the vertically running sphincter muscle are very narrow as compared to the antero-posterior limits, the surgeon can easily deviate leading to unequal division of muscle complex. Deviation from the midline may also be avoided by dividing the posterior edge of vertically running muscle complex first where it is perpendicular to and decussates with parasagittal fibers and tested with stimulator for equal contraction or both sides. If the deviation from the midline is identified by appreciating unequal contraction of muscle, the mistake is corrected at this stage before further splitting the muscle complex. At the upper end of incision, the tip of the coccyx corresponds to midline which is split in two halves. In the midline a fine midline fascia divides the anatomy in two half. In this region, staying in the midline is identified by stimulation of deep parasagittal muscle fibers. Deviation from midline is also identified by herniation of fat through the midline fascia. The midline plane is also avascular. The posterior rectal wall is identified with a characteristic whitish appearance. A mastoid retractor may be used for application of uniform traction in depth.

In cases with rectobulbar urethral fistula, the bulging rectum is seen as soon as the levator muscle
is divided. In case of rectoprostatic urethral fistula the rectum is much smaller and may not bulge through the incision. In such cases, the rectum may be identified immediately below the coccyx. Searching for a rectum in the lower part of the incision in case of rectoprostatic urethral fistula is the main source of complications in this operation. The surgeon must keep in mind that there is a white fascia that covers the rectum posteriorly and laterally that MUST be incised. The rectal dissection is continued staying as close as possible to the rectal wall without injuring the wall itself. The dissection is done in both the lateral directions turn by turn to maintain symmetry. Stay sutures are applied over the midline of the posterior rectal wall at the lower limit and an incision is given exactly in the midline. The incision is continued distally, staying in the midline while applying stitches in the edges of the rectum. Uniform traction is helpful. At the distal end of incision, a rectourethral fistula is identified as a 1-2 mm opening. Multiple 6/0 sutures are placed in a semi-circumferential manner around the fistula, above and lateral to it to give uniform traction.

An incision is given just distal to these sutures and the dissection is now done in the submucosal plane for 5-10 mm. This is then continued to a full thickness dissection till the rectum is completely separated from the urinary tract. The separation of the urethra from the rectum requires meticulous dissection and is the most important step of the operation. The fistula is closed with 3-4, 6/0 long-term absorbable sutures. The dissection is proceeded till the rectum is mobilized enough to be placed within the limits of the sphincter without any tension and at the same time avoiding any prolapse.

The rectum is then examined to judge the need for tapering. This is usually not required now due to early referral of cases, decreased incidence of megarectum and the good diverting colostomies.

The limits of the sphincter are determined electrically and marked with temporary silk sutures. The anterior limits of the sphincter must be reconstructed. The posterior edge of the levator, muscle is electrically determined and rectum is placed anterior to it. The levator is repaired with interrupted 5/0 absorbable sutures taking a bite of the posterior rectal wall to fix it in a proper position to avoid retraction and rectal prolapse. The perineal body is reconstructed. The wound is closed in the midline in layers. The anoplasty is performed within the limits of the sphincter with 16, 6/0 circumferential long-term absorbable sutures. The damaged or the ischemic part of the rectum is trimmed off. The distal rectal smooth muscle, resected during correction of anorectal malformations, shows similarities to the function reported previously on normal anal smooth muscle evaluated in vitro and thus has the functional properties of a sphincter and should be preserved as far as possible.

Patients with rectourethral bulbar fistulae, have an 80% chance of having a bowel control by the age of three. Patients with rectoprostatic have a higher incidence of associated defects (60%) as compared to those with the rectourethral bulbar fistulae (30%). The patients with rectoprostatic fistula require a more demanding perirectal dissection to mobilize the rectum that is located higher in the pelvis.

RECTOVESTIBULAR FISTULA

Cases of rectovestibular fistula with a narrow and long fistulous tract who develop constipation soon after birth should be differentiated from the patients with vestibular anus who have a good and muscular anus. The later do not require any management in the newborn period if not constipated. The baby may be kept on dilatation and a single stage PSARP at 3-6 months of age is justified in these without any colostomy. However, cases of vestibular fistula that have constipation do merit a colostomy.

The important feature here is that the rectum and the vagina share a long common wall that must be separated by creating a plane of dissection between the two. This enables the complete mobilization of the rectum so that it can be put in the proper place. The patient is placed in the prone position with pelvis elevated with a roll. The incision is given from the coccyx to the fistula site. Multiple sutures are placed in a circumferential manner around the fistula opening to provide uniform traction. Most of the dissection is the same as that for PSARP in the lateral directions. The difference is that the rectum is not opened in the midline. After lateral mobilization the dissection proceeds from caudal to cranial direction anterior to the rectum. During the dissection, two walls are made out of one, taking care to avoid perforations either in the rectal wall or the vaginal wall. If it is to happen at
all, it should be avoided in the rectum. Once the separation is complete, the limits of the sphincter are determined electrically. The perineal body is reconstructed bringing together the anterior limits of sphincter. The rest of the procedure is the same as PSARP.

Patient with vestibular fistula have an excellent prognosis, with 93% of patients having bowel control. About 70% have constipation that is incurable but manageable.

**CLOACA**

Cloaca is defined as a defect in which the urinary tract, the vagina and the rectum are all fused, creating a single common channel, and opening into an orifice at the site of the normal urethra. This represents a spectrum of malformations. The treatment differs on whether the common channel is less than or more than 3 cm in length on the cystoscopy measured from the proximal end of the common channel up to the perineum. About 2/3rd of patients have a short common channel.

The patient is placed in lithotomy position and cystoscopy is done to assess the length of the common channel.

### Plan of Surgery according to Length of Common Channel

For short common channel the patient is placed in the prone position with the pelvis elevated with a roll. The incision is given from the middle portion of the sacrum to the single perineal orifice. The entire sphincter mechanism is divided in the midline and the rectum is exposed. During the last decade, a total urogenital mobilization has been found to be beneficial for these patients. The rectum is separated from the vaginal wall by creating two walls out of one. Multiple 6/0 silk sutures are placed taking the edges of the common channel, along with the edges of the vaginal walls, to exert uniform traction. The urethra and the vagina are mobilized together. Another set of sutures are placed transversally 5 mm proximal to the clitoris and the entire common channel is mobilized as one. The dissection is proceeded till a vascular fibrous structure is identified and divided. This step allows a gain of 2-4 cm length of the urogenital structures. The purpose is to place the urethral meatus at its normal location just below the clitoris. The edges of the vagina are sutured to skin of the perineum forming the new labia. The initial common channel is divided in the midline to make two flaps that are sutured on either side. About 80% of these patients with a good sacrum have bowel control and most of them can empty their bladder voluntarily. However, remaining 20% of patients with a short common channel would require CIC.

Patients with long common channel more than 5 cm are approached through the abdomen with an incision in the midline. If the channel is between 3-5 cm the posterior sagittal approach may be tried and a total urogenital mobilization may be attempted. The separation requires delicate surgery and the decision should be made by an experienced surgeon. Seventy percent of all patients with a common channel longer than 3 cm require intermittent catheterization to empty their bladder.

Further operation depends upon the anatomy of each case. If the vagina is large as in cases of hydrometrocolpos, then it may easily reach the perineum. In cases with a short vagina, a switch procedure may be feasible in cases with two joined hydrocolpos with separate hemiuteri. In such cases, the septum may be divided and one entire Mullerian structure may be resected. The blood supply to one side should be preserved to provide the blood supply to the side that is being switched down.

If the vagina is very short, small and high, a replacement is needed. The first choice for vaginal replacement is to use a part of the rectum in babies with a megarectum. The rectum is divided longitudinally to form both, the new vagina and the neorectum. If the patient has internal genitalia, the segment of neovagina is sutured to it. If not, the upper part of the neovagina is closed. The second choice for the vaginal replacement is the use of sigmoid colon,
followed by segment of small bowel. Patients with long common channel have a high frequency of complex associated anomalies. Approximately 50% of the patients with cloaca have hydrocolpos that may lead to bilateral megaureters and hydrenephrosis.

During the first 24 hrs of life, emphasis is placed on the recognition and treatment of potentially lethal associated defects, mainly urologic, esophageal or cardiac. The baby should not be taken to the operating room without ruling out these associated defects. The most common associated anomalies involved are those of the urinary tract with renal agenesis, renal dysplasia, vesicoureteral reflux and megaureter. These children may exhibit some form of masculinization of the external genitalia with the accessory urethra or cloacal channel assuming a phallic position in an enlarged clitoris.

All babies with cloacal anomaly should undergo an ultrasound of the kidneys and pelvis before surgery. If a hydrocolpos is present, it should be drained at the same time the colostomy is performed. The colostomy should be completely diverting so as to prevent contamination of the urinary tract.

In cases of extremely long common channel that lies usually near the trigone, the bladder neck is closed and a vesicostomy is done. About 30% of these patients have duplicated Mullerian structures. The prognosis should be explained to the patients well in advance and the complications that may arise, especially during pregnancy, may be explained.

**UROGENITAL SINUS WITH NORMAL RECTUM**

A perineal approach with or without a skin flap seems to be effective for those patients with a low implantation of the vagina. However, in patients with a high vaginal implantation, this treatment frequently fails to provide a good, functional vagina due to a narrow and strictured vaginal opening. For patients with a high urogenital sinus with normal rectum a posterior sagittal transanorectal approach with a protective colostomy provides excellent exposure to the urogenital sinus.

The pelvis is approached through a midsagittal posterior incision; the coccyx is split and the entire anorectal sphincteric mechanism is divided in the midline. The rectum is bivalved in the midline including both the posterior and anterior rectal walls. The vagina is then fully separated from the urogenital sinus, mobilized and sutured to the perineum. The rectum and the sphincteric mechanism are meticulously reconstructed. A midline incision assures the preservation of anorectal innervation, and provides excellent exposure to the pelvis. Anal dilatations are not necessary to maintain a patent and supple anorectal opening because the rectum has two suture lines, one in front of the other. After the colostomy is closed, most patients have appropriate bowel control for their age.

**GYNECOLOGICAL OPERATIONS FOR CASES WITH ANORECTAL MALFORMATIONS**

It is best to do a vaginoscopy at the time of PSARP to identify a vaginal septum. The presence of vaginal agenesis is noted. The Mullerian structures are identified with delineation of the uterine anatomy. The benefits of the early repair of Mullerian anomalies include adequate repair, decreased chances of injury and good sexual functional outcome. For hydrocolpos, a vaginostomy may be done. A vesicostomy is an alternative option.

In cases with vestibular fistula or perineal fistula, a normal delivery may be planned. Cloacal anomalies would require a cesarean section for delivery. Vaginal replacement is done early for cases with cloaca. It may be done later for cases with Mayer-Rokitansky syndrome. Introitoplasty should be done after puberty but before the onset of menstruation. Vaginal dilatation may also be helpful for cases with a pliable vaginal wall.

Short-term vaginal dilatation may be done from Hegar-dilator number 14-17, if menstrual function is not adequate. Asymmetry of the duplicated uterus indicates increased chances of atresia of the less developed side. The incidence of vaginal atresia is 25% of all cases of anorectal malformations. The incidence of vaginal agenesis is 5% of all cases.

Gynecologic anomalies are common in patients with persistent cloaca, but, except for hydrocolpos, these patients remain asymptomatic in the neonatal period. To prevent future problems, the management of the neonatal cloaca must include the early clarification of the gynecologic anatomy, specifically the patency of Mullerian structures. Unilateral atretic structures and tubes connected to atretic uteri should be resected. One must be suspicious of menstrual problems in teenagers operated on early in life for persistent cloaca.
POSTERIOR CLOACA

This rare entity is identified with a separated pubic bone, with the clitoris placed posteriorly, a single orifice is located posteriorly through which both the urine and stool come out. It is defined as a defect in which urethra and vagina are fused together forming a urogenital sinus that deviates posteriorly and opens in the anterior rectal wall at the anus or immediately anterior to it. The rectum is essentially normal or may be minimally anteriorly mislocated. The diagnosis requires a suspicious observer and a meticulous examination of the female genitalia. A complete urologic evaluation is mandatory because 88% of these patients have important associated urologic defects. A posterior sagittal transanorectal approach allows a full dissection and mobilization of urethra and vagina together to be placed in a normal location. Rectal dissection and mobilization is avoided to preserve the bowel control. Most patients enjoy bowel and urinary control.

ASSOCIATED TETHERED CORD

Tethered cord has been found to be associated in 24% of all patients with anorectal malformations. The prevalence varies from 43% in the complex group to 11% in patients with rectovestibular fistula. Patients with tethered cord have a lateral sacral ratio lower than that of patients without tethered cord (0.410 versus 0.702). Tethered cord is reported to be present in 90% of patients with myelodysplasia, 60% in patients with a presacral mass, 57% of patients with sacral hemivertebrae and 56% of patients with a single kidney. The risk of having tethered cord is also reported to increase with the number of associated anomalies present. Patients with tethered cord have worse functional prognosis than those without tethered cord. A study also showed that the tethered cord occurred more frequently in patients with severe anorectal defects, sacral hypodevelopment, myelodysplasia, presacral mass, sacral hemivertebrae, or a single kidney, or in those with an anorectal defect with poor functional prognosis. Presently, there is no evidence to support the concept that tethered cord by itself affects the functional prognosis of patients with anorectal malformations. Also, there is no good evidence demonstrating that surgical untethering improves the prognosis.

FOLLOW-UP

Globally, 75% of all patients with ARM following PSARP have voluntary bowel movements. Though, half of the patients in this group still soil their underwear occasionally. Therefore, about 37.5% of all cases are considered totally continent. Constipation has been reported as the most common sequelae. Urinary incontinence was relatively common after the repair of cloacas. Male patients rarely suffer from urinary incontinence. Twenty-five percent of all cases have been found to suffered from fecal incontinence but they significantly improved their quality of life when subjected to a bowel management program. All patients born with anorectal malformations can be kept clean of stool and dry of urine, either because they achieve bowel control or because they are subjected to a bowel management program. Bowel management consisting of enemas, laxatives, and medications is successful when administered in an organized manner. It is vital to determine the type of fecal incontinence from which the patients suffer and to target their treatment accordingly.

Bowel management was found to be successful in 93% of patients in the constipation group and 88% in the diarrhea group. About 97% patients in a group of patients who had no potential for bowel control became continent for stools. Continent appendicostomy may be used to change the route of enema administration, but in only those patients for whom bowel management with rectal enemas has proved successful. This operation further improves their quality of life. The appendix must thus be preserved whenever possible in patients at risk for fecal incontinence. Segmental dilatation of the sigmoid colon may be a source of fecal pseudoincontinence and, therefore, should be ruled out when the surgeon is evaluating patients with fecal incontinence.

SUMMARY

Anorectal malformations comprise a spectrum of defects. Some of these defects are minor, with an excellent functional prognosis. Others are complex and may be associated with other defects in the urinary tract that may risk the patient’s life. The decision-making process for the management of a newborn with anorectal malformations is crucial; the timing and establishment of priorities are the key to success.
A simplified well planned approach helps to avoid the most common errors in the management of anorectal malformation. Yet, there are still many children born with severe anatomic deficiencies who cannot expect normal bowel function. For this group, a bowel management program is available to help improve their quality of life. This is discussed in detail in chapter 81.

REFERENCES

Anorectal malformations (ARM) are often associated with other significant anomalies, which can be a cause of morbidity and even mortality. The overall incidence of associated malformations in ARM varies between 30-60%.1-2

This wide variation reflects the difference in the screening protocol adopted by each center. The incidence of associated anomalies also varies according to size and sample of study population, facilities of diagnostic investigations and zeal with which associated anomalies are looked for. Because anorectal malformations occur at the critical age of embryonic differentiation (2-8 weeks), associated multisystem anomalies are not uncommon and may be seen in 40-70% of patients. Patients with high malformations are more likely to have more associated defects. It is now increasingly being recognized that associated malformations (especially urological anomalies) are the prime cause of morbidity associated with ARM. It is therefore the responsibility of the treating surgeon to observe a rigid protocol for screening these patients for the associated anomalies and instituting an early treatment. Table 74.1 enlists these associated malformations.

VACTERAL association:3 Vertebral defects, anorectal, cardiac, tracheo-esophageal fistula, esophageal atresia, renal anomalies and radial dysplasia and limb defects.

Curarino syndrome:4 Partial sacral agenesis, presacral mass (sacroccygeal teratoma or anterior meningocele) and anal stenosis. Typically there is hemisacrum with preserved first sacral segment.

Townes-Brocks syndrome:5 ARM with hand and ear anomaly. There may be cardiovascular, genitourinary malformations and mental retardation.

FG syndrome:6 ARM, mental retardation, neurological defects (marked constipation), facial dysmorphism,
hand abnormality (broad thumbs) and genital abnormality.

**Cat-eye syndrome:** ARM with coloboma of iris, choroid, micro-ophthalmia and ear anomalies.

**Klein-Waardenberg syndrome:** Facial dysmorphism, pigmentary defects and ARM.

**Caudal regression syndrome:** ARM, spinal cord anomaly, genitourinary and lumbosacral defects.

**GENITOURINARY MALFORMATIONS**

Vesicoureteric reflux (VUR) is most common associated urologic anomaly. Rectovesical fistula and cloaca may have 90% chance of an associated genitourinary anomaly while in low defects like perineal fistula, the incidence of associated anomalies is quite low (< 10%). Some series have reported higher incidence of genitourinary anomaly in low defects also. With lumbosacral spinal defects, the incidence of urological involvement is 50%. Genital anomalies in girls most commonly involve vaginal and uterine septation defects and vaginal agenesis.

The initial approach in ARM management involves decision making regarding the need for a colostomy and screening for associated malformations. The genitourinary tract is the most frequent and serious site of associated defects in anorectal malformations. The 1969 report of the surgical section of the American Academy of Pediatrics (AAP) reported a 26% incidence of associated significant urologic malformations. Parrott noted that around 40% of patients with high anomalies, 21% of intermediate anomalies and 14% of low anomalies have associated urologic malformations. Rich et al showed a 52% incidence of urologic anomalies in males with a bladder neck fistula, whereas almost 30% of females with a cloaca had associated urologic anomalies. The higher the level of the lesion, higher is the incidence of genitourinary anomalies. Overall, urinary tract anomalies occur in more than 40% of all patients with ARM (~20% in low, 50% in high).

**Screening:** An ultrasound of the genitourinary tract performed 72 hours after birth is used as the primary method of screening for urinary tract anomalies. The kidneys, ureters, bladder and urethra should all be assessed (Figs 74.1 to 74.4). The role of the voiding cystourethrogram (VCUG) is clear when there is upper tract dilatation on ultrasonography. However, most centers now recommend a VCUG in all newborns with imperforate anus. The points in favor for performing a VCUG are:

i. High incidence of VUR noted with high lesions and even in low anomalies.
ii. The morbidity associated with missed VUR and reflux nephropathy is significant but can be easily prevented by chemoprophylaxis.
iii. Urethral anomalies can be missed in males if VCUG not done.
iv. Voiding film may give additional information about the site of fistula.

Figs 74.1A and B: Megalourethra with hypospadias
v. Reflux into seminal vesicles and vas may be detected thus identifying boys who may be in risk for recurrent epididymitis and future infertility.
vi. VCUG can also identify signs, which suggest a neurogenic bladder like VUR, trabeculated bladder and high post void residue. Early management of these patients ensures preservation of upper tracts.

The ARGUS protocol devised by Boemer's et al is ideal in evaluating newborns with ARM. This protocol shown below ensures that associated anomalies are not missed without performing unnecessary investigations (Fig. 74.5). This protocol states that ultrasound KUB, a VCUG and a plain X-ray of the spine and sacrum is mandatory in all
Management of Urologic Anomalies

McLorie et al found that mortality from renal failure occurred in up to 6.4% of patients with high anomalies and even in 1.1% patients who had low anomalies.\(^{18}\) The morbidity and mortality of the genitourinary anomalies in ARM clearly exceeds those related to the ARM itself. Before undertaking the definitive repair for ARM, it is essential to avoid urinary tract infections which may be caused by a rectourethral fistula or reflux. This is best accomplished by ensuring a completely diverting proximal sigmoid colostomy and washes of the distal pouch. Hyperchloremic acidosis may occur due to intestinal absorption of urine in the presence of a large fistula.

Renal agenesis and dysplasia including the common multicystic kidney disease, can be diagnosed on ultrasonography and confirmed by radionuclide scanning. Associated contralateral renal anomalies and reflux must be ruled out in these children. Vesicoureteric reflux must be ruled out in all ARM by a VCUG. Even in low ARM, the incidence of VUR may be significant, and in a series 18 of 48 (37%) patients with low lesions had VUR.\(^{16}\) VUR is treated on the same lines as the primary reflux, with institution of prophylactic antibiotics and close follow-up. Urodynamic evaluation becomes important to rule out bladder dysfunction in the form of uninhibited contractions and hypocompliance. In these patients, additional treatment of co-existent bladder dysfunction is also needed. Early institution of anticholinergics increases the chances of resolution of VUR. Surgical intervention is indicated for the breakthrough infections, Grade IV-V reflux, in the presence of a single kidney, deterioration of the upper tract function or onset of hypertension and the new renal scarring.

Management of Lower Urinary Tract Dysfunction

The incidence of neuropathic bladder with ARM ranges between 7-18%.\(^{19}\) Voiding dysfunction in patients with ARM can be secondary to:

i. Caudal regression syndrome with sacral agenesis.

ii. Associated tethered cord syndrome or overt spinal dysraphism.

iii. Secondary to operative trauma during PSARP.

The reported incidence of urinary incontinence in low anomalies varies between 0-10%. However, up to

**Indications for urodynamics in ARM**

I. All patients with sacral anomalies

II. Cloacal anomalies

III. All patients with transabdominal dissection of distal bowel

IV. All patients with tethered or low lying cord

patients. Radionuclide studies and IVP or preferably a magnetic resonance urogram are indicated only in the presence of abnormal findings noted on US or VCUG examination, e.g. horse shoe kidney, ectopic ureter/s, ureterocele. In addition, all children with ARM and associated sacral abnormalities must have an early urodynamic evaluation. Postoperative urodynamics is also recommended in boys with rectourethral fistula who have associated sacral agenesis, in girls with cloacal anomaly and in all patients who have had transabdominal mobilization of the distal bowel. Cystometry is also recommended in all patients with voiding dysfunction following PSARP and those who have undergone detethering of the cord.
33% of patients with high anomalies have urinary incontinence.\textsuperscript{20-22} The PSARP procedure by itself does not lead to a higher incidence of neurogenic bladder as compared to other traditional procedures. Pena reported a 10% incidence of incontinence in 233 children who underwent PSARP for a high or intermediate anomaly.\textsuperscript{20} The incidence of urinary incontinence was 69% in patients with a high confluence cloaca. The incontinence inpatients with a high cloacal malformation is usually due to inability to empty the bladder and not from bladder neck incompetence.

Early urodynamic evaluation helps in instituting clean intermittent catheterization (CIC) early. It is well documented that early institution of CIC (preferably before 3 months) leads to better compliance by the parents and the child. Clean intermittent catheterization allows complete bladder emptying at low pressures and prevents upper tract deterioration. The CIC is indicated in:\textsuperscript{23}

1. High pressure bladders (> 30 cm H\textsubscript{2}O filling pressure).
3. Poor detrusor contraction leading to high residual urine.

Chronic constipation and fecal impaction following PSARP can itself lead to bladder outflow obstruction and induce detrusor instability. Proper management of constipation alone in such cases will lead to resolution of UTI and enuresis. It has also been documented that treatment of constipation can sometimes lead to urinary incontinence by reducing the leak point pressures. Prophylactic antibiotics are indicated in patients with VUR, neurogenic bladder and upper tract dilatation and also in boys with urethro-ejaculatory reflux. Anticholinergics, usually with CIC, are used in patients with detrusor hyperreflexia or detrusor hypocompliance. It must be kept in mind that anticholinergics decrease bowel motility, which may adversely affect postoperative bowel function.

SKELETAL ANOMALIES

Skeletal anomalies described in relation to ARM include radial aplasia, major lower limb defects, rib and vertebral anomalies. Expertise help from pediatric orthopedic surgeon would be required to repair or reconstruct the defects as much as found feasible, including the use of prosthesis and physiotherapy, to improve cosmesis and function.

Spinal Anomalies

Vertebral defects of lumbosacral region are most common and the overall incidence of lumbosacral anomalies noted on plain radiographs in patients with ARM ranges from 30-45% (Fig. 74.6).\textsuperscript{24-29} The sacral ratio devised by Pena is helpful in assessing sacral hypodevelopment.\textsuperscript{21} In the AP view, a line is traced from the most superior aspect of the iliac crest on both sides. A second line is drawn between the two posterior inferior iliac spines. A third line is drawn parallel to the other two, joins at the lowest radiologically visible part of the sacrum. The sacral ratio is obtained by dividing the distance between the two lower lines by the distance between the two upper lines. The average ratio in 100 normal children was 0.74 and lower ratio represented sacral hypodevelopment. The same ratio obtained on a lateral view of the spine X-ray, was 0.77 and considered more reliable.

All patients with ARM and a sacral defect should undergo a screening spinal ultrasound examination in the newborn period (before 3 months of age when the ossification of the posterior lamina begins). MRI of the spine should be obtained in older patients and inpatients with an abnormal finding on spinal ultrasonography.\textsuperscript{17} A normal plain film of the spine.
does not always rule out a tethered cord. Tethered cord syndrome can lead to neurogenic bladder, back pain and gait disturbances. It is not clear whether the tethered cord directly affects fecal continence. Though, untethering may prevent subsequent neurogenic bladder or other complications, at present, it is unknown whether it will be beneficial for improving the anorectal function.\textsuperscript{24-26} These patients require close follow-up and urodynamic evaluation at 1 and 6 months after surgery as recurrent tethering may occur. Vertebral anomalies may signify an underlying occult lesion and the hemivertebra anomalies can result in scoliosis and therefore may require bracing or operative spinal fusion to prevent further deterioration in posture.

**SPINAL CORD ANOMALIES**

With advent of magnetic resonance imaging, spectrum of spinal anomalies has been well documented and appreciated but all of them may not be significant. Tethered cord has been found in 20-50\% of patients with ARM but in absence of functional sequelae, detethering may not be indicated. Table 74.2 outlines the indications for MRI screening for tethered cord syndrome. In presence of other unequivocal neurological symptoms with bowel dysfunction, untethering may be beneficial.\textsuperscript{30} Following spinal cord abnormalities have been reported:

- Tethered cord
- Spinal canal stenosis
- Myelomeningocele
- Spinal cord syrinx
- Diastematomyelia
- Diploymelia
- Dermoid cyst
- Neurogenic bladder
- Sacrococcygeal teratoma.

| Table 74.2: Indications for MRI screening for tethered cord syndrome in ARM |
|-----------------------------|-----------------------------|
| **Absolute** | **Recommended** |
| Myelodysplasia | Bladder neck fistulas |
| Sacral ratio of < 0.6 on lateral view | Cloaca with common channel > 3 cm |
| Complex defects | Presacral mass |
| Cloacal extrophy | Hemivertebrae |
| Neurogenic bladder | Poor result despite good surgery and good prognosis defect |

**Caudal Regression Syndrome**

Rectal, genitourinary and lumbosacral spine anomalies associated with an anorectal malformation may represent a syndrome of ‘caudal regression’.\textsuperscript{9,31} Sacral agenesis is defined as the absence of all or part of two or more vertebral bodies at the lower end of the spinal column. This is associated with defective development of the S2-S4 sacral nerves. Isolated sacral agenesis occurs more frequently in babies born to diabetic mothers. Overall, up to 25\% of patients with ARM have associated sacral agenesis and 75\% of these patients have lower urinary tract dysfunction.\textsuperscript{24,26} Classically, these patients have a flat buttock and a low or absent gluteal cleft. The urodynamic pattern in children with sacral agenesis is varied. Boemers et al studied 13 patients with partial sacral agenesis and ARM.\textsuperscript{32} Three patients had normal urodynamic findings, 5 showed a hyper-reflexic pattern and 5 others had a hyporeflexic study. In 1999, these abnormalities were grouped together using the term ARGUS (Anorectal, genitourinary, sacral). Guzman et al demonstrated an upper motor lesion in 35\% patients (detrusor hyper-reflexia, detrusor sphincter dys-synergia) whereas 40\% had a lower motor neuron lesion with absent sacral reflexes and detrusor areflexia.\textsuperscript{33} The remaining 25\% of patients had a normal study. There is no correlation between the number of affected vertebrae and the type of motor neuron lesion present. A VCUG and MRI of the spine are also recommended in these children. Treatment usually involves with CIC and prophylactic antibiotic therapy.

**GENITAL ANOMALIES**

Females with high ARM frequently have vaginal and uterine septation defects and vaginal agenesis. Pena recommends evaluating the patency of the fallopian tubes and uterus in babies with common cloaca. An intraoperative hysterosalpingogram is performed during the colostomy closure to rule out atresias of the uterus and vagina. Vaginal scarring secondary to the pull through procedure often leads to coital problem (dyspareunia) and the difficulty in vaginal delivery. Vaginal delivery in patients with a history of a vestibular fistula may also worsen fecal continence. Adult males may have ejaculatory duct obstruction, weak or absent erections and retrograde
ejaculation. It has also been noted that a significant number of adults operated for high anorectal anomalies avoid sexual contact because of fecal incontinence. Careful follow-up and examination is required to assess these anomalies. Psychological support and even surgical correction of these defects are required.

GASTROINTESTINAL ANOMALIES

Either as a part of VACTERAL association or in isolation, following gastrointestinal anomalies may be seen with ARM.35

- Esophageal atresia with tracheo-esophageal fistula
- Duodenal atresia
- Malrotation
- Hirschsprung’s disease
- Duplication cyst
- Intestinal atresia

The treatment of most congenital gastrointestinal anomalies found in association with ARM, is usually done at the time of colostomy formation. Associated Hirschsprung’s disease and other intestinal dysganglionosis, though uncommon (4%) and existence controversial, do not manifest early and are usually diagnosed after definitive repair of the ARM. The congenital pouch colon, classified under the group of rare lesions in the Krickenbeck classification, is not uncommon in certain areas, including in northern India, Pakistan and Bangladesh.36 The incidence has been found as high as 20% of all high ARM cases from the authors center, and 63.6% of these having other associated anomalies.37,38 Sometimes, very rare anomalies are encountered as a pouch colon opening into the bladder and also exteriorly as a patent intestinal fistula (Figs 74.3A and B). The management of this anomaly quite complex and deserves a separate chapter.39-44

CARDIOVASCULAR ANOMALIES

Incidence ranges from 8-20%. In patients with VACTERAL, the associated cardiac anomalies may be present in 50-80% cases. Most common anomalies are ventricular septal defect, patent ductus arteriosus, atrial septal defect and tetralogy of Fallot. Reconstruction of major malformations even in an association with serious cardiac anomalies, are though, feasible in most tertiary care level centers, yet it is expensive and requires repeated hospital visits for many surgeries and follow-ups. In absence of the support from insurance or the national health delivery system, an ethical based decision may have to be taken, if the local circumstances and economic status of the parents do not permit so.45

REFERENCES

36. Gupta DK. Ethical Issues in Pediatric Surgery – Guest Lecture delivered during the Round Table Meet, 1st World Congress of Association of Pediatric Surgeons, Zagreb, Croatia, 2004.
The posterior sagittal anorectoplasty (PSARP) performed for infants and children with anorectal malformations (ARM) is a technically demanding operation and requires strict adherence to the finer operative details to achieve good results. The postoperative care of the wound, catheterization of the urinary bladder postoperatively for 7-10 days for appropriate healing of the rectourethral fistula and than a careful anal dilatation program for 10-12 weeks until the elasticity of the sphincter fibers is secured and the anus is growing itself, are vital to avoid severe complications.

These complications encountered following PSARP are listed in Table 75.1.1-5 This list does not include the complications that may be encountered with the opening and closure of colostomy. The associated malformations in ARM also have an important bearing on postoperative results and morbidity. This article discusses the management of complications following PSARP. It also stresses the technical points which are important to avoid most of the complications as listed in Table 75.1. PSARP procedure in anorectal malformations is not usually associated with mortality, however mortality if any (10-20%) is related to associated cardiac defects, associated cerebral malformations, neonatal septicemia and very low birth weight.4 Severe early complications following PSARP are rare. In a series of 792 patients reported by Alberto Pena, only 2% had complications requiring major re-operative surgery.2 It is important to note, however, that lack of experience and non-adherence to the finer details of PSARP procedure can lead to significant and serious complication, many of them may continue even life-long.

The most important long-time complications after PSARP procedure is chronic constipation. It is astonishing that in the period from 1953 when Douglas Stephens presented first his sacral approach, being very similar to Pena’s technique, up to 1982 (when Pena and de Vries introduced PSARP) fecal incontinence represented the main postoperative problem.6,7 After the introduction of PSARP, primary fecal incontinence disappeared almost completely but secondary chronic constipation with overflow incontinence became the most important postoperative problem. The reconstruction of the anal sphincters was now improved but bowel rectal motility became disturbed.5

**EARLY AND LATE COMPLICATIONS FOLLOWING PSARP**

These are outlined in Table 75.1.

1. **Wound infection or dehiscence** is one of the most common complications following PSARP. It is recommended that a divided diverting colostomy should be constructed initially which decreases the incidence of infection following PSARP. A thorough cleaning of the bowel should also be done preoperatively.

2. **Meticulous hemostasis and proper closure of the wound** without leaving any dead space also decreases the incidence of wound infection. A deep infection of the wound may suggest dehiscence of the rectal tapering and needs aggressive management.

3. **Inadequate dilatation, perianal sepsis, ischemia of the pulled down rectal pouch** due to either an excessive or an inadequate mobilization leading to
tension on the neoanus can all lead to anocutaneous or anorectal stricture.

4. Tension on the anocutaneous anastomosis and infection can also lead to retraction of the bowel. Injury to the bladder neck, vas deferens and ectopic ureter can also occur if proper care is not taken during mobilization of the rectal pouch.

5. Transient femoral nerve palsy has been reported in adolescent patients’ secondary to direct nerve compression in the prone position. Deviating from the strict midline approach of PSARP and improper (deep) placement of the self-retaining retractors can cause pudendal nerve damage and lead to postoperative neurogenic bladder.

Urethral stricture, diverticulum or recurrent fistula can all result due to improper closure of the fistula during surgery. Adequate postoperative catheterization for 12 days is also important to allow healing of the urethral suture line. Rectal mucosal prolapse can be prevented by proper fixation of the neoanus under adequate tension.

The management of primary fecal incontinence and constipation with secondary overflow incontinence would be dealt with in some detail.

### DEFECATION PROBLEMS

Long-term results of surgery for high ARM has shown that at least 25-30% of children will suffer from fecal incontinence. An additional 30% will have varying degree of constipation, occasional soiling and fecal incontinence during periods of diarrhea. Though in some cases, fecal incontinence is a complication of surgery (a mislocated rectum), in most children, fecal incontinence is secondary to the defect. Fecal incontinence, therefore depends on the type of lesion and the original reconstructive procedure. Children with sacral agenesis, and males with a rectobladder neck fistula have the highest rates of fecal incontinence followed by the females with a high confluence cloaca.

It is also now well recognized that fecal continence does not improve with time and the future continence can be predicted within weeks of stoma closure. The earlier belief that fecal continence improves with time is a manifestation of the adaptation and adjustments made by the patient himself to achieve a socially acceptable status. Regular bowel movement with evidence of straining and observation by the mother of signs suggestive of imminent defecation without staining of the napkins suggests a good outcome.

Therefore, the etiology of defecation problems after PSARP is multi-factorial and includes

I. Sacral malformations
II. Sphincteric insufficiency
III. Altered rectosigmoid motility
IV. Secondary psychological problems.

#### Clinical Evaluation of a Child with Fecal Incontinence following PSARP

All children with fecal incontinence should be evaluated systematically to identify the causative factors. In this connection it is most important to distinguish between problems arising from insufficiency of the sphincter/levator muscle complex leading to true or primary incontinence (use score A) and disturbed rectal motility resulting in chronic constipation with secondary overflow incontinence.

Complications Following PSARP

The situation is similar to the problem of vesicourethral reflux where we have to distinguish between refluxing and obstructive ureters.

Table 75.2: Lists the individual factors, which should be assessed for the different kinds of complaints. In the very few patients achieving only 0-2 points, continent improving operations may be considered.

Score A should be used for true or primary incontinence based on hypoplasia of sphincter muscles. It is like others scores published by Kelly, Holschneider, Rintala and others not useful for overflow incontinence secondary to chronic constipation.\(^5,8,11\) Rintala modified Holschneiders score from 1983 by the addition of 4 more criteria.\(^12\) But only 2 dealt with chronic constipation which is the most frequent sequel after PSARP. Therefore, this score too can not be representative for all post PSARP problems. It seems, therefore to be justified to use two different scores for the two different post PSARP diseases: Dysmotility of the rectum and the sphincter incompetence.

For patients with rectal motility disorders resulting in chronic constipation and secondary overflow incontinence score B should be taken (Table 75.3).

Evaluation: 10-12 points: No/almost no constipation (equal to good continence); 6-9 points: fair, sufficient for social life with aids; 0-5 points: bad (severe constipation).

Table 75.4: Classification of postoperative treatment according to scoring A and B (Tables 75.2 and 75.3)

Nor or almost no treatment necessary (Type I, Type II a) 10-12 points score A/B

Motility problems, chronic constipation (Type II b) (score B) 6-9 points: Diet, laxative drugs, defecation training 3-5 points: Washouts 0-2 points: Anterior resection/Soave

Sphincter insufficiency (Type II c) (Score A) 6-9 points: Biofeed back training, anal plugging 3-5 points: Motility reducing drugs (with washouts) 0-2 points: Continence improving operations

In patients getting only 0-2 points, resection of the non motile rectum might be necessary. Concerning the treatment necessary, the scores A and B can be summarized in Table 75.4. Besides, according to the treatment, a classification of the type of post-PSARP sequelae, can be introduced which seems to be more practical and more objective than the usual grading of the severity of postoperative incontinence (Table 75.5).
The treatment of constipation in this dysmotility group is a challenging problem and requires a patience and methodical approach based on sound clinical judgment. Patient have care giver confidence and motivation is absolutely essential. The treatment of constipation is based on the following principles:
1. Explaining the problem fully
2. Supporting the child and family
3. Using minimal therapeutic input
4. Ensuring complete evacuation of retained stools,
5. Establishing effective toilet routines

Prior to initiating the bowel management program, the bowel must be completely cleared by using enemas or manual evacuation. Regular use of stool softeners (such as docusate sodium), a high fiber diet and adequate fluid intake follow this. Regular bowel emptying is established using laxatives like senna, dulcolax and sodium picosulfate. This program should start early to avoid the development of a megarectum. Older children can be taught to push against a closed glottis to evacuate. Enemas are ideally given soon after a meal to act concomitantly with the gastrocolic reflex. The aim is to establish one to two bowel movements per day by adjusting the regimen. The dietary adjustments are vital for any bowel management program. Excessive milk or cheese intake should be avoided. Vegetables, fruits and other traditional high fiber foods are initiated. Cisapride has also been used successfully to treat constipation as it improves colonic motility. It is important to remember that treatment has to be continued for at least 6 months to 1 year following normalcy as recurrence or relapse rates are high. Success is dependent on perseverance and initiating treatment early.

In more severe constipated children the use of smaller or larger volume enemas or colonic irrigation are necessary to keep the colon clean. It is believed that in the presence of a clean colon, the underlying bowel hypomotility will prevent soiling. In the presence of accidents or radiological evidence of retained stools, a larger volume of enema is used. In 44 patients in Pena’s study, 41 (93%) achieved success and it took an average of 4.4 days to reach continence.

The third subgroup, Type C, focuses on fecal incontinence. These patients suffer from hypoplasia of the muscle complex, sensory deficit and lack of smooth muscle fibers. For these children laxative measures are not suitable. Their diet must rather be

</tbody>
</table>

According to Table 75.5, three main and five subgroups of continence problems can be distinguished. One should consider any more of “degrees” of continence. The main groups are:
1. Patients who are continent
2. Patients who are partial continent (either due to chronic constipation or incontinence)
3. Patients who are incontinent.

There are no aspects of clinical examination considered in these two scores because there is unfortunately only a very poor correlation between the morphology and the function. However, rectal palpation of the sphincter tone and its elasticity are the first and most important examination in children with PSARP.

**CLASSIFICATION**

Patients who are continent do not soil, are not constipated and have regular voluntary bowel movements. Patients with partial continence can by classified in three subgroups depending on the therapy necessary to get regular bowel movements.

The patients of the first subgroup, Type A, are continent with a few adjuvants like occasional diet and laxatives. The second subgroup, Type B, is the constipation group and the largest group of sequel after PSARP. These patients can be helped with enemas and a regular laxative diet. They are constipated due to more severe motility problems in the rectum, but can be treated successfully conservatively. The primary defect in this group of patients is dysmotility of the bowel, which progressively can lead to megarectum.

In more severe constipated children the use of smaller or larger volume enemas or colonic irrigation are necessary to keep the colon clean. It is believed that in the presence of a clean colon, the underlying bowel hypomotility will prevent soiling. In the presence of accidents or radiological evidence of retained stools, a larger volume of enema is used. In 44 patients in Pena’s study, 41 (93%) achieved success and it took an average of 4.4 days to reach continence.

The third subgroup, Type C, focuses on fecal incontinence. These patients suffer from hypoplasia of the muscle complex, sensory deficit and lack of smooth muscle fibers. For these children laxative measures are not suitable. Their diet must rather be
constipating. The more solid consistency of the stools increases the feeling of rectal fullness, better discrimination and allows therefore better evacuation. The use of soft anal tampons may help after sufficient bowel cleaning. These patients are not constipated do not show overflow incontinence but soil occasionally due to their partial sphincter insufficiency. However, this symptom can be treated by conservative means. With these aids the patients are sufficient continent for social life. One reason for primary fecal incontinence sometimes combined with a tendency for diarrhea is a resection of the rectum or at least a part of their sigmoid colon during the pull-through procedure. The barium enema will show absence of the sigmoid with a straight non-dilated colon running straight down from the splenic flexure to the anus. The management involves daily use of small enemas to keep the colon clean. A strict constipating diet is used along with loperamide (1-2 mg orally 3 times daily) or diphenoxylate hydrochloride with atropine (0.05-0.1 mg/kg, orally, four times daily). Sometimes probiotics are helpful too. Accidents in this group are usually secondary to failure to reduce motility of the colon. Of the 128 patients in this subgroup in Pena’s study, 112 (88%) were successfully managed by this protocol.13

However, the treatment plan has sometimes to be individualized episodes of soiling or large unexpected bowel movements are termed as accidents. In the constipation subgroup, an accident represents failure to completely clean the colon whereas in the diarrhea subgroup it meant that the colonic motility was not adequately decreased. A larger volume of enema or increasing the concentration of NaCl or adding Bisacodyl can be tried in the constipation subgroup. In the presence of a clean colon on plain radiograph, a more constipating diet or increase in drug dosage can be tried in the diarrhea subgroup. The bowel management program is considered successful if the patients remain clean for at least 3 days consecutively. Such patients can be offered the MACE (Malone Antegrade Continent Enema) procedure as an alternative to rectal enemas. Failure after 10 days of continuous trial means that a permanent colostomy may be the only alternative in these patients.

Biofeedback is useful in patients with ARM with preserved rectal sensation. The intra-anal plug electrode can be used for supervised training and can increase the sphincter tone. However, surface electrode is more comfortable in most of the cases. Biofeedback can be successful in patients with minor problems and children who are able to cooperate. Severe defects usually do not respond and the technique is suitable only between 8-10 years of age.14 Soft anal plugs are very successful additional help for patients who are able to empty their bowel almost completely. The plugging can not avoid involuntary bowel movements, bowel accidents and stool staining.15

The last main group, the incontinent group represents children who are completely incontinent. This, on one hand (Type D), may be caused by a completely insufficient muscle complex, sacral agenesis or poor prognostic defects (high rectobladder neck fistula, high confluence cloaca) or, on the other hand (Type E), rectal motility can be disturbed so seriously that it leads to an overflow incontinence with most severe constipation that can hardly be remedied even by washouts. This problem is also called pseudoincontinence.

Pseudoincontinent patients include children with good sphincters, normal sacrum, children with good prognosis defect, a preserved and well placed rectum and a technically good operation. However, they all have had a history of most severe constipation, followed by history of fecal soiling. Pseudo-incontinence should be suspected if there is a delayed onset of soiling after a period of fecal continence and a history of constipation.

A contrast enema typically shows a megasigmoid. It is important to differentiate this defect from the subgroup (Type B) which has constipation with fecal incontinence. It is recommended that such children should initially be disimpacted and then put on laxatives to provoke bowel movements. The laxatives are increased over the next few days till a spontaneous bowel movement can be induced without enemas or suppositories. If the patient remains continent then he is assigned as true overflow incontinence and will benefit from sigmoid resection. If the patient remains incontinent then he is treated as the subgroup of fecal incontinence with constipation. As mentioned above, in group E a resection of the hypoperistaltic rectum might be required or a MACE stoma considered if some motility for the transport of the cleaning liquids were preserved. Only the rare first subgroup of
children with primary total incontinence due to sphincter insufficiency (type D) may benefit from continence improving sphincter operations like gracilis transposition. This procedure is successful in one-third of the patients, improves their situation in an other third of the children but fails in the others. The stimulation of the gracilis muscle by pacemakers can not be recommended in children at present.16

**Physical Examination (Table 75.6)**

Beside clinical evaluations, the investigation of patients with anorectal malformations involves a complete review of the history including the type of defect, the pre-PSARP findings on distal cologram, the initial assessment of the spine and the gluteal cleft, and the quality of sphincter muscles noted during surgery. It is very important to review details of the PSARP technique especially the extent of the preparation on the rectal muscle wall because this part of the mobilization cutes the neurovascular fibers of the nervi erigentes resulting in disturbed rectal motility. A plain radiograph of the spine and the sacral ratio according to Pena might be calculated. A detailed history of the bowel pattern, soiling pattern and constipation is noted. Physical examination should assess the location and caliber of the neoanus, the anal tone and the configuration of the perineum and the buttocks. A barium enema and defecography can delineate the length and elasticity of the anal canal, the caliber of the bowel, the anorectal angle and the descent of the pelvic diaphragm.

**Manometry**

Electromanometric investigations are very useful to distinguish between fecal incontinence due to an insufficiency of the anorectal sphincter structures and overflow incontinence. With special regard to incontinence, the most important parameters are the anorectal resting pressure profile and the squeezing pressure profile where as in chronic constipation the adaptive reaction/compliance of the rectum and the course of propulsive waves are important.12 Manometry is the ideal objective means to assess anorectal function, however, it does not always correlate well with the clinical status because not only the force of the anorectal sphincters are measured but also that of gluteal and adductor muscles as well.17

</tr>
</tbody>
</table>

Two other reliable findings on manometry are: Presence of an inhibitory rectoanal, which is a good prognostic factor and the decreased rectal sensitivity to distension, which is a poor prognostic sign.

Anal sphincter myography has also been used to objectively assess the sphincter function.18 Dynamic defecography has been replaced by CT scan and MRI to assess-the location of the pulled through bowel in relation to the sphincters and the anorectal angle.19,20 These studies also assess the quality of the sphincter complex and help in ruling out any occult spinal lesions.

**OTHER COMPLICATIONS AFTER PSARP TREATMENT**

1. Urethral diverticulum results from improper division of the fistula during the primary procedure. The diverticulum can lead to recurrent UTI, post-micturition dribbling or calculi formation. Treatment is by surgical excision preferably through the posterior sagittal route or through an anterior perineal approach.

2. A recurrent fistula usually manifests in the first 6 weeks. If a colostomy is not present, a redo colostomy is the initial step in treatment. A redo posterior sagittal approach and transrectal excision
Complications Following PSARP

839

of the fistula by the Kraske approach is advisable.\textsuperscript{21} The rectal suture line is rotated so as not to overlap the site of fistula closure.

3. Anal stenosis may respond to dilatations. In refractory cases an anoplasty or even excision of the scar tissue may be required.

4. Colostomy closure is often followed by development of redness and edema of the perineum. The redness may also be seen following primary PSARP (Fig. 75.1). Perineal excoriation may be real nuisance and is caused by fecal urease, which converts urea to ammonia (Fig. 75.2). Aggressive treatment with zinc oxide paste, warm compresses and perineal hygiene is required. Sucralfate and Karaya gum powder has also been used recently to heal the excoriated skin.

TREATMENT OF POSTOPERATIVE COMPLICATIONS

Most of the postoperative complications are preventable (Fig. 75.3). It is pertinent to stress the important technical hints of the PSARP procedure. These are:

1. Following a strictly midline approach
2. Preservation of rectosigmoid
3. Careful not too extensive preparation of the blind pouch close to the rectal wall
4. Proper relocation of the pulled through bowel in relation to the vertical and parasagittal fibers
5. Skin lined anal canal
6. Postoperative good toilet training and dilatation program, early treatment of constipation and avoiding liquid stools.

Fig. 75.1: Redness over the suture line may be seen following primary PSARP

The cutting of the neurovascular fibers penetrating Waldeyer’s fascia destroys the nerve erigentes and reduces bowel motility which leads to chronic constipation. That is the reason why patients with little mobilization of the blind pouch like low and high type anorectal malformations suffer less frequently from chronic constipation than intermediate or higher types mobilized extensively from behind.

Dilatation should not exceed more then 1-3 month. The anal orifice should have been calibrated intraoperatively up to Hegar’s 12. During the following month it should grow elastically to Hegar’s 13 until the end of the first year of life.

Results of the Treatment of Chronic Constipation following PSARP

The incidence of constipation following PSARP varies between 10-73\textsuperscript{%}.\textsuperscript{2,19,20} The incidence of constipation is higher in intermediate anomalies as compared to high...
anomalies. Yeung et al, evaluated 35 children with low anomalies followed up for 1-7 years.\textsuperscript{19} In this study 17 (53\%) patients had constipation and 9\% had soiling. Rintala et al also showed that 42\% children (n = 40) with low anomalies had constipation and 10\% had soiling.\textsuperscript{16} Low anomalies, especially rectovestibular fistulas, are frequently associated with constipation following repair. In the same report, Rintala et al using a quantitative scoring method modified from Holschneiders score, showed that only 60\% of patients with low anomalies had good continence while the completely normal bowel function was observed in only 15\%.\textsuperscript{8,12,16} This study shows that objective evaluation of bowel function is important as patients and caregivers may not always give the true picture on history. The use of objective scores and of the Wingspread classification is mandatory to compare postoperative results.\textsuperscript{6}

Holschneider et al reported in 2001 continence in 20\% of high, 42\% of intermediate and 79\% of low type ARM.\textsuperscript{22} Partially continent were 56\% of the high, 47\% of the intermediate and 21\% of the low deformities. Incontinence was observed in 24\% of the high and 11\% of the intermediate types. Comparing constipation in relation to the kind of the operative procedure used, severe constipation occurred much less in abdominoperineal pull-through procedures (n = 0) and perineo-proctoplasties (3.6\%) than after the PSARP (52.1\% and abdomino PSARP (52.4\%).

Using the new above mentioned classification according to the kind of postoperative treatment necessary, Holschneider observed in 2002\textsuperscript{5} total or near total continence (Type A) 35.3\% of the high. 40.9\% of the intermediate and 2 children in the low type of ARM in the constipation group.\textsuperscript{5} Partial sphincter insufficiency (Type C) occurred in 26.5\% of the high and 13.6\% of the intermediate types of deformities. Fecal incontinence needing further surgical treatment (Type D and E) were reported in 10 patients most of them having high type abnormalities.

Secondary Operations following PSARP

Redo Pull-through

A redo pull-through operation is indicated in good prognosis defects with a normal sacrum where the pulled through bowel has not been placed correctly in the muscle complex. This is suggested by findings of disparity in the muscle sling thickness on either side of the pulled through bowel on a CT scan. The presence of fat around the bowel also suggests an eccentrically placed bowel. The recommended treatment for this group of patients involves a redo PSARP under colostomy-cover. The reported outcome in terms of fecal continence have been variable following redo-pull through. Pena reported a significant improvement in 52\%, mild improvement in 18\% and no improvement in 12\%.\textsuperscript{2} Mulder et al reported that 25\% of their 20 patients became continent over a follow up of 3.5 years.\textsuperscript{23} Rintala et al followed-up 16 patients with redo pull-through.\textsuperscript{24} The clinical continence status and manometric findings initially improved in 13 patients (81\%). However, on longer follow-up till adulthood, only 4 (25\%) were clinically continent. Therefore, the results of secondary surgery are variable and on long-term follow-up may not be very encouraging. This further stresses the fact that there lies a considerable responsibility on the surgeon performing the primary reconstructive procedure.

Severe Chronic Constipation, Rectal Resection

As mentioned above only the very small group of patients with severe motility disturbance of the rectum may benefit from a resection of parts of the rectum/ mobilized not propulsive blind pouch (Type E, score B). The mean reason for this most severe problem are (a) aplastic and hypoplastic desmosis of the rectal wall and (b) injury to the nervi erigentes responsible for rectal motility.\textsuperscript{23,25,26}

In the period before the introduction of PSARP the main postoperative problem was stool incontinence because the blind pouch was at least partially resected by Rehbein-Romualdi-Kiesewetter’s procedure.\textsuperscript{27-29} In contrast, after Stephens abdomino-sacro-perineal pull-through technique, the results were much more satisfactory.\textsuperscript{5,6,30,31} With the introduction of PSARP in 1982, true incontinence almost disappeared and chronic constipation with overflow incontinence became the most important postoperative problem. However, constipation can better be handled than incontinence. Therefore, it is a matter of the feasibility of the surgeon to use the tendency to constipation factor as a continence improving factor in addition to the reconstruction of the sphincter complex but without achieving severe chronic constipation.
For eventual rectal resection deep anterior resection according to Rehbein’s technique should be used keeping 4-5 cm of the blind pouch in situ and with special care of the variability of the sigmoid vessels. 

Continence Improving Operations

a. Gracilloplasty has been a common method for secondary sphincter reconstruction. Early results shown increase in the resting and squeeze pressure. However, long-term results are far from encouraging as the muscle wrap tends to weaken over time. Continuous electrical stimulation of the gracilis muscle wrap induces a transition in muscle composition, from fatigable type II fibers to fatigue resistant type I fibers. This so-called dynamic gracilloplasty used an implanted muscle stimulator to maintain a constant anal tone. Baeten et al showed promising results using dynamic gracilloplasty; more than half of the patients became continent and the anal pressures were maintained high but most of them were adults.

b. Gluteus maximus transfer operation involves dissecting the medial parts of the muscle bilaterally, splitting the ends and suturing them to each other both anterior and posterior to the rectum.

c. Levatorplasty involves detaching the lateral and posterior attachments of the levator muscle and plicating it over the pulled through bowel. The short-term results are encouraging. The improvement following levatorplasty is probably related to creation of an acute anorectal angle rather than by increasing the actual resting or squeeze pressures. Long-term outcomes in adults has not been encouraging.

d. Smooth muscle free or flapped transpositions have also been successfully used by Holschneider and others.

e. Other secondary procedures for attaining fecal continence include free transplantation of palmaris longus muscle, secondary reconstruction of a used gracilis sling and the artificial anal sphincter.

f. Mucosal ectopy and sensitivity improvement (Figs 75.4A and B): To improve anorectal sensitivity and correct rectal prolapse, a three flap anoplasty or Nixon’s flap anoplasty are very useful (Figs 75.5A to D). Various other types of anoplasty have also been tried (Figs 75.6A to C). Mucosal rectal prolapse may be trimmed and a redo anoplasty has good results (Figs 75.7A and B).

Antegrade Continence Enema (ACE)

The Malone ACE procedure was initially reported in 1990 and was based on the fact that complete colonic emptying could produce fecal continence. The success of the Mitrofanoff principle was applied to provide a continent, intermittent, catheterizable access to the proximal colon. The operation is simple, but attention to detail is very important to avoid complications.

Figs 75.4A and B: Mucosal prolapse following PSARP
Patient Selection for MACE Procedure

Pena believes that the MACE procedure should only be used when traditional bowel management is successful and is simply a more acceptable route for giving enemas. In one of every twenty patients in their series, the procedure was unsuccessful, if there was failure of conservative bowel management. Patient and caregiver motivation and counseling is absolutely mandatory. Continued postoperative support and motivation is also important. Curry et al
Complications Following PSARP

have also noted that age at operation is a significant factor in determining success; there was a 70% failure rate for patients less than 5 years as compared with 24% for those older than 5 years. The MACE procedure is not free from complications and therefore should be used as only a means for providing a more convenient and acceptable channel for enemas.

The initial procedure devised by Malone involved dividing the appendix at its base and reimplanting it submucosally in a reverse manner into the cecum. A thorough bowel preparation and preoperative broad-spectrum antibiotics are used. The modified MACE procedure involves in situ plication of the cecum around the appendix. The tip of the appendix is divided and after each plicating suture a catheter is passed to check patency. The cecum and right colon are mobilized toward the midline and the appendix is exteriorized using interposition skin flaps through the deepest part of the umbilicus. The neoappendix can also be created from the medial portion of the ascending colon or the Monti principle can be used. Recently, laparoscopic appendicostomy without cecal plication has been used with success indicating that in some cases the native valve mechanism of the appendix may be sufficient.

Results of Malone ACE Procedure

Levitt et al reported a 95% complete continence in 19 of 20 patients. Stomal stricture occurred in 2, and 3 patients developed leakage at the appendicostomy site. In 1999, Curry et al reported a 72% complete and 17% partial success in ARM patients with the MACE procedure.

REFERENCES

Congenital pouch colon (CPC), an entity found in association with anorectal malformation, particularly from south Asian subcontinent has recently gained momentum. Initially the disease entity was not very well recognized and was thus various names were coined for describing the same condition. The anomaly, mostly reported from a few major centers in North India has now been well recognized at the international forum, with its inclusion under rare anomalies in the Krickenbeck classification of anorectal malformations.

With the proper description elucidated, more and more cases are being reported from various parts of the world. A changing trend has been seen in the most common type of CPC seen over the years from complete congenital pouch colon that accounted for more than 70% of cases earlier to incomplete pouch colon that is more commonly seen now.

**NOMENCLATURE AND RELEVANT HISTORY**

The entity was first described in 1912 by Spriggs in a London Hospital Museum specimen. Table 76.1 outlines the important historical landmarks for this anomaly.

The terms commonly used to describe this anomaly are the "congenital short colon" and the "congenital pouch colon". Pouch colon needs to be differentiated from the entity short colon and the congenital segmental dilatation of the colon, both these without

any anorectal anomaly. The term "short colon" refers to a shortened length of the left colon without the anorectal anomaly, that is also narrow in caliber and the babies are usually born to the diabetic mothers.

**DEFINITION OF CONGENITAL POUCH COLON**

In this anomaly, whole or part of the colon is replaced by a pouch like dilatation that communicates distally with the urogenital tract by a large fistula. The supravelvator anomaly is associated with a colonic pouch of variable length and diameter (5-15 cm). The mesentery is very short and poorly developed, the taenia coli are absent or ill defined, the haustrations and the appendices epiploicae are also absent.

The following anatomical criteria for description of congenital pouch colon have been described by the authors:1,2

1. There is anorectal agenesis.
2. Total length of the colon is short
3. Colon has a pouch formation for a varying length in the form of a saccular or a diverticular pouch with the collection of meconium or the fecal matter in it.
4. The blood supply to the pouch is abnormal. The main pouch is supplied by the branches arising from the superior mesenteric artery, that forms a leash of vessels around the pouch.
5. The colon wall is uniformly thick and muscular, with mucosal hypertrophy.
6. The fistula with the genitourinary tract is wide, muscular and closely adherent with the bladder wall.
7. Fistulous communication is with the bladder in the males and either in the vaginal wall, the vaginal septum between the hemivaginae or in the perineum in the females.
8. There is no transitional zone between the pouch colon and the normal bowel. The bowel pattern changes suddenly and sharply.
9. The associated major anomalies, specially the genitourinary anomalies are quite frequent.

**INCIDENCE AND EPIDEMIOLOGY**

The incidence varies in different parts of the world with an increased incidence in the northern part of the Indian subcontinent and only sporadic cases reported from the other parts of the world. The cause of this unique geographical distribution has not yet been ascertained.

The incidence of pouch colon has been reported to be between 5-15% of all cases of anorectal malformation in Northern India, 8-10% in Pakistan and 1.7% in Bangladesh.2 The incidence is much higher (23%) with the high anomaly and as low as 5% with the low type of anomaly. Also, pouch colon is commonly seen in tertiary care centers catering to more serious and redo cases of anorectal malformation. There is a male preponderance that varies from 3:1 to 7:1.2

**EMBRYOGENESIS**

The exact embryogenesis is unknown. The following hypotheses have been proposed:

1. **Dickinson**: Aborted hindgut development following obliteration of the inferior mesenteric artery early in fetal life.23
2. **Chatterjee**: Improper development of the postaxial midgut or presplenic gut due to a primary disorder of the proximal end of the hindgut or postsplenic gut.24
3. **Wu**: Faulty rotation and fixation of the colon leads consequently to a disturbed longitudinal growth.21
4. **Chadha**: Varying extents of vascular insult at the time of the partitioning of the cloaca by the urorectal septum could explain the different types of the malformation.25
5. **Wakhlu**: The anomaly is a stage in the development of cloacal exstrophy and is the combined effect of defective development of the splanchic layer of the caudal fold and failure of rotation of the gut causing defective longitudinal growth of the colon.22
6. **Gupta and Sharma**: Role of pesticides, micro-nutrients or the vitamin deficiency in a largely vegetarian community with poor socioeconomic status, affecting the vascular supply in the growing hindgut of the fetus at a critical window period of gestation.2 Any genetic link, though suggestive of a strong geographical distribution of the anomaly still needs to be confirmed.

Thus, the following factors may have a role to play:2

1. **Early vascular insult**: This cannot be ruled out as the blood supply is always abnormal to the pouch. It is only the superior mesenteric artery that is prominent and supplies the whole distal bowel. The
in inferior mesenteric artery is present only in 50% cases of the distal pouch colon.

2. 

Environmental factors: The high density of cases in the northern Indian subcontinent strongly suggests environmental factors with deficiency of iodine or vitamin B as the possible factors contributing to this anomaly. In this region, the land is very fertile and farming is the main occupation. Pesticides and fungicides are used liberally and the population is mainly vegetarian. Also, most cases of anorectal anomalies belong to the low socioeconomic status. These factors may be responsible for precipitating the anomaly at a window time after the conception when the hindgut is developing and differentiating into urinary and intestinal tracts.

3. Genetic predisposition needs to be ruled out in view of the typical geographical distribution.

**CLASSIFICATION**

Various classifications have been described to identify the type of anomaly. A widely accepted classification was based on the length of normal colon present proximal to the dilated pouch as given by Narsimha Rao et al. (Table 76.2).^{20}

Wakhlu et al. simplified the classification, depending on the length of normal colon and the management planning in relation to the need for coloplasty (Table 76.3).^{22} However, this classification was not found practical as the length of 8 cm was not sufficient for performing a pull through.

The Krickenbeck classification of anorectal malformation laid stress on the classification of anomalies that best decide the management options to keep the descriptions universal and to compare the results globally. Thus the authors had classified the anomaly into "Incomplete" and "Complete" pouch colon based on the feasibility to use the remaining colon that would be more important while performing the pull through (Table 76.4).^{1,2}

Initially, in India, complete congenital pouch colon was more commonly seen and accounted for more than 70% of cases till 1985. Interestingly, during the past two decades, it is the incomplete pouch colon that has become much more common now (75-80%). Associated genitourinary malformations (cloacal anomalies, double vagina, extrophy) are also more common in girls.

In complete congenital pouch colon, a large dilated thick walled pouch occupies most of the left side of abdomen. Cecum, if present almost always opens into the sac from right side. It may be associated with an absent, rudimentary or double appendix. There is associated malrotation. The pouch with poorly developed mesentery is supplied by the superior mesenteric artery on the superior and right side and an arcuate extension of superior mesenteric artery on the left side. Inferior mesenteric artery is present only in incomplete pouch colon and supplies the lower half of left lateral side of pouch. The genitourinary fistula of the pouch opens into the posterior wall of the bladder in males. Fistula is usually quite broad and thick walled. In females, colocoloacal fistula is the most common followed by colovaginal and colovestibular fistulas. There may be double or septate vagina and the fistulous communication may open in one of the hemivaginae or between the two into the cloaca.

**HISTOPATHOLOGY OF THE POUCH**

Grossly, the wall of the pouch is thick, the taenia coli are absent or ill defined, hastruation and the appendices epiploicae are absent. The main pouch is supplied by a leash of vessels around it. The authors have found the following histological features in patients with pouch colon.

The most salient feature is the disorganization of the muscle coat in an arborhizing manner.^{1} This is possibly responsible for the absence of normal

### Clinical Presentation

The presentation is usually in the early neonatal period with an absent anal opening and distension of the abdomen with or without meconia (Figs 76.3A and B). There may be associated bilious vomiting with early gross distension of abdomen. In the female child, the anomaly is often associated with a cloacal anomaly and the baby passes meconium from the abnormal opening. Colonic perforation may occur early in cases of grossly distended pouch colon presenting with peristaltic activity in these cases, requiring the removal of dilated pouch and retaining only the normal bowel.

1. The muscle coat is not clearly differentiated into inner circular and outer longitudinal muscles, and is arranged in a decussating pattern. The circular muscle may be incomplete in 50% cases (Fig. 76.2A).
2. The ganglion cells are mature and present in all cases with the presence of normal or occasionally hypertrophic nerve bundles. The pouch wall consists of normal ganglion cells though these may be reduced in number and smaller in size. However, giant ganglia are also seen in 10% cases (Fig. 76.2 B). Nerve bundle hypertrophy has also been reported but is not the regular feature.26
3. Congestion of the mucosa and focal hemorrhages are seen commonly.
4. Ectopic heteroplastic tissue has also been reported.27

**CLINICAL PRESENTATION**

septicemia, gross abdominal distension and features of peritonitis.

Late presentation may be seen in a female child with a large colocolacal fistula as the child remains decompressed. The child may also present with a colostomy done by a person not aware of this condition, as an undiagnosed case.

INVESTIGATIONS

In cases with suspected pouch colon with gross abdominal distension in geographical areas where it has high incidence, the diagnosis may be made with an erect skiagram in addition to the conventional invertogram done for anorectal malformations (Figs 76.4A and B). A large loop of bowel with single air fluid level occupying more than half of the total width of abdomen and displacing the small bowel to one side (usually right) is the classical picture seen. The pouch is proximal to the pubococcygeal line in the invertogram. An early perforation is also suggestive of pouch colon especially if the baby comes from an area where pouch colon is commonly seen.
A detailed work up of the baby at the time of definitive surgery includes ultrasound of abdomen, intravenous urogram and voiding cystourethrography and echocardiography to evaluate for associated anomalies. Spiral CT with 3-D reconstruction of pelvic musculature or MRI of pelvis are optional to study pelvic musculature.

### Fallacies in Diagnosis

The following causes may lead to fallacies in diagnosis:
- Massive dilatation of sigmoid in anorectal malformation.
- Hydrometrocolpos (with fistula).
- Pneumoperitoneum.
- Localized pneumoperitoneum following perforation in patients with anorectal malformation presenting late.
- In female babies with rectouterine fistula where the massive dilatation of uterus with meconium and gas may mimic pouch colon.\(^2\)
- If colon is fully decompressed by a large fistula, with the genitourinary tract.

### ASSOCIATED ANOMALIES

Genitourinary system is most commonly involved with associated anomalies followed by gastrointestinal, vertebral, limb and cardiac anomalies. Table 76.5 summarizes associated anomalies found with congenital pouch colon.\(^2\) The most common associated anomalies are vesicoureteric reflux, kidney anomalies, absent appendix, double appendix and bicornate uterus.

### MANAGEMENT

Timely diagnosis and planned management is essential to get the best outcome for any case. Preoperative resuscitation is mandatory as in all cases with anorectal malformation presenting in the newborn age with nasogastric decompression and catheterization of the bladder.

The aim of surgery is to utilize the available length of colon for absorption and storage capacity as well as capability for propelling fecal matter onward with a continent anal opening.

Figure 76.5 outlines the algorithm for the surgical management of pouch colon that depends upon the choice of the surgeon, condition of baby at presentation, technical skill of the surgeon and the available facilities.
In incomplete congenital pouch colon, the pouch can be excised (Figs 76.6A and B). In complete congenital pouch tubularisation of the pouch in the form of coloplasty is needed (Fig. 76.7). A tube length of about 15 cm is just enough to serve the purpose of colon for adequate propulsion of fecal matter as well as to utilize the colonic surface for water absorption and form formed stools and to avoid the complications of a long and non-functional bowel (Figs 76.8A and B). At present single stage surgery for congenital pouch colon is not routinely advocated as there is unacceptably high mortality associated with it.

With the most common type of CPC now being incomplete congenital pouch colon (than the complete congenital pouch colon that was more commonly seen earlier), better results are expected after surgery as it is preferred to excise and do away with the abnormal colon and its related complications.

Fig. 76.5: Algorithm for management of congenital pouch colon

Fig. 76.6A and B: A. Operative photograph of an incomplete congenital pouch colon. B. An operative specimen of an incomplete pouch colon that was excised

Fig. 76.7: To perform coloplasty, a tube is formed along the antimesenteric border to lengthen the colon preserving the vascular arcade. (Reproduced from Gupta DK, Sharma Shilpa. Congenital pouch colon, in Anorectal Malformations, 1st edition, Ed. John Hutson and Alex Holschneider, Springer Heidelberg, 2006;11:211-22 with kind permission of springer science and business media)
The preferred approach is proximal diversion in the form of "End colostomy" after division of fistula and (i) excision of the pouch in incomplete pouch colon and (ii) coloplasty in complete pouch colon. The other forms of proximal diversion are: (i) Proximal ileostomy in complete pouch colon and (ii) Transverse Colostomy in incomplete pouch colon.

A window colostomy is a simple surgery in which an opening is made on the anterior surface of the colonic pouch without attempting to ligate the fistulous connection. It can be done with minimum anesthesia especially in a sick neonate, may provide adequate decompression and a time period to allow for weight gain and be fit for second stage. However, it is associated with the well known complications and a mortality as high as 15-20% and is thus not favored by most including the authors (Table 76.6). The mortality rate following the coloplasty procedure performed with an end colostomy in the newborn period, is also reported to be high, hence it is wiser to perform an ileostomy at birth and defer the coloplasty for a later date.

Excision of the pouch in toto with an end colostomy (using normal colon) is the preferred procedure, wherever feasible. An attempt should be made to close the fistulous communication with the urinary tract and excise the pouch even in cases presenting with colonic perforation.

The coloplasty is done after mobilising the pouch completely by division of the inferior mesenteric
artery (if present) and incising the pouch on the antimesenteric border, preserving the vascularity (Fig. 76.9). The tube is fashioned over a red rubber catheter to obtain uniform calicer. The coloplasty may be brought out as an end colostomy on the abdominal wall for a staged procedure. It can be pulled down also to the proposed anal site as a definitive procedure in the neonates but it is risky and associated with high morbidity and even mortality. Variable results have been reported by different authors.\textsuperscript{1,2,28,29}

The pouch has been used to reconstruct the vagina and the anorectum both at the same time. In this case, the pouch was split longitudinally in analogy with Bianchi’s intestinal lengthening procedure and used to create the vagina and reconstruct the anorectum with the preserved blood supply.\textsuperscript{30}

**COMPLICATIONS**

Most of the complications associated with congenital pouch colon are related to the window colostomy (Table 76.6). Recurrent urinary tract infection occurs due to persistent colourinary fistula and associated vesicoureteric reflux. Incomplete decompression of pouch through the window colostomy requires regular washouts.

Suture line leak following the coloplasty has become negligible ever since proximal ileostomy has been used. Minor wound dehiscence occurs in 4-5% of patients. Mortality following coloplasty has been reduced to less than 5% since it is being performed as a staged procedure.

Colonic dilatation has been a problem following pull through procedure utilizing the coloplasty segment in long-term follow-up of patients. This may be due to the fact that the colonic pouch is abnormal histologically and due to the disorganized muscle coat and the abnormal peristalsis, has a tendency to dilate. The utilization of a shorter segment of the pouch for coloplasty is thus recommended.

**RARE VARIANTS**

There are few cases that are unique and different from the usually seen cases of pouch colon.

A case with imperforate anus associated with duplication of descending colon, double pouch colon type IV, duplication of the urinary bladder, and a bifid penis has been described.\textsuperscript{31}

Other unusual variants include the presence of two pouches with an intervening segment of normal colon, presence of associated rectal atresia, pseudoeystrophy bladder and associated duplicated eystrophy bladder (Figs 76.10A to C).\textsuperscript{32-34} The lower urinary tract and part of the hindgut develop from the allantoic diverticulum. The embryologic basis of the association of pouch colon with duplicate bladder eystrophy has been proposed as malposition of allantoic diverticulum with the yolk sac resulting in anorectal malformation or sequestration of a part of allantois, infraumbilically and improper mesodermal progression giving rise to duplicate bladder eystrophy.\textsuperscript{34}

The authors have encountered a case in which there was a lumen opening through the umbilicus giving the appearance of a patent vitellointestinal duct through which stool was coming out (Figs 76.11A to C). On exploration, the opening led to a structure that was composed-half of bladder wall and mucosa and the other half of colonic wall and mucosa. This was an abnormal pouch colon opening with a fistula into the bladder. There was no segment of normal colon. The ileum opened into the structure made of
bladder and colonic tissue directly. Ileostomy was done. The pouch colon variant composed of bladder and colonic wall was excised and the bladder fistula was closed.

**RESULTS**

The results depend on the condition of the perineum, muscle complex and associated anomalies. The presence of a good perineum is essential to attain good continence results and prevent mucosal prolapse. A bad perineum with sacral agenesis in a complete congenital pouch colon may suffer from poor continence status postoperatively.

During the initial follow-up, the baby passes frequent loose stools but subsequently the frequency of defecation decreases and the consistency becomes semisolid to solid. The colon on follow-up examination shows normal caliber in most of the cases; however, dilatation of the tube coloplasty is a serious problem, though rare.

In author’s experience, as the anatomy and the histology of the pouch colon is abnormal, even the tube made from the dilated pouch does not work well and does not contribute effectively to the colonic motility.

The continence results vary in different series due to many factors including the available infrastructure, the NICU care and the surgical expertise. Babies with incomplete pouch colon fair comparatively well with normal continence and physical, motor and behavioral development. Cases of complete pouch suffer from increased frequency of stools, rectal prolapse and skin excoriation, especially during the initial years though the frequency decreases with the growth of the child and the dietary modifications. Many children operated for pouch colon and who had been totally incontinent, have attained continence at puberty.

**Figs 76.11A to C:** A. Newborn presenting with a patent pouch colon opening at the umbilicus, B. The baby had associated bifid scrotum and meningomyelocele C. Operative photograph demonstrating the pouch made up of colonic and bladder wall.
PROGNOSIS

The prognosis depends on the weight of the child, age at presentation, presence of sepsis and perforation, associated congenital anomalies and most importantly on the type of pouch colon. The prognosis is better in cases of incomplete pouch colon as cases of complete pouch colon suffer from recurrent watery diarrhea due to short length of large bowel. The presence of other serious associated anomalies also affects the prognosis. Excision of the pouch and end enterostomy has been associated with maximal survival.

Overall mortality of congenital pouch colon in the newborn age was previously as high as 30-40% but has now come down to 10-20% with growing awareness of this condition and improvement in the surgical management and neonatal care.4

REFERENCES

The presence of a cloaca is physiological in some reptiles, birds and a few mammalian. However, in humans it represents a malformation occurring at a very early stage of development. A cow with a malformation resulting from the confluence of the genital, urinary, and intestinal tracts was first described by Aristotle.\(^1\) Johann Friedrich Meckel introduced the term “cloaca congenita” in the early 1800s.\(^1\) However, cloacal malformations were only rarely reported until 50 years ago.\(^2\)

Persistent cloaca is considered as the most challenging of all types of anorectal malformations. The surgery of the most complex of these anomalies should only be performed by one specially trained in these anomalies to achieve the desired goal of bowel and bladder control. Hendren has published the most comprehensive reports on cloacal malformation repair.\(^3-9\) The posterior sagittal anorectovaginourethroplasty (PSARVUP) allowed direct exposure to the complex anatomy and the voluntary muscles of urinary and fecal continence. Pena has contributed greatly to the treatment of this malformation with the introduction of the total urogenital mobilization after the use of PSARP worldwide.\(^10-16\) The treatment differs on whether the common channel is less than or more than 3 cm in length on the cystoscopy measured from the proximal end of the common channel up to the perineum.\(^11-17\) About 65% of the patients have a short common channel.

This anomaly had a poor prognosis until a few decades ago, with a mortality rate greater than 50%.\(^18\) The prognosis has improved considerably in recent years, and surgical repair with good functional outcome is now possible.

**DEFINITION**

A persistent cloaca is defined as a confluence of the rectum, vagina, and urethra into a single common channel at the site of the normal urethra.\(^17\) The incidence of these malformations reported previously varied between 1 per 40,000 and 1 per 250,000 live births.\(^19\) However, with growing awareness, the incidence is now considered around 1 in 50,000 live births, comprising around up to 10% of all cases of anorectal malformations. The incidence of cloacal extrophy still remained much rare with an expected incidence of 1 in 2,500,000 live births.

**EMBRYOLOGY**

The aetiology of persistent cloaca is unknown but an embryological basis does exist. Cloacal malformations result from the failure of the urorectal septum to join the cloacal membrane during the fourth to sixth weeks of embryonic development. This failure could result in a persistent communication between the rectum and the urogenital sinus.\(^20\)

The tail gut immediately distal to hindgut starts to regress by apoptosis on day 12th of gestation in a craniocaudal direction and has regressed completely by day 13.5.\(^21,22\) The tail gut regression and the urorectal septum play an important role in the process of cloacal separation by cellular proliferation and differentiation. Rupture of the anal membrane plays an additional role. However, Kluth et al reported that the embryonic cloaca never passes through a stage that is similar to any form of anorectal malformations in neonates including the cloaca.\(^23\) They feel that the development of the septum is more passive than active. Based on studies in appropriate animal models,
the process of maldevelopment starts early in the embryo.\textsuperscript{23} The cloacal membrane is always too short in its dorsal part in abnormal embryos and the region of the future anal opening is missing in contrast to normal mice embryos.\textsuperscript{24} The hindgut remains attached to the sinus urogenitalis, thus forming the rectourethral fistula.\textsuperscript{23}

Several experimental models of anorectal malformations including persistent cloaca exists. They are based on the teratogenic effect of ethylenethiourea in the rat, adriamycin exposition of rat fetuses or etretinate a long-acting Vitamin A analog in mice.\textsuperscript{25-27} A molecular basis for anorectal malformations was first shown by Kimmel et al.\textsuperscript{28} In the murine model of ARM, Gli3\textsuperscript{-/-} mutants had anal stenosis and ectopic anus, Gli2\textsuperscript{-/-} mutants showed imperforate anus and rectourethral fistula. Gli2\textsuperscript{-/-}Gli3\textsuperscript{+/-} mutants developed a cloacal abnormality. Possible etiologic role for homeobox genes, such as HLXB9 with mutations resulting in anorectal- and spine abnormalities have also been suggested.\textsuperscript{29}

The cloacal plate, a vertically orientated midline plate of epithelial cells in the caudal half of the genital tubercle, is the key structure to understanding early anorectal and urogenital development that varied between the different animal models.\textsuperscript{30} In rats the plate maintained a vertical height along its length, while in humans and pigs it reverted to a two-layer membrane dorsally, shortly before it degenerated, to expose both the anorectal and urogenital tracts. In sheep the plate was taller ventrally than in the other species but also reverted to a short membrane dorsally that exposed the hindgut when it degenerated. The anterior part of the cloacal plate persisted in all embryos as the urethral plate, which then participated in the formation of the urethra in the male and the vestibule in the female. Given the similarities between porcine and human development, the pig may be the most legitimate animal model for the study of anorectal and urogenital anomalies in humans.\textsuperscript{30} Persistent Cloaca may occur either in an isolated fashion or as a part of a spectrum of anomalies involving multiple organs.

**CLASSIFICATION**

**Classification of Persistent Cloaca**

A detailed description of the varying anatomy of cloacal malformations has been published by Hendren and Pena in many publications.\textsuperscript{3-7} Hendren distinguishes between anomalies of the perineum, sinus urogenitalis, vagina and rectum.

**Hendren’s Description of Various Cloacal Anomalies**

**Perineum**

According to Hendren there is a wide range of deformities of each pelvic structure. At the mild end of the spectrum of perineal malformations there is an almost normal looking vaginal opening with an anal orifice which is situated very close but not incorporated in the urogenital sinus. In the next degree the vaginal introitus might be incompletely formed and the anus displaced forward with a dysplastic perineum between both openings. There might be a large sinus urogenitalis opening and the anal opening just behind it, or a single perineal opening covered by the clitoris which could be hyper- or hypoplastic. In a very few cases an accessory hypoplastic urethra can be observed at the tip of the phallus in addition to the proximal urethra fusing with the urogenital sinus. The accessory urethra may have a large diverticulum also. The perineal skin can be covered by an hemangioma and abnormal pigmentation.

**Sinus Urogenitalis Variations**

The urogenital sinus (UGS) may show an ending on the tip of the clitoris, a subclitoral meatus, a wide opening to a short common channel or a long sinus with the junction of urethra, Vagina(s) and rectum above the PC line. By using this anatomical projection of the upper border of the prostate and the I-point representing the plane of the upper border of the internal anal sphincter, high, intermediate and low types of cloaca can be distinguished according to the Wingspread classification of anorectal malformations.\textsuperscript{31} However, there are so many variations of anomalies of the vagina, urethra and rectum in cloacas, that this classification was not very helpful to classify cloacas.

Nevertheless it is important to distinguish between high and low cloacal deformities because a urogenital sinus less than 3 cm of length can be treated by total sinus urogenitalis advancement whereas in longer channels an abdominal approach is necessary.\textsuperscript{11}
Vaginal Variations

The two most common variations are a single vaginal opening in the upper urethra with the rectal opening below this orifice and a double side by side vagina with the rectum ending on the septum between both vaginas. In cases of hemivaginas and an incomplete septum the rectal fistula can be situated high on the septum, in cases with two separated vaginas it can usually be found between both vaginal openings.

There might be variations, e.g. two vaginas but atresia or even absence of one, double diverging vaginas, two separate vaginas or one or two vaginas entering the bladder.

Rectal Variations

The rectum can enter the UGS separate and below the vagina, may enter the posterior wall the vagina or even in the bladder coursing between the two halves of the uterus. It can be positioned between and anterior of two vaginal openings or it may run as a long fistula all along the posterior wall of the vagina down to the urogenital sinus. The fistulous tract may open in the septum between two hemivaginae. The rectal pouch at the upper end of the fistula is very high up in these cases, sometimes even above the peritoneal reflection.

Pena’s Description

Pena has now the largest world experience in the management of cloacal malformations. As cloaca has a spectrum of anomalies, it can not be classified in separate groups. However, Pena has classified these anomalies into two main groups: (a) those with a common channel length of less than 3 cm and (b) those with a common channel length of more than 3 cm. The length of the channel may be as long as 10 cm.

Holschneider Classification of Persistent Cloacas, 2006

*Type I:* Forme fruste anteposition of anus with ultra short UGS and normal female genitalia

*Type II:* Low cloacal malformation short UGS < 3 cm (confluence below PC line)

*Type III:* High cloacal malformation long UGS > 3 cm (confluence at or above PC line)

*Type IV:* Vagina and/or rectum into bladder cavity.

Posterior cloaca and cloacal extrophy have been grouped as rare cloacal malformations.

In the Authors’ Opinion, the Following Considerations Need to be Kept in Mind while Managing a Case of Common Cloaca

1. Firstly, the true common cloaca needs to be differentiated from a urogenital sinus with a normal or anteposed anal opening. The exact anatomy may be delineated by good clinical examination, dye study, imaging or panendoscopy.

2. The presence of a pouch colon (not uncommon in Indian Subcontinent) needs to be ruled out as it affects the management plan in a child born with common cloaca.

3. It is also very important to establish whether the bowel is opening in the cloaca as a fistula or as a normal sized muscular bowel. Patients having a fistulous anomaly require urgent fecal diversion.

4. Presence of associated hydrometrocolpos. The presence of a valvular opening between the urethra and the vagina may lead to one way flow of urine to the vaginal cavity leading to dilatation of vagina, infection and foul smell.

5. Presence or absence of associated other anomalies, which are not uncommon in babies born with persistent cloaca, e.g. unilateral renal agenesis.

6. Whether the urogenital sinus is stenosed or not. A narrow UGS may be just enough to be utilized for the purpose of reconstruction of a new urethra. However, if a girl presents at a higher age with a wide urogenital sinus, the anomaly may possibly be managed with a perineal approach to reconstruct the urethra and the vagina and perform an anal transposition.

7. The presence of urinary incontinence suggests a higher malformation and thus the need to consider surgical options including urinary diversion procedures well in advance.

8. Whether the cloacal opening is a true opening or a covered anomaly giving the appearance of a cloaca.

Babies born with vesico-intestinal fissures require urinary and bowel diversions and despite all advancements can not be ensured a continent and normal quality of life. Parents need to be counselled properly so that they can have the treatment options.
Types of Persistent Cloacal Anomalies

The exact anatomy of the anomaly needs to be defined for proper management. For all practical purposes, a 3 cm length may be described as the borderline between low and high anomalies as advocated by Pena.

Figure 77.1 describes various types of persistent cloaca from a practical point of view. These have been described in Table 77.1. A number of rare variants have also been reported in literature.

Cloacal exstrophy is much rare. The clinical presentation includes the presence of an exomphalos, extrophied caecum flanked by two hemibladders containing ureteric orifices. A proximal opening leads to the ileum that may prolapse. Two appendiceal appendages may be seen. The distal opening leads to a blind large bowel segment that may be of variable length. The diagnosis of the other rare variants of cloaca requires a high index of suspicion.33

Anterior and Posterior Cloacal Malformations

A new entity called posterior cloaca has also been described by Pena and Kessler.34 It is an extremely rare variant (< 1% as only a few cases are reported till date). In these patients, the rectum is placed at the normal site or minimally mislocated anteriorly. The vagina and urethra fuse together to form the UGS but the UGS instead of opening in the perineum, opens in the anterior rectal wall. As most cloacal anomalies are anterior, thus in reference interms of location, most cloacas would mean an anterior cloacal anomaly in almost 99% cases.

Association with Congenital Pouch Colon

An association with congenital pouch colon is not uncommon. In such cases, the rectum is quite high, very much dilated and opens in the bladder or the vagina with a wide fistula. The wall is thick and the blood supply is also abnormal.35-37 The rectum may open as a fistula or with a normal sized opening. The fistula may be long and run parallel to the posterior wall of the bladder and the urethra. The opening of the fistula may be located in the vaginal septum or in one of the hemivaginae or in the bladder.

CLINICAL PRESENTATION

The most striking clinical feature that brings the patient to the doctor is the absence of anal opening and the presence of a single perineal orifice (Figs 77.2A and B). The external genitalia appear smaller and are under developed. The newborn may present with an abdominal mass, due to a distended vagina (hydrocolpos) and is present in 50% of patients with persistent cloaca. The sacrums should be examined. The presence of associated anomalies should be looked for.

There have been instances when the diagnosis could not be made in the newborn period and the children have presented as late as at the age of 10-13 years.38 Girls with a single opening on their perineum should always be suspected to suffer from a cloacal malformation. Rarely cloacas have been reported in boys in whom the urethra and rectum are coalescing into a common channel that connected to the external surface in the perineal or anal area.39 In girls, an abdominal mass and severe abdominal distension can be observed resulting from hydrometrocolpos and/or rectal obstruction. Additional malformations of the lower limbs, genitalia, the skin (hemangioma), the urogenital tract, vertebrae and cardiac, gastrointestinal and other deformities may occur.
Fig. 77.1: Types of persistent cloacas. The main types are type I to IV. The rare variants include A-K. UGS: Urogenital sinus.
ANTENATAL DETECTION

Cloacal anomalies are rare and have variable presentations, these are difficult to diagnose correctly by ultrasonography antenatally.\(^{40-43}\)

The anatomy of cloacal malformations is variable, thus ultrasonography findings could vary according to the type of anomaly in different cases.\(^{44-49}\) Serial ultrasounds may show changing features of a cloacal anomaly, consisting of fetal ascites, intra-abdominal cystic structures with debris, a cystic pelvic mass, hydrometrocolpos, hydronephrosis, and oligohydramnios.\(^{40,43}\) Linear calcifications in the abdomen along the peritoneal surface indicate calcified meconium from meconium peritonitis.\(^{52}\) This may occur, apart from intestinal perforation, in cloacal malformations, when meconium spills into the peritoneal cavity through the fallopian tubes.\(^{53}\) As the condition progresses, an inflammatory reaction in the fallopian tubes causes tubal occlusion, hydrometrocolpos, and the progressive disappearance of the ascites.\(^{52}\) The dilatation of the vaginal cavity further contributes to the upper urinary tract obstruction (hydroureteronephrosis) by direct ureteral compression. Urologic, spinal, and cardiac abnormalities are the most commonly associated features and account for 50-68% of all cases.\(^{41}\)

Maintenance of amniotic fluid is a dynamic process involving fetal urine production, fetal swallowing, secretion of the oral and respiratory tracts, and intramembranous flow (fluid transfer across the placenta, the umbilical cord, and fetal skin). The lack of a urinary outlet and renal agenesis are almost invariably associated with oligohydramnios. Cloacas are thus usually associated with oligohydramnios. However, occasionally the pathologic features are not always associated with oligohydramnios and cases with hydramnios with fetal hydrometrocolpos have also been reported.\(^{43}\)

The ability of ultrasonography to detect fetal anomalies may be limited by maternal obesity, amniotic fluid alteration, and inadequate fetal lie. The prenatal ultrasonographic diagnosis of cloacal anomalies may be confirmed by the use of a Fetal Magnetic resonance imaging (MRI) that reveals excellent fetal images regardless of maternal obesity or fetal position. Fetal Magnetic resonance imaging (MRI) allows proper delineation of the cloacal anomaly, hydrometrocolpos, septate vagina, uterus didelphys and associated renal malformations.

ASSOCIATED MALFORMATIONS

More than 80% of all patients with a cloaca have an associated urogenital anomaly. Sacrum and vertebral anomalies are common. Patients with long common channel have a high frequency of complex associated anomalies. Approximately 50% of the patients with cloaca have hydrocolpos that may lead to bilateral mega ureters and hydronephrosis. The most common

associated urinary tract anomalies involved are renal agenesis, renal dysplasia, vesicoureteral reflux and megaureter.

During the immediate assessment of the newborn, emphasis is placed on the recognition and treatment of potentially lethal associated defects, mainly urologic, esophageal or cardiac anomalies (Table 77.2). Some of the children exhibited masculinization of the external genitalia with the accessory urethra or cloacal channel assuming a phallic position in an enlarged clitoris.

All babies with cloacal anomaly should undergo an ultrasound of the kidneys and pelvis before surgery. If a hydrocolpos is present, it should be drained at the same time the colostomy is performed. The colostomy should be completely diverting so as to prevent contamination of the urinary tract. In cases of extremely long common channel that lies usually near the trigone, the bladder neck is closed and a vesicostomy is done. About 30% of these patients have duplicated Mullerian structures. The prognosis should be explained to the patients well in advance and the complications that may arise, especially during pregnancy, may be explained.

Tethered Cord

A tethered spinal cord, intravertebral fixation of the filum terminale has a known association with anorectal malformations and is particularly common in patients with persistent cloaca (in approximately 40% of patients). Preoperative ultrasound can give suspicion of tethered cord syndrome sometimes associated with lipoma of the spinal cord or diastematomyelia. Anomalies of the sacrum are commonly associated with the tethered cord. Patients with anorectal malformations and tethered cord have a worse functional prognosis regarding bowel and urinary function. Motor and sensory disturbances of the lower extremities may result. Controversy still exists on whether or not an asymptomatic child with an incidentally diagnosed tethered cord should be operated or not. Many patients who had been untethered have been reported to have a retethering postoperatively due to postoperative scarring. If the child suffers from incontinence and there is neither sacral agenesis nor deficient muscle complex, surgical de-tethering is recommended.

INVESTIGATIONS

A skiagram lumbosacral spine is useful to look for associated vertebral defects. Plain radiography of the sacrum in the anterior-posterior and lateral projections can reveal sacral anomalies, such as a hemisacrum and sacral hemivertebrae. The skiagram should be performed in a strict sagittal position with the legs elevated and the anal dimple marked. The complete lumbosacral spine should be visible. There is a clear correlation between the degree of vertebral and sacral malformations and the occurrence of neurogenic voiding and defecation disorders. A complete destruction of S2- S4 is called Lower Motor Neuron Lesion (LMNL) and shows clinically as an always dribbling bladder. A severe deformity of higher lumbar neurons with intact sacral reflex activity, resulting in an autonomic or reflex bladder, is called Upper Motor Neuron Lesion. However, the majority of the patients suffer from a Mixed Motor Neuron Lesion (MMNL) with a varying amount of residual urine and uninhibited detrusor contractions.

The sacral ratio measured by the distance from the coccyx to the sacroiliac joint divided by the distance from the sacroiliac joint to the top of the pelvis in a lateral radiograph gives an idea about the functional prognosis. Normal sacrum has a ratio of 0.77. Bowel control has never been observed in patients with ratios less than 0.3 by Pena’s team. Abdominal and pelvic ultrasonography may be done to look for associated anomalies before the baby is discharged. Spinal ultrasonography in the first 3 months of life is useful to look for tethered cord. At a later age, MRI may be used.

After birth, once the colostomy has been created, a high pressure hydro soluble contrast distal colostogram may help to delineate the detailed anatomy. A properly performed genitogram through the single perineal opening may further elucidate the anatomy (Figs 77.3A and B).

Cystoscopy and vaginoscopy are essential components for evaluation of the patient with persistent cloaca. The combination of imaging, dye study and panendoscopy, provides reasonable information whether a laparotomy will be required in addition to the perineal approach, and the assessment of the internal organs, the vagina(s), rectal fistula, bladder neck and urethral orifices besides measuring the length of the common channel. Without endoscopic
aid it is usually not possible to catheterize the bladder because the fusion of the proximal urethra with the UGS is almost sharply angulated in the direction of the pubic bone. This may be helpful to teach the parents to allow later intermittent catheterization by the mother until the final reconstruction is performed. In many cases however, the urine is first passed in the vagina before being evacuated through the common channel. In these patients it is sufficient to perform intermittent catheterization in the vagina. Only very few children with cloaca need a vesicostomy or vaginostomy.

The investigations should also be directed to identify the associated urologic anomalies and presence of hydrocolpos that need to be managed within the newborn period to avoid serious complications. An obstructive uropathy may be overlooked and later present with life threatening sepsis and acidosis.

TREATMENT

The goals of management in cases of persistent cloaca in the newborn period are:
1. Achieve satisfactory diversion of the gastrointestinal tract
2. To detect associated anomalies
3. Identify and manage a distended vagina, if present
4. Divert the urinary tract, when indicated.

Colostomy

The preliminary intervention should consist of a colostomy either in the transverse colon (or rarely even the high sigmoid colon) keeping in mind that the left colic- and the sigmoidal arteries are essential for later reconstructive pull-through procedures. Diversion of the fecal stream using the transverse colostomy, is most commonly employed. Transverse colostomy placed in the ascending colon and a distal mucous fistula are recommended. The defunctionalized colon so obtained, is used for the future rectal pull-through; thus, adequate length must be ensured when the colostomy location is chosen. Also, an access to this distal colon is vital for radiological evaluation. Complete diversion of the fecal matter is necessary to prevent urinary infections.

Drainage of the Hydrometrocolpos

A catheter drainage or open drainage should be introduced in the bladder and/or vagina in case of hydrometrocolpos. The distended vagina is a common cause of an obstructed urinary tract with pressure on the trigone; therefore, once the vagina is decompressed, the urinary tract may no longer be obstructed. If the hydrocolpos is not drained during the newborn period, it can become infected and can lead to vaginal scarring. Many patients require antimicrobial prophylaxis for urinary tract infections for associated vesicoureteral reflux. After the recovery of the baby, further detailed studies especially by endoscopy are necessary with introduction of stents in all visible urethral, vaginal and rectal openings. These probes are important for a detailed X-ray study immediately after the endoscopy.

Definitive Repair of Cloacal Malformations

The final goals of management in cases of persistent cloaca during definitive repair are:
1. To place all the three orifices at their normal locations, with good cosmesis.
2. To achieve bowel control
3. To attain urinary control
4. To attain ability for normal sexual function.

It may be difficult to attain all these goals in complicated cases. The prognosis depends on the length of the common channel, sacral development and the presence of associated anomalies.
Principles of Surgery

The length of the common channel determines the extent of surgical repair. The length of the common channel can vary from 1 cm to sometimes more than 5 cm at the time of definitive repair. If the common channel is quite short (about a cm), a perineal approach may be sufficient if the surgical access is allowed. For a common channel of 1-3 cm, the posterior sagittal approach should be used to repair the defect without an abdominal approach. For patients with a common channel longer than 3 cm, a laparotomy is usually required. The plan of surgery depends on the length of common channel and the anomaly. Figures 77.4 and 77.5 describe the algorithm for options of management for these cases.

The surgical procedure combines the advantages of the Posterior Sagittal Anorectoplasty (PSARP) introduced by De Vries and Pena in 1982 with the classical abdomino perineal approach. However, the appropriate technique depends on the individual case and malformation. The repair can usually be performed using only the posterior sagittal approach. For more complex anomalies, an abdominal approach is added to mobilize a very high vagina or the rectum.

The principle previously followed was to separate the rectum from the vagina, the vagina from the sinus urogenitalis to pull both structures down to the perineum and to reconstruct the urethra from the UGS. Often, the vagina and urinary tract were separated to gain length. With the introduction of the total urogenital mobilization, the rectum is mobilized first. Then, the vagina and urinary tract are mobilized together (total urogenital mobilization), with the goal that these structures reach the perineum. If total urogenital mobilization does not adequately lengthen the vagina, the vagina and urethra must be separated, which is a technically challenging maneuver. Care must be taken not to cause any ischemic injury to the urethra or the vagina. Vaginourethral fistulae are more likely after this. The rectum is placed within the limits of the sphincter mechanism, determined with an electrical stimulator.

Fig. 77.4: Flow chart for management of cloaca with low confluence

Fig. 77.5: Flow chart for management of cloaca with high confluence

U = Urinary bladder, V = Vagina, R = Rectum
UGS = Urogenital sinus, RVF = Rectovaginal fistula, TUM = Total urogenital sinus mobilization
The main challenge involves the repair of the vagina, the urethra, and the associated urologic defects. The surgeon must be prepared to open the bladder and to reimplant the ureters, if necessary. Complex vaginal mobilizations are often required, and vaginal replacement with small intestine or colon is frequently necessary. A large vagina can be mobilized more easily and has more alternatives for vaginal repair. A vaginostomy performed in the newborn period must be taken down at the time of the definitive repair as it may be tethered to the abdominal wall and prevent mobilization of the vagina. Approximately half of the patients have various degrees of vaginal or uterine septation that can be totally or partially repaired during the main operation or deferred for definitive repair until puberty.

**Operative Procedure**

The patient is placed in lithotomy position and pan-endoscopy is done to assess the length of the common channel, the bladder, the vagina and the rectum/fistula.

**Perineal Urethrovaginoplasty**

For low anomalies or anomalies with a low urogenital sinus, the perineal route can be used for the urethrovaginoplasty. A low urogenital sinus with a vaginal septum can be handled at the same time (Figs 77.6A to M). This approach is particularly useful for the cases that have had a PSARP in the past, leaving the UGS as such or a misdiagnosed UGS.

**Total Urogenital Sinus Mobilization (TUM)**

For short common channel the patient is placed in the prone position with the pelvis elevated with a roll. A posterior sagittal approach is used initially to separate the rectum. The incision is given from the middle portion of the sacrum to the single perineal orifice. The entire sphincter mechanism is divided in the midline and the rectum is exposed. During the last decade, a total urogenital mobilization has been found to be beneficial for these patients. The rectum is separated from the vaginal wall by creating two walls out of one. Multiple 6/0 silk sutures are placed taking the edges of the common channel, along with the edges of the vaginal walls, to exert uniform traction. The urethra and the vagina are mobilized together. Another set of sutures are placed transversally 5 mm dorsal to the clitoris and the entire common channel is mobilized as one. Gentle uniform traction on all these sutures distributes tension and avoids damage to the very thin structure of the UGS. The wall of the urogenital sinus is then divided completely ventral to the sutures and dorsal to the clitoris. The dissection proceeds lateral and ventral to the UGS and includes step by step the vagina and urethra together. The dissection is proceeded with till a vascular fibrous structure is identified and divided. These vascular fibrous ligaments attached to the pelvic rim must now be divided to free the vagina, urethra and bladder without dividing the blood supply to these structures. The dissection goes on until enough length has been gained to connect the vaginal edges to the perineum. This step allows a gain of 2 to 4 cm length of the urogenital structures. The purpose is to place the urethral meatus at its normal location around 5-8 mm below the clitoris. The edges of the vagina are sutured to skin of the perineum forming the new labia. The initial common channel is divided in the midline to make two flaps that are sutured on either side. By this procedure the urethra and the vagina are shortened but without any loss of function. The uterus and the bladder are pulled down deeper in the pelvis.

**Repair of High Cloacal Malformations**

The baby is prepared and draped circumferentially so that the surgeon can work with the patient in supine position through the abdominal route, jack-knife position for the posterior sagittal access and in lithotomy position for the perineal stage of the procedure. The baby should be draped in a way that it can easily be turned to each position inside sterile drapes.

If the channel is between 3-5 cm the posterior sagittal approach may be tried and a total urogenital mobilization may still be attempted. Patients with long common channel more than 5 cm are approached through the abdomen with an incision in the midline. The separation requires delicate surgery and the decision should be made by an experienced surgeon.
Figs 77.6A to M: Operative steps in the management of a case of common cloaca (Type II- Low UGS and High rectovaginal fistula). Excised specimen of pouch colon.
POSTERIOR SAGITTAL ANO RECTOVAGINOURETHROPLASTY (PSARVUP)

For the posterior sagittal approach, the incision starts from the lower part of the sacrum and goes down through the centre of the external sphincter ani fibers to the orifice of the UGS. The parasagittal and sphincter fibers are divided exactly in the midline. The coccyx is divided and split in the midline for about 1 cm. It is easier to find the levator structures close to the coccyx than in the anal region and to open them from proximal to distal with a fine needle tip diathermy. Once the levator muscle structures are divided strictly in the midline the rectum and the UGS should be identified. The rectal fistula usually enters at the posterior wall of the vagina. In cases with double vaginas it is not infrequent that the rectal orifice is situated on the septum separating the two vaginas. In a few cases it can only be reached by an abdominal approach.

The sagittal incision has to be enlarged proximal to the visceral structure being in most cases the rectum, in others the vagina. It is now important to identify all openings which become evident: one or two vaginas, the rectal fistula and the orifice of the proximal urethra which is usually the most distal opening in the cloaca. Besides, the urethra is sharply angulated in the direction of the os pubis. The urinary catheter in the UGS is now introduced in the urethra and bladder and then the rectum is separated from the Vagina and the vagina from the urethra. Series of fine 6-0 silk traction sutures may be used for traction. The separation of the rectum from the vagina and the vagina from the urethra is the most difficult part of the procedure because rectum and vagina share a common wall and the vagina covers the dorsal wall of the bladder neck.

The urethra may be surrounded on its lateral sides by vagina.

Muscle fibers from the external bladder sphincter can hardly be seen in this situation and the ureters may run to ectopic orifices in the bladder neck. To avoid urinary incontinence, as much as possible the paraurethral tissue should be preserved. The separation of the rectum and vagina becomes easier only up to 1 -2 cm above the entrance of the fistulae in the UGS because the walls of the rectum, vagina and the urethra are now well developed.

Once the vagina and rectum are completely mobilized, the urogenital sinus is trimmed or simply closed by a running suture of absorbable material. A second layer is performed with interrupted sutures of para-urethral tissue. One should try to reconstruct the urinary sphincter which could be identified by electrostimulation.

Associated Pouch Colon

The pouch colon associated with persistent cloacas require prior diagnosis to achieve good results and avoid mishaps. Each case is handled according to the anatomy. If there is an incomplete pouch, excision of the pouch is done (Fig. 77.6). If there is a complete pouch, coloplasty of the pouch is done (Figs 77.7A to C).

Vaginal Reconstruction

Further operation depends upon the anatomy of each case. If the vagina is large as in cases of hydrometrocolpos, then it may easily reach the perineum. However, lot of careful dissection is needed to mobilize the hugely dilated vagina. In cases with a short vagina, a switch procedure may be feasible in
cases with two joined hydrocolpos with separate hemiuteri. In such cases, the septum may be divided and one entire Mullerian structure may be resected. The blood supply to one side should be preserved to provide the blood supply to the side that is being switched down.

If the vagina is very short, small and high, a replacement is needed. The first choice for vaginal replacement is to use the part of the rectum in babies with a mega rectum. The rectum is divided longitudinally to form both, the new vagina and the neo rectum. These structures are based on the sigmoid vessels for the vagina and of the descending colon based on the left colic artery for the rectum. If the patient has internal genitalia, the segment of neovagina is sutured to it after the free passage of the fallopian tubes has been secured. In absence of these, the upper part of the neovagina is closed. The second choice for the vaginal replacement is the use of sigmoid colon, followed by the segment of the small bowel. The lower rectum can also be used according the technique of Harrison in form of a J-loop with one single long arcade. The distal part of the J-loop forms the vagina, while the proximal segment, the new rectum. The deepest point of the J is implanted in the perineum to create the separate vaginal and rectal orifices. However, the procedure requires meticulous care to preserve the blood supply (Fig. 77.8).

In case of a vaginal perforation during this procedure, the vagina is rotated by 90 degree so that the urethral suture line and the vaginal sutures are separated and rectovaginal fistula are avoided. The vagina should be implanted next to the urethral orifice and inside the labia. A perineum of 1.5 cm of length is then constructed and the rectum fixed inside the external anal sphincter fibers. Nixon’s cutaneous flap anoplasty has also been used to increase anorectal sensibility.

**POSTOPERATIVE CARE**

The urinary catheter remains in place for approximately 10-14 days. In complicated cases, one may have to resort to a suprapubic cystostomy tube. Anal calibration is performed 2 weeks after the operation, followed by a program of anal dilatations. The anus must be dilated twice daily, and the size of the dilator is increased every week. The final size to be reached depends on the age of the patient. Once the desired size is reached, the colostomy can be closed.

**COMPLICATIONS**

To avoid complications, in most cases of cloaca, the rectal pull-through should not be performed first as an isolated procedure. In the majority of cases, all three systems, i.e. rectum, vagina, and urinary tract can be repaired simultaneously. Most complications can be preventable or reduced by adhering to specific principles.

1. *Urethrovaginal fistulae*: This is the main operative complication. It requires a reoperation. Cystoscopy and vaginoscopy may be performed before colostomy closure to ensure that there is no urethrovaginal fistula.
2. Vaginal stricture or atresia
3. Urethral strictures
4. Inadequate drainage of hydrocolpos may lead to urinary tract infections, pyocolpos, and/or vaginal perforation.
5. Colostomy complications, including a colostomy sited too distally
6. Persistent urogenital sinus after rectal reconstruction.
7. *Fecal incontinence*: Continence is more likely in patients with a low cloaca and in those with a normal sacrum. About 80% of patients with a low cloaca and good sacrum have bowel control. Approximately, 70% of patients can achieve voluntary movements. For patients with...
Pediatric Surgery—Diagnosis and Management

incontinence, a bowel management program is successful in keeping the patient clean and dry. In those in whom bowel management is unsuccessful (< 3%), a colostomy may be the best option to ensure good quality of life.

8. Urinary incontinence: Urinary control varies based on the length of the common channel. Intermittent catheterization is required in 70% of patients with persistent cloaca who have a common channel longer than 3 cm, compared with 20% in the group with a common channel shorter than 3 cm. In patients with urinary incontinence, urinary diversions, such as the Mitrofanoff procedure and the use of intermittent catheterization, are usually successful in keeping the patient dry of urine. In most patients, the bladder neck is competent and the patients who require catheterization remain dry between micturitions. If catheterization is not performed, overflow incontinence occurs. Occasionally, the bladder neck is not competent in these patients, a urinary diversion, such as a Mitrofanoff procedure may be helpful. Seventy percent of all patients with a common channel longer than 3 cm require intermittent catheterization to empty their bladder.17

9. Gynaecological problems: The precise gynecologic anatomy must be ascertained during the main repair or at the time of the colostomy closure. Approximately one third of the patients may have obstructed Müllerian structures that can lead to severe problems due to retrograde menstruation.17

OUTCOME

Most patients of common cloaca can be repaired with a satisfactory functional and anatomic result with the posterior sagittal midline approach, often together with an abdominoperineal approach.7 Hendren in 1998 reported on 195 cases of cloacal repair.5 Out of a follow up of 141 cloacal patients, 82 had spontaneous bowel movements and satisfactory control, 38 used enemas to evacuate, 9 had a colostomy and 7 suffered from fecal soiling. Regarding urinary control, 83 voided spontaneously, 40 patients catheterized to empty, 4 had urinary diversion, 1 had a continent diversion and 5 patients were wet. Also, 24 of these were the adult patients when followed up. Seventeen had experienced coitus and 7 had babies, all except one by caesarian section.

Patients with cloacal malformation have a high incidence of bladder dysfunction with recurrent urinary infections and incontinence.54 Urodynamic assessment has been reported to be necessary to detect bladder dysfunction in these patients. Some authors have reported that surgical reconstruction by total urogenital mobilization can cause further deterioration of bladder function, particularly in the group with a long common channel.54

Gynecologic results in 22 teenagers were reported by Levitt et al.55 Seven girls are menstruating, six had primary amenorrhea because of absent or atretic uteri. Nine patients suffered from obstruction of one or more Mullerian structures that did not allow menstruation. Renal outcome is less favorable. Warne et al identified 64 patients with cloacal malformations aged 0.5-19 years at the time of the study.56 Also, 83% were born with a structural abnormality of the urinary tract, including renal dysplasia (27%), ectopic kidney (14%), solitary kidney (13%), duplex kidneys (9%), and ureteropelvic junction obstruction (5%).52 VUR was observed in 53%, sacral abnormalities in 57% of the patients. Chronic renal failure developed in 32 (50%) patients with a glomerular filtration rate of less than 80 ml per minute per 1.73 m². Moreover, 17% progressed to end stage renal failure, 6% required renal transplantation and 4 died of chronic renal failure. Therefore careful postoperative follow up is obligatory in these patients.

Pena has recently reported a review of 339 cases of cloaca.17 A total of 265 patients underwent primary operations and 74 were secondary. All patients were approached posterior sagittally; 111 of them also required a laparotomy. Also, 122 underwent total urogenital mobilization. The average length of the common channel was 4.7 cm for patients that required a laparotomy and 2.3 cm for those who did not. Vaginal reconstruction involved a vaginal pull-through in 196 patients, a vaginal flap in 38, vaginal switch in 30, and vaginal replacement in 75 (36 with rectum, 31 with ileum, and 8 with colon).17 A total of 54% of all evaluated patients were continent for urine and 24% remained dry with intermittent catheterization through their native urethra and 22% through a Mitrofanoff-type of conduit. Seventy-eight percent patients with a common channel longer than 3 cm required intermittent catheterization compared with 28% when their common channel was shorter than 3 cm. Sixty percent of all cases have voluntary bowel
movements (28% of them never soiled, and 72% soiled occasionally). Forty percent were incontinent for stools but remained clean when subjected to a bowel management program.17

**CLOACAL EXSTROPHY**

In cloacal exstrophy, the results are worse and the mortality and morbidity is high.57 However, Lund and Hendren achieved an overall survival rate of 98% in 50 cases observed over a period of 25 years.58 Of the 40 reconstructed cases, 31 were dry. Acceptable bowel continence was achieved with wash out enemas in 19 of 25 pull-throughs.

Patients with cloacal exstrophy have complex anomalies of the genitourinary and gastrointestinal tract with a spectrum of colonic length. Often, colon is lost during the initial management by use of ileostomies and for urologic and genital reconstruction.59

In a series of 53 patients of cloacal exstrophy treated over a 26-year period, including typical cloacal exstrophy,25 or a covered variant (16), and complex anorectal malformations with short colon (10), the patients’ ability to form solid stool was assessed via bowel management involving a constipating diet, anti-diarrheals, bulking agents, and a daily enema through the stoma.59 Patients who underwent successful bowel management through the stoma were offered a pull-through. Of 20 available for follow-up after pull-through, 17 are clean with bowel management (85%), 2 (10%) have voluntary bowel movements with occasional soiling, and 1 is incontinent but noncompliant.59

Indication for pull-through depends on successful bowel management through the stoma, which depends on the ability to form solid stool. To maximize this potential, it is crucial to use all available hindgut for the initial colostomy and avoid use of colon for urologic or genital reconstruction. Most patients have poor prognosis for bowel control but can remain clean with bowel management.59

**OTHER UNUSUAL FORMS OF CLOACA**

These have been described in Fig. 77.1. Their management requires a high suspicion for accurate diagnosis.

The rare forms of cloaca like urogenital sinus with anteriorly placed rectum can be managed with PSARVUP with or without TUM. Vaginal reconstruction will be needed for cases with vaginal agenesis. If the Mullerian structures are present and are patent, the upper part of the neo vagina can be anastomosed to the Cervix. Cases of posterior cloaca need to be tackled with a different approach altogether. Fortunately these are extremely rare.33,34 Pena has also operated upon a few cases with a transpubic approach.

**SUMMARY**

In conclusion, the surgical management of a persistent cloaca represents the most serious technical challenge in pelvic pediatric surgery. It should be performed in specialized pediatric surgical centers by a team of pediatric surgeons/urologists who are well trained in the management of cloacal anomalies. A careful lifelong follow-up of the patients into adulthood is necessary.

**REFERENCES**

Albeit, there has not been much development in the understanding of the embryological and clinical aspects of patients with anorectal malformations (ARM), yet, the surgical management of these children has seen a major paradigm shift with the development of posterior sagittal anorectoplasty (PSARP) as proposed by Alberto Pena in 1982.1 Another recent development has been the review of the subject by the world experts and proposing the new classification in 2005 at Krickenbeck (Germany), with an attempt to include all types of anorectal malformations, both major and minor, and the rare anomalies and evaluating the postoperative outcome based on various operative techniques practiced world wide.2,3

Recent Advances in the Field of ARM Include4

1. Attempt on the antenatal detection—Introduction of Fetal MRI.
2. Utilizing the new Krickenbeck Classification for ARM — 2005.
3. Referral of cases with ARM to trained pediatric surgeons at tertiary care level.
4. Avoiding the colostomy at primary center in favor of single stage repair.
6. Appropriate diagnosis of ARM before performing colostomy.
8. Early single stage definitive surgery – even in the newborn period.
9. Laparoscopic assisted pull through.
10. Robotic pull through, if the facility and the expertise is available.
11. Regular follow-up for assessment of continence.
12. Bowel management program to make the patient socially acceptable.

The aim of management of ARM is now shifted from saving life to ensuring a near normal quality of life.4 Though antenatal detection has been attempted yet the features to detect this anomaly before birth are often missed on prenatal ultrasonography. Thus, the incidence of prenatal detection of babies with ARM is almost negligible at present.

Management is now based on the accurate scientific information about the muscle complex and the associated malformations. The investigations like echocardiogram, ultrasonography for various abdominal organs and the magnetic resonance imaging have helped to delineate the associated anomalies in detail.5 A high pressure distal colostogram and a 3D spiral MRI have helped to delineate the anatomy of the defect, level of the lower end of the pouch, the presence and also the size of the fistulous communication thus offering the information for adopting the most appropriate surgical procedure for the correction of the defect in a particular baby.6 The definitive surgery is now done at an earlier age with the increasing popularity of the single stage procedures not only in females but in males also, not only in infancy but in the newborn period also, not only for the full-term but for the premature babies as well.4,7,8

A regular follow-up for the assessment of continence is quite essential for successful management.9 Finally, a dedicated bowel management program can provide the patients with a happy and acceptable quality of life, free from routine hassles due to incontinence.10
ETIOLOGY

Despite much generated interest to elucidate the exact etiology, it still remains poorly understood. These malformations however are believed to result from arrests or abnormalities in the embryological development of the anus, rectum and urogenital tract.

Genetic predisposition has been seen in only a few families. Sex linked and autosomal dominant inheritances have been suggested.

If anorectal malformation is the only abnormality in the family, an autosomal dominant mode of inheritance may be likely. However, the presence of multiple associated malformations may indicate recessive inheritance and subsequent pregnancies should be regarded as high risk requiring full antenatal investigative workup.

Trisomy 13 is associated with anorectal malformations. It is also seen in association with trisomy 21,18 and Townes Brocks syndrome. Currarino syndrome is associated with mutations of the homeobox gene HLXB9. Apparently there is no racial predilection. Pena has noticed a positive family history in cases of rectoperineal fistula.

The etiology of ARM may be multifactorial. The anomaly has usually been found in families from developing countries with lower socioeconomic status, thus suggesting possibly the role of nutritional and environmental factors like liberal use of pesticides in the fields, leading to the embryological defects.

A significantly higher incidence has recently been reported from Italy, in children born after assisted reproductive techniques (odds ratio 13.31, 95% confidence limits 4.0-39.6). This is in agreement with the result of a recent epidemiological study in Sweden. Though, further studies are necessary to define the risks involved and identify the causes, the couples undergoing assisted reproductive techniques, should be informed of the general risks of the congenital anomalies, especially ARM.

An increased incidence of ARM has also been seen in fetuses whose mothers have had diabetes or thalidomide toxicity.

INCIDENCE

The global incidence of ARM anomaly is taken as 1:5000 live births, However, few geographical areas have reported a higher incidence of this anomaly, e.g. 1:1832 from Calcutta. A recent study on the incidence of anorectal malformations in the province of Alberta, Canada has reported the incidence as high as 1: 2162 with a marked rise in male predominance (1.7:1).

ANTENATAL DETECTION

There have been recent attempts to diagnose anorectal malformations antenatally with the development of sophisticated equipment. The initial reports held that anorectal atresia can be diagnosed only from 22 week gestation onwards. However, recent reports have picked up the anomaly as early as 12 weeks of gestation by transvaginal ultrasonography as a cystic echogenic structure, with a distal tapered appearance low down within the abdomen and pelvis. Also, a dilated colon may be picked up on ultrasound examination in a fetus at 12 weeks of gestation. Dilatation of the colon has been reported to be clearly seen in the first and the third trimester of pregnancy, but it is difficult to detect it in the second trimester.

Meconium, as a semisolid mixture of enteric secretions and sloughed cells, usually appears in the fetal colon from approximately 15 week onwards as a normal physiologic process. Apart from the small size of fetal structures early in pregnancy, the difficulty of diagnosis results from the changing physiologic characteristics of the fetal gastrointestinal tract. The presence of isoechoic meconium within the dilated bowel may cause the loss of the cystic appearance. Decompression of the fluid-filled bowel into the urinary tract, via the fistula, may cause disappearance of the dilated bowel.

Fetal meconium is usually hypoechoic or isoechoic to adjacent abdominal structures on antenatal sonography. Hyperechoic meconium is associated with pathologic conditions, such as meconium ileus, meconium peritonitis, and anorectal malformations, though hyperechoic meconium has been reported as a normal variant, particularly in the third trimester. The sonographic detection of a meconium concretion in the fetal bladder strongly suggests the presence of an enterovesical fistula.

Enterolithiasis with anorectal malformation has been described in which the intra-luminal calcification was identified using an ultrasound. Ultrasonography can thus differentiate between enterolithiasis and meconium peritonitis and the prenatal diagnosis of...
rectourinary communication may be made when enterolithiasis is present.\textsuperscript{23}

In one of the series, fetal MRI has been found useful to pick up four cases of anorectal malformations including one with cloacal malformation.\textsuperscript{24} A prenatal diagnosis of fatal VACTERL association, may allow the medical termination of pregnancy.\textsuperscript{25}

**WINGSPREAD, USA (1984)**

The ARM conference organized by D Stephens and Durham Smith from May 25-27, 1984 in Wingspread, Wisconsin, USA, formed a platform for the international authorities on the subject to share their experiences and suggest a universal classification.\textsuperscript{3} The emphasis then was laid on the relation of the rectal pouch to the levator muscle complex which was like a hammock. This allowed the classification of the anorectal anomalies into high, intermediate and low, depending upon if the terminal rectal pouch had crossed the levator sling or not (Fig. 78.1). Also, the surgical procedures were aimed at passing the rectal pouch through the puborectalis muscle sling, so as to reach the proposed anal site, using a perineal or a sacroperineal approach, with or without combining the same with the additional abdominal route.

**PSARP ERA: NEED FOR A NEW CLASSIFICATION**

Things changed substantially with the popularity of Posterior Sagittal Anorectoplasty (PSARP) approach.

---

**Fig. 78.1:** Classification of anorectal malformations 1984 (Wingspread Classification)
described by Alberto Pena in early 1980s, for the surgical correction of all types of the anomalies (high, intermediate and low). This approach is now practiced worldwide for its simplicity and accuracy in defining the structures by remaining strictly in the midline posteriorly.

A number of rare anomalies, not previously recognized but included in the Wingspread classification, were also reported, e.g. perineal groove, H-type of anorectal anomalies, rectal ectasia, rectal atresia and most importantly the pouch colon, mostly reported from the Indian subcontinent.

Additional associated anomalies were also reported, like the tethered cord (25% of all ARM anomalies). Consequently, there was lot of confusion regarding the nomenclature and the uniformity in the clinical diagnosis and the investigative and surgical approach for these malformations. The postoperative results were also difficult to be assessed and compared in the presence of many operative techniques being followed, despite the fact that a number of complicated scoring systems were described in the literature. A need was thus felt for new international classification and development of international standards for assessing the postoperative outcome.

**KRICKENBECK CLASSIFICATION (GERMANY, 2005)**

The Krickenbeck classification was formed during the expert group conference held in Krickenbeck, Germany from 17-20 May, 2005 (Fig. 78.2).

The goals of the Krickenbeck Conference on ARM was to develop standards for an International Classification of ARM based on a modification of the type of fistula and adding the rare and regional variants, and design a system for the comparable follow up studies incorporating all known major surgical techniques being practiced world wide.

Table 78.1 outlines the Krickenbeck classification. The lesions were classified into major clinical groups based on the fistula location (perineal, rectourethral, rectovesical, or the vestibular), cloacal lesions, those with anal stenosis and no fistula. Rare and regional variants of ARM included pouch colon, rectal atresia or stenosis, rectovaginal fistula, H-fistula and others.

The Krickenbeck classification also enabled various operative procedures used for the treatment of various types of malformations, to be more comparable to each other than with the Wingspread classification. Also it was decided that for the follow-up studies, not only the site of the fistula should be documented but also an additional grouping according to the operative procedure should be done, e.g. perineal operation, anterior sagittal approach, sacroperineal procedure, posterior sagittal anorectal plasty (PSARP), abdominosacral pull-through, abdominoperineal pull-through and laparoscopically assisted pull-through (Table 78.2).
It was emphasized that the groups should be analyzed on the basis of the associated conditions such as sacral anomalies and tethered cord. A standard method for postoperative assessment of continence was also determined as outlined in Table 78.3.

The new International diagnostic classification system, operative groupings and a method of postoperative assessment of continence was developed by consensus of a large group of experts representing all the continents and involved in the management of patients with ARM. This allowed for a common standardization of diagnosis, management and comparing the postoperative results.

The need for the change in classification was felt, as the earlier classifications did not pertain to the management options adopted. Also, the rare anomalies seen in some parts of the world especially pouch colon from South East Asia were included.2,3

**CONGENITAL POUCH COLON (CPC)**

Congenital pouch colon is a condition associated with anorectal malformation defined as an anomaly in which all or part of the colon is replaced by a pouch-like dilatation, which communicates distally with the urogenital tract via a large fistula.26-29 The mesentery of the colonic pouch of variable size (5-15 cm in diameter) is short and poorly developed, the wall is very thick, the Taenia coli are absent or ill defined, and haustration and the appendices epiploicae are absent. The main pouch is supplied by the branches arising from the superior mesenteric artery, which form a leash of vessels around it. This condition is more common in the northern India, although sporadic cases have also been reported from other parts of India, Nepal, Pakistan, Bangladesh as well as from the rest of the world.30,31

Due to the paradigm shift seen with this anomaly in the recent past in its clinical presentation, the authors had proposed a simple and practical new classification.26

1. **Incomplete CPC**: Where the length of the normal colon is adequate for performing the pull-through, without the need for doing a coloplasty. The procedure would involve excision of the pouch with an end colostomy at birth and a definitive pull-through later. A single-stage pull-through in the newborn stage can also be undertaken in experienced hands, if the condition of the baby also permits.

2. **Complete CPC**: Where there is either no or insufficient length of the normal colon left to permit a pull-through procedure. In this situation, a coloplasty procedure would be required to retain only about 15 cm length of CPC in the form of a tube, to be brought out as an end colostomy. A pull-through procedure should be attempted later and not at the time of performing coloplasty in the newborn stage, otherwise it may result in high morbidity and even mortality.

In this anomaly, all babies present with an absent anal opening. The distal communication of the pouch is in most instances with the genitourinary system. Most patients would present within the first 2-3 days of life.
The male baby presents early with anorectal agenesis and gross abdominal distension. As the fistulous communication is usually large and with the urinary bladder, the passage of gas or frank meconium per urethra is a good indicator pointing the presence of pouch colon. The association of bilious vomiting with gross abdominal distension in a case of ARM, is also strongly suggestive of CPC in endemic areas.

The female baby presents with perineal fistula in the vestibule or a common cloacal malformation. In patients with CPC and colonic perforation, the baby may present with septicemia, gross abdominal distension (pneumoperitoneum) with prominent veins, fluid and electrolyte imbalance and peritonitis.

The aim of surgery is to utilize the available length of colon for the absorptive function and storage capacity as well as for propelling the fecal matter onward with a continent anal opening. However, as the pouch musculature is abnormal, the authors prefer to excise the pouch if it is found feasible, as in cases with incomplete CPC where there is an adequate length of normal colon present.26 However, in babies with the complete CPC, an attempt is always made to do coloplasty and retain a limited length of colon (15 cm or less) and preserve its functions as much as possible. It is important that the length of the coloplasty segment should not be more than 15 cm, lest, it starts dilating and causes re-pouching, fecoloma formation and constipation in the postoperative period.

**RECTAL ATRESIA**

This entity has also been included under rare variants in the Krickenbeck classification.2 Rectal atresia is characterized by the presence of the proximal rectum, which ends at or above the pubococcygeal (PC) line, and a well-formed distal anus that is in its normal location and has a normal appearance, which is about 1-3 cm in depth. The two pouches may be connected to each other by a fibrous strand surrounded by the puborectalis sling. The anal canal and lower rectum are well surrounded by the sphincter complexes and hence the outcome after surgery is generally good.32

**Classification of Rectal Atresia**

**(Fig. 78.3)**32

- Type I: Rectal stenosis (rare)
- Type II: Rectal atresia with a septal defect
- Type III: Rectal atresia with a fibrous cord between the two atretic ends (common)
- Type IV: Rectal atresia with a gap
- Type V: Multiple rectal atresia with stenosis (A), and multiple atresia (B)

**INVESTIGATIONS FOR ARM**

There has been an improvement in the sophistication of the investigative modalities. The associated anomalies can be scanned in a reasonably short time by a careful clinical examination, abdominal ultrasonography including echocardiography, an invertogram and babygram including the chest, abdomen and spine. The cross table prone lateral invertogram is an alternative technique that can be utilized to replace the invertogram for the same purpose.

The level of the terminal bowel can also be determined by ultrasonography.33 In a recent series, the authors have used infracoccygeal transperineal USG using a 7-10-MHz linear-array transducer to determine the type of imperforate anus correctly in all cases.33
A pouch to perineal distance of less than 1 cm is suggestive of a low anomaly. The relationship of the terminal bowel to the sacrum, the urogenital organs and the surface can thus be visualized. Sensitivity of inzertography performed in 22 patients was only 27% with a mean error of measurement of 0.84 cm, and the difference between measurements and real distance was statistically significant. While the sensitivity of perineal USG (22 children) was 86% (mean error 0.12 cm) and with no significant difference between measurements and the intraoperative findings (p > 0.001). This study reported that perineal US was extremely useful in the newborn period and provided reliable information on which the decision can be based for either preliminary colostomy or a definitive operation.

The high distal colostogram is a very useful tool to delineate the anatomy prior to definitive surgery. It has recently been recognized that there is a close relationship between spinal cord tethering (SCT) and congenital anorectal malformation (ARM). Pena has advocated the use of spinal ultrasound in babies less than 3 months age to detect a tethered cord. The incidence may be as high as 25% in children with ARM. Spiral computed tomography with three-dimensional reconstruction of the pelvic musculature, or magnetic resonance imaging of the pelvis are optional for studying the pelvic musculature.

Whether any surgical treatment in the form of prophylactic detethering is needed, remained a controversial issue. Some authors recommend routine MRI of patients with ARM and early untethering surgery in children with the spinal cord tethering. However, most surgeons including the authors are of the opinion that such children should be kept under observation and treated surgically only if the symptoms appear due to tethered cord, e.g. Weakness of legs, recurrent urinary tract infection, loss of control over the bladder and bowel, in-ordination of leg movements. Surgery would however, be indicated if associated anomalies like diastematomyelia with or without a bony spur, dermoid cyst, diplomyelia, syringomyelia, anterior meningocoele co-exist or else if the parents insist for the surgery. The surgery should be performed by the specialists in the field and the risks, if any should be explained to the parents beforehand.

MANAGEMENT OF ARM

The surgical approach using PSARP allowed surgeons to view the anatomy of these defects clearly, repair them under direct vision, and learn about the complex anatomic arrangement of the junction of rectum and genitourinary tract.

The main concerns in correcting these anomalies for the surgeon today remain the bowel control, urinary control and the sexual function. Adherence to specific principles in technique can prevent a large number of the postoperative complications.

Repair in the Neonatal Age

Moore has recommended operative repair within the first 7 days without a prior colostomy because the anocortical neurocircuitry pathways develop in the perinatal period or within first few days after birth. If act of defaecation is not initiated soon after birth by doing a primary repair, the advantage is lost.

There is now a declining trend for performing a colostomy in cases with ARM. It is being avoided wherever feasible to reduce the number of surgical procedures and also the nuisance to the patient and the parents. However, the risks involved must be weighed with the benefits expected. The neonatal single stage posterior sagital anorectoplasty (PSARP) is a significant change in the management of anorectal malformations in the recent past. This can be done safely both in males and females with or without a fistula. It is possible to perform a pull through operation even in the premature babies in the neonatal age, but should be done only by the experienced surgeons and under good anesthesia cover in the neonatal ICU setup. It is expected that these babies are likely to have better continence due to development of efficient nerve pathways from birth itself. Many surgeons today are routinely performing a single stage primary repair especially in females with a vestibular anus.

Laparoscopic Assisted Anorectal Pull-through

Introduction of laparoscopic assisted anorectal pull through (LAARP) for high imperforate anus by Georgeson et al in 2000 has opened a new alternative for repair of high imperforate anus, with the possible advantage that the rectum can be placed in the center
of sphincters without any midline surgical division. In LAARP performed in 11 patients of high ARM, seven patients (1 girl and 6 boys) underwent divided sigmoid colostomy at birth and 4 boys underwent primary LAARP without colostomy.41

**Laparoscopic Technique**

With a sharp and diathermy dissection, the rectal pouch is exposed laparoscopically, down to the urethral or vaginal fistula. The fistula is then clipped at two places and divided in between. The pelvic floor musculature is then assessed and the levator sling identified. Externally, an electrostimulation is used to define the center of the anal dimple. An 8 mm skin incision is made, centered at the strongest cephalad contraction. Using a minimal blunt dissection on the perineum, a hemostat is guided by transillumination from the laparoscopic light source. A trocar, consisting of a radially expandable sheath over a Varess needle, is passed through this defined plane in the external sphincter muscle complex and advanced into the pelvis between the 2 bellies of the pubococcygeus muscle guided by the laparoscopic visualization. This perineal trocar therefore formed a passage through the center of the striated muscle complex and the levators. The rectal pouch, which had been dissected out laparoscopically, is now grasped using the perineal trocar and exteriorized to the perineum. Anorectal anastomosis is performed with absorbable interrupted suture. In this series, all the patients had a brisk and symmetrical anal contraction with perineal electrostimulation.

Yamataka et al also reported the use of endosonographic probe to enhance the accuracy of positioning of rectum in the muscle complex during the laparoscopic pull through.43 Endosonographic probe was inserted into the proposed route of dissection in the muscle complex, and utilized to measure the thickness of surrounding muscle. With this, it is possible to make an immediate assessment of the symmetrical distribution of muscle complex just before the completion of the actual pull-through.

Thus, laparoscopic pull-through offers the advantages of minimal invasion, dissection of fistula, under vision deep in the pelvis, with laparoscopic magnification, placement of rectum in the center of the muscle complex without actually dividing the muscle complex. However, follow-up studies regarding the quality of continence achieved following this technique are awaited.

Kubota et al, reported the initial experience with the use of a combination of laparoscopic dissection, pinpointing the center of anal sphincter by electrostimulation and identification of the urethra by using ultrasonographic images from the perineum, to facilitate the creation of an appropriate pull through canal in the muscle complex.44 However, only a limited expertise is available with this technique at present.

**CONTINENCE**

Using the PSARP approach, the reported results of continence have improved markedly worldwide, as has been outlined in Table 78.3. The fecal and urinary incontinence can occur even with an excellent anatomic repair, due mainly to associated problems such as a poorly developed muscle complex, deficient sacrum (specially if more than 3 pieces are missing), deficient nerve supply, and spinal cord anomalies. For these patients, an effective bowel management program, including enema and dietary restrictions has been devised to improve the quality of life.37 The bowel management program has been discussed in a separate chapter.

Artificial bowel sphincter is not popular in children and has however, been used successfully in 2 patients with anorectal malformation with fecal incontinence.45

**RESEARCH IN ANORECTAL MALFORMATIONS**

An experimental model for anorectal anomalies has been induced by ethylene thiourea (ETU), in fetuses...
REFERENCES

Rectal Ectasia is defined as a state of massive focal dilation of the rectum and sigmoid colon due to primary muscle defect or a secondary response to obstructive anorectal condition. Rectal ectasia may thus be occasionally encountered either as a separate entity or associated with anorectal anomalies. Ectasia should thus be suspected not only in all patients with chronic constipation but also in association with anorectal malformation.

Various terminologies that have been used in the past to describe this entity include; balloon like rectum, colonic inertia, megarectum, terminal fecal reservoir syndrome, congenital funnel anus, pseudo-Hirschsprung’s disease and rectal inertia.

**CLASSIFICATION**

Rectal Ectasia can be broadly classified into two types based on the etiology.

A. *Primary rectal ectasia*: This is congenital in origin with no known cause for the ectasia. It may occasionally be due to midanal sphincter defect or the deficiency of the rectal musculature. However, 2-5% cases of anorectal malformations may present with congenital rectal ectasia.

B. *Secondary rectal ectasia*: This develops after birth, usually as a result of distal obstruction, secondary to fecal impaction or surgery at the anorectum. Postoperative anal stricture after an otherwise good surgical repair of anorectal malformation may also result in rectal ectasia. The dilatation of the ectatic rectum will depend on the degree and duration of the obstruction. The presence of fecoloma in the rectum initiates a vicious cycle and worsen the dilatation further.

**EMBRYOLOGY AND PATHOPHYSIOLOGY**

Various theories have been proposed to explain the development of primary rectal ectasia.

1. The cloaca that is divided by the urorectal septum into urinary and rectal passages may be initially more voluminous than normal before partition in cases of anorectal malformation with consequent oversized passage or passages after partition.
2. The rectum is normally modelled into two ampullae, one in midrectum that becomes the mature rectum and one in the region of the future anal canal. Primary rectal ectasia occurring in association with anorectal anomalies may be an example of developmental overgrowth of the upper or lower primitive ampullae or both.
3. The temporary tail gut, an extension of the undivided cloaca is initially quite voluminous, but becomes atrophic and disappears before partition of the cloaca is complete. Incorporation and persistence of part of the tail gut into the rectum may result in anorectal ectasia.
4. It may be a variant of segmental dilatation of the intestine that is a well-known cause of obstruction.
5. Primary hypomotility of distal rectum has been proposed.
6. Weakness of the posterior rectal wall or defect in the external anal sphincter. The authors have found a primary deficiency of the musculature of the posterior rectal wall and the external anal sphincter, resulting in rectal inertia followed by rectal ectasia. This explains the clinically and radiologically evident posterior rectal shelf in few cases of primary rectal ectasia. A mid-sphincteric defect as the possible cause of constipation in anterior perineal anus has also been suggested.
Rectal Ectasia

The primary pathology in the causation of primary rectal ectasia is deficiency in the smooth muscle wall causing weakening and dilatation of rectal wall. Secondary rectal ectasia develops as a result of outflow obstruction. Elasticity of the rectal wall permits the normal rectum to expand to approximately double the caliber but it returns to its normal size. In the newborns, ectasia beyond this diameter is predictive of a primary developmental ectasia. If the rectal ampulla is developmentally ectatic, the dilation may persist and lead postoperatively to fecal accumulations, further enlargement, troublesome constipation, and soiling. Hypertrophy and dilation may occur as a result of propulsive activity against an obstruction or upon a retained meconium bolus in the terminus of the bowel after a defunctioning colostomy. On histological background primary and secondary rectal ectasia can be differentiated by examining rectal specimens—hypertrophy and hyperplasia of smooth muscle cells in acquired cases, normal or smaller size in newborns indicating primary or developmental anomaly. Dysplastic nitrergic neurons in the rectum of a patient with rectal ectasia have also been demonstrated.

The ectatic bowel has been reported to show a proliferation of nerve fibers in keeping with the degree of circular smooth muscle hypertrophy, thus representing a reactive phenomenon secondary to the functional obstruction. Rectal ectasia may also present in adults as a result of a neuropathic process as an underlying mechanism.

**CLINICAL PRESENTATION**

Rectal ectasia usually presents with refractory constipation either primarily or persistent constipation after a reconstructive surgery for a known cause of obstruction usually anorectal malformation. The patients usually present after 6 months of age, the most common period being around 1-3 years. However, secondary rectal ectasia may present in adults also Rectal ectasia may or may not be associated with megasigmoid colon. Paradoxical diarrhea may occur due to peristalsis pushing the feces against the puborectalis sling and levator diaphragm. These muscles fatigue, relax, and temporarily lose the important sphincter functions that control the entrance to the rectoanal canal. Soft feces are then propelled by peristalsis over the fecal masses to escape constantly from the anus called “hold back-dyschesia cycle or pseudo-incontinence” inspite of good surgery.

Paradoxical diarrhea and incontinence resulting from anatomically defective sphincters must be differentiated by rectal examination. Digital palpation of strongly contracting sphincters of the anal canal or satisfactory pressure profiles in the anal canal indicates that the leakage is more likely to be paradoxical. The proximal ectatic bowel remains large and dilated even after a defunctioning colostomy.

Adults diagnosed as rectal ectasia are usually symptomatic since childhood with the most common symptom being soiling and impaction. A per rectal examination is essential in all cases. This may be repeated after cleaning the rectum with repeated enemas for better defining the anatomy and feeling the sphincter complex.

**Posterior Rectal Shelf**

This entity can be well appreciated if looked for with suspicion in any case of unexplained constipation. It may be picked up on a barium enema or on per rectal examination (Fig. 79.1). The posterior rectal shelf is ballooning of the rectum only posteriorly in which the finger in the rectum can be brought very close to the

![Fig. 79.1: Contrast study delineating the posterior rectal shelf](https://mebooksfree.com)
perineum with very less intervening tissue. Typically, the child presents with chronic constipation, straining at stool and ability to pass small amount of hard fecal matter by rubbing the bottom against the floor/toilet seat. A posterior shelf on barium study requires careful evaluation for the mid-sphincteric and rectal wall defects.

INVESTIGATIONS

The most useful investigation is barium enema. However, it is difficult to distinguish between primary and secondary rectal ectasia unless there is a history of previous surgery or anal stenosis or an anal stricture. Contrast study may delineate the dilated rectum with or without a posterior rectal shelf (Fig. 79.1).

Manometry will usually show a normal rectoanal inhibitory reflex unlike in patients with Hirschsprung’s disease.

On rectometrographic studies, the elasticity coefficient of the rectal wall has been reported as decreased in patients of rectal ectasia as compared to controls ($P$ less than 0.01). The colonic transit time may show rectosigmoid stagnation. Rectal pressure was similar at the level of conscious sensation of filling, regardless of rectal capacity, suggesting a motor, rather than a sensory, abnormality. The amplitude of the rectoanal inhibitory reflex has been reported as decreased ($P$ less than 0.001) as compared to controls in a series, thus sometimes mimicking the findings of Hirschsprung’s disease, but increasing rectal distension always induced a relaxation of the internal anal sphincter. The megarectum in rectal ectasia thus tolerates large amounts of fluid without sensation and lacks elasticity.

Persisting ectasia in infancy when associated with anorectal malformation can be demonstrated by distal cologram (Fig. 79.2).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes habitual constipation, ultrashort segment Hirschsprung’s disease and Pouch colon syndrome. Rectal punch or suction biopsy should be performed to rule out Hirschsprung’s disease in suspected cases. Segmental dilatation of the colon that also causes chronic constipation in children is also an important differential diagnosis. Sigmoid volvulus is a reported complication of segmental dilatation of the colon.

TREATMENT

An effective medical therapy would be helpful in the majority; however, surgery may be needed if the ectasia is too much and for too long in which the symptoms are not likely to improve with the conservative medical management. The initial treatment depends on the consistency of the stool as judged by digital examination.

Medical Management

Medical management is indicated only in those cases where no inciting factor can be identified. The principles of medical management are to keep the bowel clean till the ectatic segment reduces to its original size. This is done with dietary modifications, laxatives and if the need arises then enemas and manual evacuation. Bulk forming agents are given. Constipating agents are to be avoided. Fecaliths may need digital disintegration and saline washouts. Toilet training is an essential component of the medical management. The child is trained to attend to the toilet everyday at a fixed time and spend enough time till he is successful in evacuating the bowel by using his abdominal muscles additionally. Medication in adequate amounts is needed to maintain a suitable stool consistency. While the rectal ectasia persists, relapses are prone to occur, necessitating vigilance and even repeating the local bowel toilet regimen.
A minimum trial with medical management of 6 months duration should be given under continuous supervision before resorting to surgical options. Patients with associated huge megacolon, with consequent constipation are usually refractory to conservative treatment.  

**Surgical Treatment**

The surgical management depends on the primary pathology and is considered only if the medical management fails. The main principle is to excise or plicate the redundant bowel to prevent postoperative incontinence or constipation. Resection or tailoring of the ectatic segment should be done during primary reconstructive procedure if rectal ectasia is recognized peroperatively in association with anomalies like anorectal malformation or anal stenosis. The large bulk of the walls of the intact wide rectum may impair the reconstruction of the sphincter muscles at the time of the anorectoplasty, thus lessening the ultimate degree of continence.  

Figure 79.3 shows the operative photograph of a case of rectal ectasia.  

If a prominent posterior shelf is identified, a rectal wall plication may be done with effective results. A mid-sphincteric defect, if detected on surgical dissection can be repaired in layers. Various techniques have been used for treating rectal ectasia:  

1. Posterior sagittal route tailoring. Tapering of the dilated segment of rectum through posterior sagittal route has also been a preferred method with desirable results.  
2. Endorectal pull-through. Resection of the abnormal bowel by an endorectal pull-through has been reported to give good to excellent results.  
3. Swenson’s pull-through.  
4. Duhamel’s pull-through has also been tried in few cases with good postoperative results.  
5. Plication of the dilated segment through posterior sagittal route. The authors prefer this method as it has less morbidity, preserves the sphincter complex, pelvic nerve plexus is not disturbed, strengthens the deficient rectal muscle and has been found to produce good postoperative results.  
6. Anterior resection. This is indicated for patients with hugely dilated rectum, not amenable to evacuation and medical management. Excision of the dilated bowel is done and the normal sized bowel is anastomosed to the distal rectum at the peritoneal reflection.  
7. Resection of an ectatic sigmoid segment with colorectal anastomosis has been done with good postoperative outcome (Fig. 79.4). Resection of the terminal bowel may be done up to the dentate line when associated with low anorectal malformation. If rectal ectasia is not recognized at the time of surgical reconstruction it may lead to megarectosigmoid, resulting in severe constipation and overflow incontinence postoperatively.  
8. Sphincteromyectomy and-plasty. An incision is placed on the dentate line at 6 o’clock and the internal sphincter muscle is identified. The
incision is extended to this muscle and blunt dissection is done between the internal and external sphincter muscles advanced cranially 5 cm from the dentate line. All layers of anus and lower part of rectum upto 5 cm are clamped 1 cm apart. The mucosal and muscular layers are then divided for the 1 cm strip. The rectum at the proximal end of the strip is pulled through to the dentate line and anastomosed thus forming the posterior part of the anus.

9. Vertical reduction rectoplasty (VRR) has also been found to be beneficial in correcting rectal diameter, compliance and sensory function in most patients with rectal ectasia. It has been reported to have low morbidity.

10. Formation of a J pouch has also been described to treat patients with rectal ectasia associated with megasigmoid.

PROGNOSIS

The prognosis of primary rectal ectasia is usually good if diagnosed appropriately and well in time. The prognosis of cases with secondary rectal ectasia depends upon the etiological factor responsible for the ectasia and its management. In cases with associated megacolon, resection of the dilated part of the colon and low coloanal anastomosis has been reported to relieve the severe constipation in all cases.

REFERENCES

Fecal incontinence and constipation are common chronic problems affecting the pediatric surgical population. Constipation accounts for 3% of all pediatric outpatients visits. It may be a manifestation of an underlying medical or surgical disorder although can be acquired as a functional problem in infancy, childhood and adolescence. Almost 95% of all cases of childhood constipation are idiopathic in etiology. Fecal incontinence is a socially embarrassing condition. The child and parents often deny the problem and therefore the true incidence is underestimated. Disturbed defecation patterns often have a disruptive influence on family life. Most conditions leading to fecal incontinence in children are congenital in origin and present during the early crucial years of life interfering with the child’s social and educational development. Even in Western societies with improved support structures, incontinent patients attain significantly lower educational levels than the normal population. Many patients experience double incontinence (fecal and urinary incontinence) so there is a need to develop comprehensive support services in pediatric surgical centers to cater for children with this severe disability. Greater understanding of the long-term outcome of congenital colorectal malformations may also lead to improved care pathways for successful management.

NORMAL ANATOMY AND PHYSIOLOGY

Fecal continence is an individual’s ability to perceive rectal distension, distinguish between solid, liquid and gas content and achieve evacuation in a socially acceptable environment. This is achieved through the presence of normal anorectal anatomy and physiology. Knowledge of normal mechanisms promoting continence is crucial to understand and manage fecal incontinence and constipation effectively.

ANATOMY

The rectum is normally empty and acts as a reservoir. It joins the anal canal at the level of the levator ani muscle. The puborectalis muscle slings around the anorectal junction and forms an angle of approximately 90 degrees at rest and helps maintain continence during periods of raised intra-abdominal pressure as encountered during coughing and sneezing episodes. The circular smooth muscle layer continues as the internal anal sphincter and is in a tonically contracted state. The external anal sphincter is a striated muscle, which along with the puborectalis forms an important voluntary continence mechanism (Fig. 80.1).
PHYSIOLOGY

Physiology of fecal continence depends on:
1. Normal rectal sensation which perceives stretching on rectal distension. It triggers the rectoanal inhibitory reflex which promotes the reflex relaxation of the internal anal sphincter.
2. Normal anal sensation which differentiates between solid, liquid and gas contents.
3. Voluntary contraction of the puborectalis and external anal sphincter (innervated by the pudendal nerves) which inhibits defecation under socially inappropriate circumstances.
4. Intact internal sphincter tone (controlled by sympathetic and parasympathetic fibers), which prevents soiling. Its rhythmic relaxation allows sampling which helps differentiate between solid and fluid matter.

NORMAL DEFECATION

Normal defecation depends on the ability of the colon to deliver feces to the rectum. The colon has 2 types of physiological contractions: (a) the segmental non-propagated contractions that allow mixing and (b) high amplitude propagated contractions (HAPC) that empty the colon contents into the rectum. There are 2 main stimulants of HAPC: (i) awakening from sleep and (ii) ingestion of meals (gastrocolic reflex). These contractions by distending the rectum with feces initiate the rectoanal inhibitory reflex leading to relaxation of the internal anal sphincter. This allows sampling by the sensitive anal mucosa that differentiates between fluid and feces. This is perceived at cortical level leading to the desire to defecate and depending upon whether the circumstances are socially convenient, defecation is either facilitated or the desire to defecate over-ridden. If socially convenient the rectum contracts with complete relaxation of both internal and external anal sphincters resulting in stool evacuation. However, if over-ridden, the puborectalis and the external anal sphincter contracts inhibiting defecation.

DEFINITIONS

Incontinence is defined as the involuntary passage of stools in a socially inappropriate environment. It is usually due to deficient neural or muscular control of the anorectal sphincter mechanism.

Constipation is more difficult to define and definition varies according to person, age, and culture. Since defecation patterns vary widely among children, it is almost impossible to give a single definition that is acceptable and applicable to all. The infrequent and difficult evacuation of hard stools less than 3 times per week is a useful criteria. Though fecal incontinence is easier to define, grading is more difficult. Soiling, smearing and accidents are various terms used to define degrees of incontinence but there is no universally agreed definition for these terms. This makes comparison and evaluation of various treatments for fecal incontinence and constipation difficult. Constipation and incontinence can occur alone or they can coexist in same individual. Broad management strategies for treating these entities are similar therefore they may be classified together based on etiology (Table 80.1).

| Table 80.1: Classification of constipation and fecal incontinence based on etiology |
|----------------------------------|----------------------------------|
| **Idiopathic functional constipation** |
| Idiopathic fecal incontinence |

Motility disorders
- Functional gastrointestinal dysmotility of prematurity
- Slow transit constipation

Medical disorders
- Cow’s milk protein allergy
- Endocrine disorders such as hypothyroidism, hyperparathyroidism
- Drugs, e.g. opiates, vinca alkaloids
- Cystic fibrosis
- Generalised hypotonic disorders, e.g. Down’s syndrome

Surgical disorders congenital
- Anorectal malformations (ARM)
- Hirschsprung’s disease and allied neuropathies such as neuronal intestinal dysplasia (NID), hypoganglionosis
- Myelodysplasia
- Mechanical obstruction due to duplication cyst or pelvic masses, e.g. sacrococcygeal tumor type IV

Acquired
- Anal fissure
- Operative trauma following anorectal surgery, e.g. for Hirschsprung’s disease, sacrococcygeal tumor
- Colorectal strictures, e.g. secondary to necrotising enterocolitis (NEC) or inflammatory bowel disease (IBD)
- Spinal trauma and direct trauma to the anorectal region
HISTORY AND CLINICAL EXAMINATION

Thorough history regarding time of onset, severity, progression and response to treatment is very helpful in suggesting a diagnosis. Time of passage of meconium is essential as 94% of full-term neonates and 76% of preterm babies pass meconium within 24 hrs of life and failure to do so is highly suggestive but not diagnostic of HD. Gestational age at birth is important as premature babies are slow to open their bowels. A history of onset of constipation after the first month of life makes a diagnosis of Hirschsprung’s disease unlikely. Associated urinary symptoms should be recorded and may suggest deficient neurological control. The onset of constipation may coincide with weaning or change in diet. Dietary history and medications should be reviewed. Clinical examination of the abdomen, spine and perineum is important. The abdominal findings give information on the degree of fecal loading. Examination of the spine may detect spina bifida occulta. Inspection of the perineum provides useful knowledge about the development of the anorectal muscle complex in ARM patients, as a flat perineum is associated with poor sphincters. Subtle anorectal malformations such as anal stenosis, anterior perineal anus may be detected which are important causes of constipation. A digital rectal examination is not mandatory. However, when performed may provide information regarding sphincter tone. An explosive bowel action after withdrawal of the finger may suggest Hirschsprung’s disease.

INVESTIGATIONS

The investigative protocol is shown in Table 80.2.

Biochemical Examination

Hypocalcemia and hypothyroidism may lead to constipation. Thyroid function tests and serum calcium are part of the investigative protocol for constipation in newborns. In babies with delayed passage of meconium, gene probe analysis should be performed to rule out cystic fibrosis, which is especially common in Caucasian populations.

Radiology

Abdominal X-ray: It may demonstrate the degree of fecal loading (Fig. 80.2). In those patients with severe fecal impaction it may guide the first line of management, e.g. manual evacuation. Spinal anomalies may also be readily apparent.

Colon transit studies: Transit time is closely related to defecation frequency. In 1-3 month old babies transit time from mouth to anus is approximately 8 hours, by 2 years it is 16 hours and in school age children ranges from 26-36 hours. The study involves ingestion of ten radio-opaque beads daily for 6 consecutive days and an abdominal X-ray is performed on day seven (Fig. 80.3). This investigation helps to differentiate pancolonic dysmotility (colonic inertia) and evacuation obstruction by the pattern of bead distribution. In colonic inertia, e.g. pancolonic dysmotility “scattered beads” are apparent on the X-ray study whereas in evacuation disorders where there is delayed transit principally in the descending and rectosigmoid regions ”beads” are confined to the left colon/rectum.
**Contrast enema:** Contrast studies can prove diagnostic in conditions such as Hirschsprung’s disease. It provides information about the degree of fecal impaction and recto sigmoid dilatation in patients with constipation, which can aid in planning treatment, e.g. bowel resection, ACE procedure.

*Rectal biopsy:* A suction rectal biopsy is carried out in infants with suspicion of HD, whereas in older children a formal full thickness rectal biopsy is indicated. Though full thickness biopsy is the gold standard, the advantage of suction biopsy is that it does not require general anesthesia. The specimen must be deep enough to contain submucosal tissue and should be taken from an area at least 2-3 cm above the dentate line to avoid the normal hypoganglionic region. The absence of ganglion cells along with the presence of numerous thickened acetylcholinesterase positive nerve fibers is diagnostic of HD. Other features that may be seen on rectal biopsy are hypoganglionosis, giant ganglia, etc. Laparoscopy may also be utilised to obtain serial biopsies from the colon, rectum and small bowel.

**Anorectal Manometry**

Manometry is a useful adjunct in the investigative protocol for constipation and incontinence. It can suggest the diagnosis of HD by the absence of the rectoanal inhibitory reflex in older children (Fig. 80.4).
It is not reliable in newborns. It can be performed at the outpatient department and involves placement of a transducer probe in the anal canal and an inflatable balloon in the rectum. The balloon is inflated to distend the rectum and initiate the rectoanal inhibitory reflex. Normally, distension of the rectum by balloon inflation causes relaxation of the internal anal sphincter. The transducer probe detects the basal tone of the internal sphincter and records the decrease in tone when the rectoanal reflex causes the sphincter to relax (Fig. 80.5). It may also note paradoxical contractions during defecation, which are found in a group of children with delayed transit due to rectosigmoid colonic dysmotility (evacuation obstruction).

**MRI Anorectal Region**

MRI of the anorectal region is a good modality to evaluate the development of the sphincter muscle complex. In patients who have had previous anorectal reconstruction it can provide information about the anatomy of the “pull through bowel” in relation to the muscle complex.

MRI of the spinal cord MRI demonstrates the extent of cord involvement in patients with spina bifida and also in patients with spinal tumor and spinal injury. In individuals with anorectal malformation (both high and low) it can detect associated tethered cord, which may be a further cause of constipation/incontinence. Golonka et al report an incidence of tethered cord in 26.8% of high ARM anomalies and 50% of low malformations.

**TREATMENT**

Treatment of the underlying medical cause where identifiable such as hypothyroidism or hyperparathyroidism should be undertaken.

The therapeutic options available are given in Table 80.3.

---

**Fig. 80.5:** Normal manometry trace demonstrating lowering of internal sphincter tone (arrow indicates fall in pressure in anal canal) on rectal distention
Table 80.3: Therapeutic strategies in the management of chronic constipation and fecal incontinence

### Medical treatment
- Dietary manipulation
- Laxatives suppositories
- Enemas
- Prokinetic agents (e.g. Cisapride)
- Bowel training program
- Biofeedback
- Anal plug
- Botulinum toxin injection (internal sphincter achalasia)²³

### Surgery
- Manual evacuation
- Antegrade continence enema (ACE)
- Colon resection (partial or total)
- Diverting stomas (permanent or temporary)
- Anorectal myectomy (Hirschsprung’s disease, internal sphincter achalasia)²⁴
- Artificial sphincter
- Gracilus neosphincter

**MEDICAL MANAGEMENT**

### Constipation

Aggressive medical management is the mainstay of treatment for constipation and fecal incontinence. The main aim is to ensure regular bowel emptying to evacuate the rectum and prevent fecolith formation. Though first line treatments may entail dietary manipulation, it is unclear if this is as effective in children as in adult practice.²⁰ Measures adopted include increased fiber intake and regular fluid intake. Recently cow’s milk protein allergy has been shown to be an important cause of constipation.²¹ An aggressive laxative regime provides the next option and a combination of various osmotic, stimulant and bulk laxatives are commenced depending on the obstinacy of constipation. Doses can be modified according to response. The type of laxative(s) utilised are varied and include bulk-forming agents (e.g. isphaghulla husk), stimulant laxatives (e.g. bisacodyl, docusate, senna or sodium picosulphate). Fecal softeners (e.g. liquid paraffin, olive oil) or osmotic laxatives (e.g. lactulose, polyethylene glycol) are useful. The key to the success of medical management is adequate parental counseling. This enables the carers to understand the mechanisms involved, the goals of treatment and the importance of active participation as well as expectations of the time scale involved to achieve satisfactory outcomes. The aims are to ensure regular bowel emptying to reduce fecaloma formation. In refractory cases of constipation (fecalomas and soiling), manual evacuation of the bowel is generally recommended prior to commencing laxative therapy. Manual evacuation not only disimpacts the megarectum, it also achieves temporary dilatation of the anal sphincter. Thus by breaking the vicious cycle of painful defecation and sphincter spasm may permit anal fissure(s), if present, to heal. These measures may cure up to 50% of children.¹ Other children will need further evaluation and investigations. Some patients require regular enemas or suppositories on a long-term basis to aid regular evacuation. Cisapride, a prokinetic agent has been shown also to benefit selected cases.²² Botulinum toxin is an option in the treatment of chronic constipation due to internal sphincter achalasia as an alternative to internal sphincterotomy that was used for post-operative cases of Hirschspring’s disease having constipation.²³,²⁴

### Fecal Incontinence

Fecal incontinence is due to inadequate neuromuscular control or may be seen in association with ‘overflow’ states in children with severe constipation. While appropriate management of constipation can control fecal incontinence due to constipation and ‘overflow’, problems due to deficient neuromuscular control are more difficult to manage and require long-term care and support. Normal continence is rarely achieved with treatment and the aim is to promote social continence. If the bowel can be emptied adequately and regularly at socially convenient intervals then a reasonable degree of continence can be achieved. Various methods used to attain these goals include regular suppositories, daily bowel washouts and/or enemas. In patients with gross incontinence constipating agents such as loperamide (imodium) may be of use. Biofeedback is another option before contemplating surgery.

Biofeedback training is a technique, which can be used as an adjunct to other measures to control incontinence.²⁵ It is based on the principle of learning through reinforcement using the patient’s ability to control bodily functions. An air filled manometric anal probe is attached to a color monitor and the amplitude and duration of voluntary anal sphincter contractions
are assessed and demonstrated to the patient. Visual feedback cues are provided to demonstrate how the muscles work and the children are then taught to identify sphincter contractions from gluteal and abdominal effort (e.g. valsala maneuver) and to perform sphincter exercises during the sessions and while at home. The overall aim is to enhance the child’s understanding of their condition and to promote the individual’s sense of control and self-esteem.

**SURGICAL MANAGEMENT**

**Antegrade Continence Enema (ACE)**

The formation of a continent stoma to perform antegrade colonic enemas (ACE) has been an important development in the management of children/adolescents with troublesome constipation and fecal incontinence. The procedure was first reported in 1990 by Malone et al.26 The ACE is based on the principle of administration of a large volume enema via an appendicostomy stoma.27 It works on the basis of the Mitrofanoff principle. Though originally described for patients with incontinence, its use has been extended to children with intractable functional constipation/soiling where it may be of some benefit. Stoma reversal can be performed in some patients when normal bowel motility has been restored.

**Procedure:** Though originally described as an appendico-cecostomy by reversing and reimplanting the appendix in a submucosal cecal tunnel thereby creating a continent stoma; pediatric surgeons now perform a simple orthotopic appendicostomy by imbricating the cecum with a series of sutures around the base of the appendix (optional) creating a similar continent channel. We employ a mini-abdominal incision below the “bikini line” and prefer to site the stoma in the right iliac fossa. Other surgeons prefer to site the stoma at the umbilicus. The stoma is fashioned by means of a broad based lateral skin flap that is tubularized and sutured to the mouth of the appendix hence burying the appendix and reducing skin discharge.

Various modifications have been reported to prevent stomal complications.28 The procedure has also been performed laparoscopically.29 If appendix is not available (e.g. previous appendicetomy or utilized for a Mitrofanoff) tubularized cecum, ileum, or ureter can be employed.28 Recently a button device has been described.30 Based on the principle of percutaneous endoscopic gastrostomy (PEG), a cecostomy catheter can be inserted percutaneously with the aid of a colonoscope.31 If large volumes of enema are needed to achieve effective “washouts” particularly in patients with a large redundant sigmoid colon a modified left continent colonic ACE (sigmoid ACE) can be created to permit effective evacuation of the distal colon.32

An indwelling catheter is left in situ for 2-3 weeks to permit the stoma to mature and washouts can be started on the fourth postoperative day. Washout regimes include use of normal saline or tap water with one teaspoon of salt per 0.5 liters (volume varying from 100 to 1000 ml), given using an IV administration set while the child sits on the toilet. Each patient develops his or her own individual regimen by a process of trial and error. Most regimes employ a phosphate enema followed by a saline washout at 24, 48 or 72 hourly intervals. The technique of catheterization is easy and more acceptable to the child than retrograde enemas. On average it takes about 30 minutes every other day to ensure regular bowel emptying. Children can opt for an indwelling catheter or a button device in preference to regular intermittent self-catheterization. Crucial to good outcomes is appropriate patient selection and involvement of a nurse specialist who provides counseling and support for the child and family. Caution should be exercised when contemplating the ACE in young children. We rarely offer the procedure in those less than 5 years, as cooperation is required to achieve regular catheterization. The younger child may also fail to comprehend the intended benefits of the operation. Inadequate colonic washouts, stomal complications including stenosis, fecal and flatus problems are reported with this procedure.33 Hyperphosphatemia has been described with use of phosphate enemas in young children.34 Good functional outcomes are best achieved in those patients with adequate bowel motility and a degree of sphincter function.35

**Colonic Resection**

Partial or total colonic resection is performed in intractable cases of constipation who do not respond to maximal medical therapy or the ACE operation. The extent of resection may be guided by contrast studies...
specific pediatric surgical problems presenting with constipation and fecal incontinence are discussed here to provide a better perspective on individualized management.

**ANORECTAL MALFORMATIONS**

The principles of management of anorectal malformations are to surgically correct the anomaly keeping in mind that continence is influenced by neural (absent sacrum, deficient sacrum) and muscular development at birth. Surgery is integral to good outcomes and special expertise is mandatory to achieve such results. Most patients with imperforate anus do not have normal anal sensation and also have impaired rectal sensation as well as altered colonic motility. They are not able to recognize liquid stool content and rectal distension adequately. Continence is never normal in these patients. Control is dependent on the extent of sphincter muscle development present at birth. Rectosigmoid motility is altered in patients with anorectal malformations and constipation is common. Pena considers abnormal rectosigmoid motility the most important single factor influencing bowel control and continence. Ensuring daily regular bowel emptying should ensure many patients remain "clean" even if they have inadequate sphincters. Patients with low anomalies have a tendency to constipation and soiling. Those with high or intermediate anomalies experience incontinence, soiling and/or constipation. Management begins at the time of colostomy formation where the two stomas should be sited with an adequate gap to prevent spillage of bowel content into the distal rectum thus ensuring it is kept empty and narrow in caliber. Washouts should also be given periodically to empty the defunctioned rectum. An anal dilatation program to prevent stenosis of the neoanus should follow the "pull through". Following colostomy closure, vigilant
follow-up is required to assess the adequacy of bowel emptying. If emptying is not adequate or the child has developed incontinence a bowel management program should be initiated with the aim of emptying the rectum and distal colon daily so that soiling is minimized. A good laxative program should be commenced where constipation is a major problem. Regular emptying is achieved by use of suppositories, enemas or high colonic washouts. If colonic transit is fast, a combination of the above regimes with constipating agents like loperamide may be useful. The bowel management program needs to be individualized for each patient. If retrograde enemas are not having good results then formation of an ACE stoma should be considered. Those patients with severe constipation where a contrast enema study shows severe segmental dilatation of the rectosigmoid, should be considered candidates for megasigmoid resection. A "redo" pull through may be considered if the MRI suggests that the rectum has not been positioned adequately in relation to the sphincter complex. However, outcomes following "redo" PSARP are not good.43

A further important group of patients are those with "pouch" colon where there is usually no rectosigmoid and thus reservoir function is lost. The colon is like a cesspool. These children have increased frequency of stools due to lack of colonic absorption capacity. They are difficult to manage. The response to bowel management programs is not good. A permanent stoma may be an option in these patients. Graciloplasty may be considered in grossly incontinent patients although pediatric experience is limited. Aids like the anal plug (based on tampon principle) are also useful in achieving improved quality of life.44 These are easy to use and offer useful control for short periods of time.

**MYELODYSPLASIA**

Spina bifida patients are characterized by inadequate voluntary sphincter function and poor anorectal sensation. Colonic motility is also disturbed.45 Urinary incontinence is also variable. Bowel function depends upon the level of the spinal lesion. Patients with high lesions (thoracic or thoracolumbar) have slow colonic motility and absent anorectal sensation with loss of voluntary sphincters and internal sphincter dysfunction. These patients are prone to fecal loading and very difficult to manage. Those with lumbosacral lesions have slow left colonic transit time however, they can usually achieve bowel emptying by using the gastrocolic reflex to prevent fecal loading.45 Intact anal resting tone implies that fecal leakage is unusual in these children. The main problem is the "automatic" nature of bowel emptying. A regimen of rectal stimulation at appropriate time intervals will help to achieve an acceptable level of continence. Patients with sacral spinal lesions usually have some voluntary sphincter activity and some anorectal sensation so they are continent but deficient rectal sensitivity predisposes them to constipation.45 Management consists of dietary modifications, regular rectal stimulation, enemas and washouts. The ACE procedure has been used in difficult cases but careful patient selection is required to achieve optimum results.

**SUMMARY**

Patients with fecal incontinence and constipation constitute a significant proportion of the pediatric surgical workload in many units. While constipation is often self-limiting, incontinence is usually incurable and this disability requires long-term comprehensive management to provide an acceptable quality of life. Problems should be anticipated and support should be provided at an early stage to pre-empt deterioration of anorectal function. A multidisciplinary approach (radiologists, gastroenterology technicians and surgeons) including family liaison with a clinical nurse specialist remains pivotal to a successful bowel management program.

**REFERENCES**

The main goal of a bowel management program is to improve the quality of life in children with fecal incontinence. A well established bowel management program needs dedication, determination and consistency with an aim to keep the child clean for 24 hours. At the Krickenbeck Conference, besides a new International diagnostic classification system, a method of postoperative assessment of continence was developed by the expert group to manage patients with ARM. These methods should allow for a common standardization of comparing postoperative results. The initial management options already adopted by the patient include; alterations in diet, suppositories, laxatives and enemas. Some authors advocate perineal exercises but the results are equivocal and depend a lot on patient’s compliance and anatomy.

PRELIMINARY ASSESSMENT

As a surgeon, it is imperative that the child is examined thoroughly to assess the need of a second operation that may treat the incontinence. This is relevant especially in cases of anorectal malformation if:

a. The child was born with a good sacrum, good sphincter mechanism and a malformation with good functional prognosis.
b. The rectum is mislocated.
c. The length of the colon is intact with a demonstrable rectosigmoid region.

The redo PSARP (posterior sagittal anorectoplasty) can be performed and the rectum can be relocated within the limits of the sphincter mechanism. Approximately 50% of the children re-operated by experienced surgeons under these circumstances have a significant improvement in bowel control and do not require bowel management to remain clean. In a large series of 303 who had undergone re-operation for anorectal malformations, a mislocated rectum was present in 76 cases. Surgery may be beneficial in the management of children with chronic intractable constipation and documented abnormalities in motility.

If constipation is a persisting problem with overflow and rectal ectasia is documented, the surgical treatment may be warranted. Anterior resection is considered if the rectum is hugely dilated. Surgical results in patients with gross megarectum are good.

Indications of Bowel Management

1. Anorectal malformations
2. Spina bifida
3. Chronic idiopathic constipation
4. Hirschprung’s disease
5. Inflammatory bowel disease
6. Trauma causing fecal incontinence
7. Operated case of rectal carcinoma
8. Colonic dysmotility
9. Other colorectal disorders.

Fecal continence is an important achievement in a child’s development and is an important assessment for evaluating the results in the diseases mentioned above.

Functional soiling is a self-limiting problem and usually disappears at puberty. The high incidence and importance of chronic idiopathic constipation as an entity in itself and a contributing factor to fecal incontinence has been recognized. Organic fecal incontinence is a consequence of congenital
malformations affecting the anorectum, anal sphincters or the spinal cord. Inability to control bowel function may be permanent, as in patients with myelodysplasia; self-limiting, as in patients who have fecal soiling after a pull-through operation for Hirschsprung’s disease; or partial, as in many patients who have undergone repair of an anorectal malformation.12

Management of anorectal malformations requires an accurate clinical diagnosis, proper planning of treatment in the newborn, meticulous anatomic reconstruction, and comprehensive postoperative care with the goal of having a child who is clean and dry, with an excellent quality of life, because they either have the capacity for continence or can be kept artificially clean with a comprehensive bowel management program.6 Globally, 75% of all patients of anorectal malformations have voluntary bowel movements. Half of this group still soils their underwear occasionally. Therefore, only about 37.5% of all cases are considered totally continent.5

Objectives of a Bowel Management Program

The goal of a well established bowel management program is to teach patients and their parents or guardians how to administer a daily enema in order to clean the colon and prevent incontinence.

The bowel management program includes:
1. Use of daily enemas tailored to each patient.
2. Observation with supervision for a week.
3. Parents are taught how to give the enema everyday in a controlled environment.
4. Daily abdominal skiagram to assess the result of the enema.
5. Psychological support.

Through trial and error, the correct amount and type of enema suitable for each patient is determined. The medical staff also considers what, if any, dietary restrictions or medications are needed to help the child control his/her bowels.

Fecal Incontinence

Fecal incontinence is defined as the incapacity to voluntarily hold feces in the rectum.

A child with fecal incontinence must be evaluated so that the medical team can distinguish between actual fecal incontinence and pseudoincontinence (overflow fecal incontinence).

Real Fecal Incontinence

The presence, the passage of stool and the perception to differentiate between solid and liquid stool and gas, is damaged. The etiology for fecal incontinence in anorectal malformation and some cases of Hirschsprung's disease is a defect in the sphincter mechanism and the striated muscle complex that surrounds the normal rectum, apart from neurologic deficiency associated with sacral agenesis. In cases of spina bifida, the contraction and relaxation of the muscles, as well as sensation, are both deficient.

Pseudoincontinence

In over flow fecal incontinence, the child suffers from severe constipation and fecal impaction. When the impaction is treated and the patient receives enough laxatives to pass stool, he or she becomes continent.

Overflow fecal incontinence results due to dilatation of the rectum and the sigmoid, a condition defined as megarectosigmoid. These children also suffer from a hypomotility disorder that interferes with the complete emptying of the rectosigmoid.1 Fecal impaction and pseudo overflow fecal incontinence can occur in a child with a good prognosis type of defect who though underwent a technically correct operation yet did not receive an appropriate treatment for constipation.

Physical Causes of Fecal Incontinence

About 70-80% of all children with anorectal malformations who have undergone a correct and successful operation will have voluntary bowel movements after the age of 3. About half of these patients soil their underwear on occasion usually related to constipation.1 If the constipation is treated properly, the soiling frequently disappears. Thus, approximately 40% of all children have voluntary bowel movements and no soiling.

Children with good bowel control still may suffer from temporary episodes of fecal incontinence, particularly severe diarrhea. About 25% of all children with anorectal malformations despite a good operation suffer from real fecal incontinence and they must undergo bowel management to stay clean.5
Physical Elements of Fecal Incontinence in Anorectal Malformations

Children born with anorectal malformation often do not experience the following:

1. **Sensation within the Rectum**

2. **Motility of the Rectosigmoid**

Normally, the rectosigmoid acts as a reservoir and remains quiet for periods of 24-48 hours, then a peristaltic wave allows the complete emptying of the rectosigmoid after which it remains quiet. If the rectosigmoid is slow, the stool stays stagnant and constipation occurs. As a result, the child may suffer from overflow incontinence and will soil. In the absence of a rectosigmoid, the child passes stool constantly, which may result in colonic hypermotility.

3. **Muscles**

Children with anorectal malformations lack some degree of development of the muscle complex or voluntary sphincters that normally surround the rectum and anus and therefore are incapable of holding in stool. The more complex the defect, the less developed is the muscle complex.

**Prognosis for Bowel Control (Table 81.1)**

It is possible for a surgeon with wide experience to predict in advance the functional prognosis of a child with anorectal malformation after definitive repair.1

A normal sacrum and a prominent midline groove with good gluteal muscles are indicators of good bowel control vis-a-vis an abnormal sacrum with a flat perineum and poorly developed muscles.

Children with anomalies with good prognosis like vestibular fistula, perineal fistula, rectal atresia, rectourethral bulbary fistula, imperforate anus with no fistula and a common cloaca with common channel less than 3 cm have a strong likelihood to have voluntary bowel movements by age 3.1 However, the child will still need supervision to avoid fecal impaction, constipation and soiling.

Children with anomalies with poor prognosis for bowel control include a very high cloaca with a common channel longer than 3 cm, recto-bladder-neck fistula and complex malformations.1 These children will most likely need a bowel management program to remain clean and be socially acceptable at 3-4 years age.

For children with rectoprostatic urethra fistula, there is a 50% chance that they will have voluntary bowel movements.1 Toilet training is recommended for these children by the age of 3. If this is unsuccessful, bowel management should be implemented at the time of potty training so that the child can remain clean and avoid social discomfort.

**MANAGEMENT**

**Pseudoincontinence**

Enemas and/or colonic washouts are used to clean the mega-rectosigmoid and remove the impaction. Then the constipation is prevented through administration of large doses of laxatives.1 The laxative dosage is adjusted daily until the proper amount of laxative is reached in order to completely empty the colon every day.

The diagnosis of overflow pseudoincontinence is made if the child becomes continent after the constipation is treated adequately. In case medical treatment fails due to a severe megasigmoid, surgical resection of the dilated sigmoid colon may be considered. After the sigmoid resection, the amount of laxatives required to treat these children can be significantly reduced or possibly even abolished.

However, before this is done, real fecal incontinence with constipation should be ruled out. A fecally incontinent constipated child subjected to this management would be changed to the one with diarrhea, which becomes much more difficult to manage.

Table 81.1: Prognostic signs for bowel control
**Constipation (Colonic Hypomotility)**

Constipation is the most common sequelae of anorectal malformations. The aim is to teach the parents to clean their child’s colon once a day with an enema or a colonic irrigation. No special diet or medications are necessary for children with colonic hypomotility or constipation. Their condition guarantees that they will remain clean in between enemas. The real challenge is to find an enema capable of cleaning the colon completely. Soiling episodes or severe "accidents" occur when there is an incomplete cleaning of the bowel.

**Loose Stools and Diarrhea (Colonic Hypermotility)**

This group is more difficult to manage. Most of these patients have been treated before the invention of PSARP with operations that included resection of the rectosigmoid (reservoir). Rapid transit of stool results in frequent episodes of diarrhea as even when an enema cleans the colon rather easily, stool keeps on passing fairly quickly from the cecum to the descending colon. Diarrhea is the most common aggravating factor for fecal incontinence, and antidiarrheal medications such as loperamide and diphenoxylate or bile acid binders may help. Thus a constipating diet and/or medications are needed to slow down the colon.

The treatment starts with enemas, a very strict diet, and under medical supervision, Imodium may be prescribed.

Once clean, the child can choose one new food every two to three days observing the effect on his or her colonic activity. If the child soils after eating a newly introduced food, parents are advised to eliminate that food from the diet on a permanent basis. The most liberal diet possible should be sought for the child. If he or she remains clean with a liberal diet then the dose of the medication can gradually be reduced to the lowest dose effective. Often the strict diet does not need to last forever. After two months of successful bowel management a child may have one of the "no eat" foods that he or she has been craving for. If the child soils after eating that food, then it stays on the no-eat list. The parents may introduce just one new food a week and observe the effect on the bowel movement pattern.

**Teamwork**

The bowel management program is most successful when the parents and skilled health professionals work together. Each member of the team should understand the sensitivity of the issue with a good communication and rapport between the members to achieve a successful outcome.

The bowel management program is tailored to individual patients and differs from child to child. A routine is usually achieved within a week while the family, patient, physician, and nurse undergo a process of trial and error designing the program to the specific patient. This requires a lot of dedication and the results are gratifying.

**Enema**

The type and amount of daily enema required to control the bowels varies from patient to patient.

There are different types of solutions to use for enemas. There are available as the prepared solutions or solutions that can be prepared at home based on water and salt. One and a half teaspoon of table salt added to a liter of tap water is the right combination to use as a home made enema solution. Children should never receive more than one phosphate enema a day because of the risk of phosphate intoxication. Children with impaired renal function should also use phosphate enemas with caution. The “right” enema is the one that can empty the child’s colon and allow him to stay clean for the following 24 hours. This can be achieved only by trial and error. A larger volume of saline solution is necessary in those children who have hypomotility as compared to those who have hypermotility who tend to empty their colon more rapidly. The solution of the enema should be at body temperature to decrease cramping. The consistency and the amount of stool evacuated after the enema should be examined to determine if it was effective. Administered on a regular basis, the enema should result in a bowel movement followed by a period of 24 hours of complete cleanliness. If one enema is not enough to clean the colon, (as demonstrated by an X-ray, or if the child keeps soiling), then the child requires a more aggressive treatment. If the saline enema produces inadequate results, then other additives can be added to increase the potency of the solution.
enema. The additives that can be added to the saline enema include phosphate, mild soap, glycerine and castile soap. The use of phosphate enemas is convenient and can be added to saline enemas.

A Foley catheter (22/24 Fr) is used as an alternative to the normal catheter when the enema solution administered leaks. The goal of this procedure is to use a balloon to act as a plug to avoid leaking during the enema process.

**Best Time of the Day to Administer an Enema**

The timing of the enema plays a role in how efficiently it cleans the bowel. The recommendation is to give an enema after the main meal of the day in order to take advantage of the gastrocolic reflex (this reflex happens after each meal), but more importantly, the enema should be given when it is the best time for the parents and the child to have time to do the enema efficiently and have one hour to devote to the administration.

It is advisable to give the enema at the same time every day in order to create a routine. It is also important to consider that if the enema is given every other day, the child should expel the amount of stool due for two days. No more than 48 hours should elapse between enemas.

**Steps for Administering the Enema**

1. The child should be in a position that facilitates delivery of the fluid as high up into the colon as possible. A small child can be placed on the parent’s lap with the head down and buttocks on the lap. The older child may lie prone on a bed with a pillow under their abdomen or in a knee-chest position (Figs 81.1A to C). Adolescents may try self-administration of these enemas with the knee-chest position while lying on their side. Lying on right or left side to administer enema may be just as effective if comfortable.

2. A lubricated 22-24 F Foley catheter should be gently introduced through the anus for approximately 4-6 inches.

3. Using a 30 cc syringe filled with air or warm water, 15 cc is instilled and then the catheter is pulled back. If the balloon comes out, the catheter is pushed back and the remaining 5 cc of water is instilled then pulled back again. This may be continued till the full 30 cc. The balloon should never be inflated right at the anus.

4. As soon as the balloon is inflated, the syringe from the catheter is removed to prevent the balloon from deflating. While keeping tension on the catheter to avoid leaking, the flow of enema fluid is started.

5. When the enema is complete, the solution should not be released for 5-10 minutes for optimal effect. The enema fluid should be retained as long as possible and this depends on the child and the quantity of fluid introduced.

6. When retention time is up, the child is placed on the toilet and at this point is deflated the balloon allowing the catheter to slip out.

7. The child should sit on the toilet for 45 minutes to allow enough time for the enema to be most effective for complete emptying of the colon. It is very important to be sure that the child empties

---

**Figs 81.1A to C:**

A. Small baby on the lap  
B. Older child raised on a pillow in prone position  
C. Knee-elbow position for easy access taking the advantage of gravity to push the enema solution
his or her colon, otherwise a more aggressive enema is necessary which can cause additional discomfort.

**Toilet Training**

Toilet training for stool is a long-term goal for children with anorectal malformations. Parents of children born with a good prognosis type of defect should be encouraged to use the same strategies for toilet training as those followed by families with typical children.

Between ages 2-3 years old, parents are advised to sit their child on the toilet after every meal. Allowing him or her to play with toys is encouraged while on the toilet. Just as in training any child, parents are encouraged to toilet train as a game and not as a punishment.

Parents should sit with their child and not argue or force the child to remain seated. If the child gets up, the parents should put the toys away.

The child should be rewarded for a bowel movement or voiding while on the toilet.

If the child is not successfully toilet trained by school age, a family has two alternatives: Not to send the child to school for another year and continue attempts at toilet training or begin the Bowel Management program.

It is recommended to begin the bowel management program by the time their child is 3-4 years old. The family may decide when and how to start bowel management with the goal to have the child in school wearing a normal underwear without being ridiculed by his or her classmates who are already toilet trained.

**Continent Catheterizable Channel**

Adolescents often feel their privacy is being infringed on when a parent continues to help them with bowel management. A continent appendicostomy (Malone antegrade colonic enema or MACE procedure) allows the child to be more independent and can further improve his or her quality of life.\(^1\)\(^,\)\(^6\) If the child no longer has his/her appendix, a continent neo-appendicostomy may be created from the colon. Before implementing the Malone procedure the child should be perfectly clean with his or her regular bowel management and should be absolutely motivated, both in terms of the surgery and the administration of the enemas as well as in his or her ability to evaluate the effects.

To manage overflow incontinence of children with anorectal malformations and Hirschsprung’s disease, laparoscopic technique to allow antegrade enema treatment has been described as a technically straightforward, effective, and reversible method for the placement of a cecostomy button.\(^17\)

**Duration of the Program**

Patients with a poor prognosis type of anorectal defect will require the bowel management program life long. However, as anorectal malformations is a spectrum of defects, it is conceivable that later in life, some children may stop using enemas and remain clean, following a specific regimen of a disciplined diet with regular meals (three meals per day and no snacks) to provoke bowel movements at a predictable time. Discontinuing the daily enemas may be attempted if the child is completely clean with bowel management, cooperative and understands that there’s a risk it won't work and one might have to return to the bowel management program by daily enemas. For children with constipation, a daily laxative given at the same time each day is recommended. The dose of the laxative can be adjusted by trial and error. It is best to first try the less aggressive and natural types of laxative, and then, depending on the child's response, use medications with more active ingredients. The first choice is a laxative type of diet; the next choice is a bulk forming agent. If this medication does not work, a laxative with senna is indicated. After a few weeks, the family and child can decide whether they want to continue with the new regimen or go back to the bowel management program. This decision is up to the family and the child, and is based on the quality of life experienced with each method.

**Electrical Stimulation and Biofeedback Exercise**

Electrical stimulation and biofeedback exercise of pelvic floor muscle has been reported as an effective adjunct to bowel management program for the treatment of fecal incontinence in children following surgery for anorectal malformation.\(^7\) Perineal exercises are found to be more effective around puberty.

**RESULTS**

More than 90% of the children who follow bowel management remain artificially clean and dry for the
entire day and can have a completely normal life. The bowel management program has been in practice for over 20 years. There are no known negative effects that can be attributed to the use of enemas or colonic irrigations. If the specific recommendations of the manufacturer are followed for a phosphate enema, problems of phosphorus intoxication or hypocalcemia have not been seen. Too much salt in the saline solution can lead to sweating, feelings of nausea, and hypernatremia.

Sometimes after a period of successful bowel management, the child becomes incontinent again. This is an indication that something has changed in the child’s habits and a thorough evaluation becomes necessary. If the abdominal skiagram shows a large amount of stool in the colon after the enema, the enema solution needs to be adjusted. It can take a week of enemas and skiagrams to make this determination. If the skiagram shows a clean colon then the “accidents” are due to increased motility and it may be necessary to introduce some medications to slow down the colon and to observe a more strict diet.

There are centers where at longer follow-up, there is a significant percentage of subjects who still soil while following a bowel management program. This is explained by the small number of nurses and bowel management specialists who are involved in the rehabilitation process and by the lack of appropriate information about functional prognosis that are conveyed to the parents. Thus psychologic support in bridging the gap between cure and care is critical.

Twenty-five percent of all cases of anorectal malformations that suffered from fecal incontinence significantly improved their quality of life when subjected to a bowel management program.

At good centers, almost all patients born with anorectal malformations can be kept clean of stool and dry of urine, either because they achieve bowel control or because they are subjected to a bowel management program.

ACKNOWLEDGEMENTS

The authors acknowledge the team of Bowel Management program at Children’s Hospital, Cincinnati for carrying out a successful bowel management program. The active members of the team are Alberto Peña, Mark Levitt, Cathy Bauer, Tracy Ashworth and Lindsey Foley. This chapter is based on the 42nd and 43rd workshop on Pediatric Anorectal and Colorectal Surgical workshop, June, 2006 and 2007 at Cincinnati, USA led by Alberto Peña and Mark Levitt.

System requirement:
- Windows XP or above
- Power DVD player (Software)
- Windows Media Player version 10.0 or above
- Quick time player version 6.5 or above

Accompanying DVD ROM is playable only in Computer and not in DVD player.
Kindly wait for few seconds for DVD to autorun. If it does not autorun then please follow the steps:
- Click on my computer
- Click the drive labelled JAYPEE and after opening the drive, kindly double click the file Jaypee
DVD CONTENTS

DVD – 1

- Gastric Transposition  DK Gupta
- Colonic Interposition  A Hamza, DK Gupta
- Thal Fundoplication  KW Ashcraft
- Kasai’s Portoenterostomy  R Ohi, M Nio

DVD – 2

- PSARP in a Male  A Pena
- PSARP in a Female  A Pena
- Common Cloaca  A Pena
Pediatric Surgery
Diagnosis and Management

Editor
Devendra K Gupta MS, MCh, FAMS, FAAP, FRCrS (Hon.), DSc (Hon. Causa)
Professor and Head
Department of Pediatric Surgery
All India Institute of Medical Sciences
New Delhi, India

Associate Editor
Shilpa Sharma MS, MCh
Diplomate National Board
Assistant Professor of Pediatric Surgery
Postgraduate Institute of Medical Education and Research
(Dr RML Hospital, New Delhi)
PhD Scholar, Department of Pediatric Surgery
All India Institute of Medical Sciences
New Delhi, India

Guest Editor
Richard G Azizkhan MD, PhD (Hon.), FACS, FAAP
Surgeon-in-Chief
Lester W Martin MD Chair of Pediatric Surgery
Cincinnati Children’s Hospital Medical Center
Professor of Surgery and Pediatrics
University of Cincinnati College of Medicine
Cincinnati, Ohio, USA

Foreword

This book marks an important milestone in the growth of pediatric surgery in India. Its significance is indicated by the fact that it has been officially sponsored by IAPS, the Indian Association of Pediatric Surgeons.

The IAPS has grown, from a modest beginning in 1965, into a vibrant organization with more than 900 members. Thirty to thirty-five new members join each year after completing their training in 23 centers in the country. It is, therefore, time for it to have its own standard compendium of information relevant to the needs of its members. Trainees too need an authoritative textbook written by experts who are familiar with the needs of a developing country like India. Unfortunately, books written and published in the West are too exhaustive, often prohibitively expensive and largely unrealistic for our needs. I have no doubt that pediatric surgical trainees in neighboring countries of Asia will also appreciate the significance of this book.

There are more than 400 million children below the age of 12 years in India and the volume of surgical work is simply astounding. The kind of experience that a pediatric surgeon gets in India is the envy of many a surgeon in the developed world. Yet it is not very often that Indian authors find a place in the list of contributors to books published in the west and one gets the impression that children’s surgery hardly exists in this vast subcontinent. Our authors need to be recognized for their rich and authentic experience. At the same time, our trainees need to be acquainted with the wide range of expertise from abroad. They need to have a broad vision, yet focused to the needs of a country like India. This is another valid reason for bringing out this book.

It is commendable that Professor Devendra K Gupta, Chief of pediatric surgery at the All India Institute of Medical Sciences has been chosen as the Editor. Professor Gupta is a highly regarded leader in pediatric surgery, recognized nationally and internationally for his writings. He has a wide base of valuable experience, which is admirably reflected in his editorship of this book. He has, very wisely, taken a younger colleague Dr Shilpa Sharma as Associate Editor to bring in, open-minded dynamism of the youth in the editing process. Significantly, he has also succeeded in getting the able guidance of Prof Richard Azizkhan, of Cincinnati, USA, as Guest Editor.

Professor Gupta has chosen contributors who are either working in India or who have been associated with Indian departments of pediatric surgery for some time. In fact, nearly one third of the contributors are working in countries abroad. It is noteworthy that authors have been selected not so much for their prominence in the profession as for proficiency in their fields of interest. In the fast changing world of medicine, dynamic young surgeons have acquired new expertise and amassed enormous experience that would be unimaginable in the West. I heartily welcome this move to include younger authors. They may not be well known today, but they certainly need to be taken note of, for they will be the leaders of tomorrow.

It usually takes several years to produce a multi-authored book – it is hard work collecting manuscripts and making the matter suitable for publication. Often, the information is outdated, if not obsolete, by the time the book is published. I would like to compliment the editors for bringing out this book as quickly as they have. The information provided is current, and presented with clarity of expression. Surgical techniques are described in a way that facilitates understanding. Wherever necessary, the subject has been discussed by more than one author so that varying points of view are accommodated.

I feel assured that this book will become an invaluable aid to pediatric surgeons not only in India but also in other parts of the world. With this book the editors have given an international identity to Indian pediatric surgery. This in itself is a commendable achievement.

Purushottam Upadhyaya
MS, FRCS, FAMS
Emeritus Professor and Advisor
Himalayan Institute of Medical Sciences
Dehra Dun, India
Foreword

Professor Devendra Gupta deserves to be congratulated for his enormous effort in producing this valuable textbook in pediatric surgery. This book which comprises 130 chapters and 132 contributors from all five continents of the world provides an authoritative, comprehensive and complete account of various surgical conditions in children. This detailed reference text is suitable for both specialist pediatric surgeons as well as trainees in pediatric surgery as it covers both common and uncommon paediatric surgical conditions. The book has the added attraction because it covers recent developments in the care of children with congenital malformations and acquired surgical conditions. There are full chapters devoted to ethics in pediatric surgery, robotics, stem cell therapy, tissue engineering, laser applications in pediatric surgery, nanotechnology and computers.

Professor Gupta was successful in persuading well known pediatric surgeons to provide an authoritative and complete account of their respective topics. Pediatric surgical community should find this book a useful reference in the management of childhood surgical disorders.

We applaud the efforts of Professor Gupta and contributors for this comprehensive textbook in pediatric surgery.

Prem Puri  MS, FRCS, FRCS (Ed), FACS
President, World Federation of Associations of Pediatric Surgeons
Preface

“It is not enough to begin. Continuance is necessary. The reason of failure in most cases is lack of perseverance.”

Though there are number of high quality books available in pediatric surgery, yet most of them are not accessible to the majority of pediatric surgeons in the world due to their high cost. The proposal from the Indian Association of Pediatric Surgeons (IAPS) to publish a multi-authored pediatric surgery book that was complete in all respects and still affordable, was quite a challenge. The Editor accepted this responsibility to bring out a book that would be of international quality, high in scientific value and still low in cost. To accomplish this task, the help and support received from Dr Shilpa Sharma as the Associate Editor and Prof Richard Azizkhan as the Guest Editor were simply outstanding and are greatly acknowledged.

The initial concept for the book was to include many pediatric surgical sub-specialties, e.g. General Pediatric Surgery, Neonatal Surgery, Pediatric Oncology, Pediatric Urology, Cardiothoracic Surgery and others, all in a single book. However, since the contents became too voluminous, this book was restricted to “Pediatric Surgery—Diagnosis and Management”, primarily to cover general pediatric surgery; yet still these required two volumes to keep the book handy.

The scope of the book remains very broad and covers the spectrum of General Pediatric Surgery. It includes some relevant basic science, embryology and pathophysiology, diagnosis and management, as well as complications and includes long-term results. The descriptions and pictures of operative procedures have also been added wherever indicated. Many subjects have been covered by more than one expert still without duplicating the text.

The book with about 1200 figures (Clinical photographs, flow charts, X-rays and the ones drawn by the artist) makes it unique. The book also includes chapters on Nanotechnology, Minimal invasive procedures, Endoscopic procedures, Lasers, Robotic surgery, Stem cell regeneration, Tissue engineering, Computers and Molecular genetics to offer state-of-the-art information to the pediatric surgical community. The book also extends to adolescent surgery as it includes the chapters on Empyema, Intestinal obstruction, Bariatric surgery, Tuberculosis, Hydatid disease and Bezoars.

The authors in this book have been outstanding. Their contributions have been excellent. I was rather bestowed with faith to edit their work (Chapters, photographs, charts, tables, references, etc.), so as to maintain uniformity and regular flow of thoughts.

A foreword for this book has been written by Prof P Upadhya who had not only been my teacher and the Founder Professor and the Chief of the Department of Pediatric Surgery at the All India Institute of Medical Sciences, New Delhi, but also a perfectionist, and an academician with utmost human values. Prof Prem Puri, President of WOFAPS who is known internationally for his deep interest in research and surgical care has not only applauded our efforts but written a Foreword as well.

The support received from the colleagues and the staff from the department at All India Institute of Medical Sciences, New Delhi (AIIMS), especially from Mr Ved Grover, is greatly appreciated. I also thank my wife, Dr Rani and the daughters Dr Malvika and Deepika, for being the force behind to complete this book.

The book has been published by M/s Jaypee Brothers, the reputed exclusive Medical Publishers from New Delhi. Shri JP Vij, Chairman and Managing Director; Mr Tarun Duneja, the Director (Publishing), had shown special interest while publishing this book.

It is hoped that the book would serve its purpose if it reaches the pediatric surgical community in the developed and the developing world alike, for its scientific contents, quality of production, affordability and balanced approach.

When you light a lantern for another, it brightens up your path as well —Nichiren Daishonin.

Devendra K Gupta
On behalf of the Indian Association of Pediatric Surgeons (IAPS), I take great honour and privilege to write a brief message for the long awaited book “Pediatric Surgery—Diagnosis and Management”, edited by Prof DK Gupta. The book published by Jaypee Brothers, New Delhi has been creditably supported by the rich experience of Prof Richard Azizkhan from Cincinnati Children Hospital, USA and Dr Shilpa Sharma from New Delhi.

It was the year 2000 that after the success of “Textbook of Neonatal surgery” published by Dr DK Gupta, the IAPS wanted more such books in the specialty and thus requested Dr Gupta to bring out the much needed book in Pediatric Surgery that would be complete, informative, affordable and at the same time matched with the best international standards in its presentation and scientific contents. It is commendable that the editors have accomplished this daunting task so well that would be beneficial for the pediatric surgical community.

This book, Pediatric Surgery—Diagnosis and Management, is first of its kind from the developing part of the world. It is well divided in sections, and covers the complete spectrum of diseases including recent advances. Despite being a multi-authored book, it has been dominated by the Indian contributors, reflecting the maturity of pediatric surgery specialty in India. Many chapters have been covered by more than one expert known for their professional standing in the field, so as to incorporate the differing views of various experts. Chapters have been supplemented generously with operative techniques, line diagrams, charts and clinical photographs to make the book educative and informative.

I am sure this book would be an asset and reach a large number of pediatric surgeons. It should serve as a reference book in general pediatric surgery not only to the postgraduates and the pediatric surgeons but also the institutional libraries across the world.

Anirudh Shah
President, Indian Association of Pediatric Surgeons
Ahmedabad
The Editors would like to thank the Indian Association of Pediatric Surgeons (IAPS), for giving us the singular honour and the major responsibility to write this book for the benefit of the pediatric surgical fraternity especially from the developing world.

The editors admire the support that has been received from the authors from around the world. The willingness, with which all of them gave us their valuable time, leaves us personally indebted.

The Editors acknowledge the blanket permission granted by MBD publishers to reproduce the published material free of charge (text, photographs, diagrams, charts, tables, etc.) from the Textbook of Neonatal Surgery, edited by DK Gupta, New Delhi 2000, in various chapters of this book. Though, every effort has been taken by the contributors to acknowledge the published text, color photographs, charts and diagrams reproduced/quoted from the books and the journals, an inadvertent error, if any, in any chapter of this book, would only be due to an oversight.

We also appreciate the support and the encouragement received from the World Federation of Association of Pediatric Surgeons (WOFAPS), Asian Association of Pediatric Surgeons (AAPS), the Federation of Association of Pediatric Surgeons from SAARC Nations (FAPSS) and the International Foundation for Pediatric Surgery and Research for producing the book aimed at improving the surgical care of children around the globe.

Finally, our appreciation to Shri JP Vij, Chairman and Managing Director of Jaypee Brothers, Mr Tarun Duneja, and members of the publishing team, including the artists, for their hard work and special interest taken to produce a book of this quality.
To
The students of Pediatric Surgery,
“at all levels”,
in their quest for knowledge

SECTION 5

Hepatobiliary System
ANATOMY AND EMBRYOLOGY

Normally the gallbladder lies on the undersurface of the liver in a slight depression of the anatomical right lobe (Fig. 82.1). It is composed of a fundus that protrudes from the margin of liver substance, a larger body and becomes somewhat narrower at the neck before connecting to the common bile duct by an occasionally tortuous cystic duct. The lining mucosa assumes a valve like spiral configuration (of Heister) toward the neck and there is often a pouch-like arrangement (of Hartmann) where gallstones may lodge. The junction of cystic and common bile duct is normally "T" shaped although occasionally the cystic duct runs alongside the CBD or shares a common wall before entering it distally. Calot's triangle is bordered by the cystic duct, common hepatic duct and the liver and contains the cystic artery and a fairly constant lymph node (of Lund). The venous drainage is via multiple veins running directly into liver substance across the gallbladder bed.

Embryologically, bile ducts are derived from two distinct elements. Intrahepatic bile ducts appear from about 7 weeks while the extrahepatic bile ducts are derived from the budding foregut endoderm. Each branch of portal vein is surrounded by a layer of mesenchyme and a cylindrical double cell layer of darkly staining cells derived from hepatoblasts termed the ductal or limiting plate. Remodeling of this layer occurs to form a network of interconnected bile ducts enveloped into the mesenchyme but retaining the connections with the intrahepatic bile canaliculi. This process begins at the porta hepatis and extends back into the more peripheral areas of liver tissue. Bile is first observed in cholangioles and then the fetal gut from 12-14 weeks gestation implying completion of biliary continuity.

CONGENITAL ANOMALIES OF THE GALLBLADDER

The majority of configuration anomalies of the gallbladder are asymptomatic and therefore usually incidental findings. Thus, bilobed gallbladders, duplications and diverticula have all been described either as findings at cholecystectomy or in anatomical postmortem reviews. Similarly, the position of the gallbladder may vary and it has been found on the left side of liver or buried within the liver substance as an intrahepatic gallbladder. The classic paper documenting these type of anomalies is that of Robert Gross who recorded several anatomical variants in an extensive literature review in 1934.¹

Gallbladder agenesis, can occur as an isolated anomaly but is usually found in association with biliary atresia or with duodenal atresia. In cases where
biliary atresia is the predominant defect, the anomaly is simply a reflection of a generalised development defect of the biliary tree with the affected infant presenting with conjugated jaundice. Coughlin et al reported two infants with duodenal atresia (one also with an imperforate anus and hypospadias) where at operation an otherwise normal common bile duct was found but no evidence of a gallbladder. There were no sequelae.

A septate or multiseptate gallbladder arises from incomplete vacuolation of the lumen during development and has been reported. The septum may include muscle fibers within its structure, which supports it as a congenital anomaly. Occasionally in adults, an acquired septum may form due to recurrent inflammation. Such septation appears to predispose to stone formation secondary to bile stasis. However, even in the absence of complications these anomalies can be symptomatic. St-Vil et al described a three-year-old boy found to have an "hour-glass" deformity due to a gallbladder diaphragm with a pin-hole separating both elements. The fundal part appeared inflamed and long-standing abdominal discomfort and failure to thrive was cured by cholecystectomy. Tan et al have described a case of multiseptate gallbladder in association with a fusiform choledochal cyst malformation.

Sometimes, although structurally normal, the histological architecture of the gallbladder may vary. For instance, Santonja et al described a case of histological replacement with tissue resembling gastric wall architecture.

INFLAMMATORY CONDITIONS OF THE GALLBLADDER

Acute Hydrops

Hydrops of the gallbladder is the term used for an acute, symptomatic, distension of the gallbladder, which can occur in the absence of inflammatory change, calculi or any congenital anomaly. The etiology is not clear although the condition frequently follows upper respiratory tract infections and non-specific viral illness. Mesenteric adenitis and Kawasaki disease (mucocutaneous lymph node syndrome) have been reported as associated conditions. The largest series in children is that of Chamberlain and Hight who reviewed 29 cases with a mean age at presentation of 5 years and a preponderance of boys. The presenting symptoms included abdominal pain, vomiting, tenderness in the right hypochondrium and, in about half of all cases, a palpable gallbladder. Hydrops is commonly misdiagnosed as appendicitis in the older child or intussusception in infants although a correct diagnosis can be made without difficulty with ultrasonography. It can be differentiated from a mucocele of the gallbladder by the demonstrable absence of gallstones and by the absence of pyrexia or leucocytosis.

Hydrops may be treated conservatively with intravenous fluids, gastrointestinal rest and usually antibiotics. This is largely successful with the function of the gallbladder returning eventually. If, however, the case is diagnosed at laparotomy then either cholecystectomy or cholecystostomy is appropriate.

Acute Acalculous Cholecystitis

Acalculous cholecystitis (AC) may occur without a history of any preceding illness but certainly in developed countries it is more usually a complication of trauma or sepsis. Associated illnesses have included leptospirosis, cholera, AIDS, scarlet fever, burn wound infection with pseudomonas and Salmonella typhimurium and typhoid fever. Some authors have speculated that, unlike gallstone-associated cholecystitis, there is an underlying ischemic component in some cases. There appears to be an increased prevalence of AC in some sub-saharan African countries such as Nigeria, although the cause is unknown. Rarely, infection of the biliary tree with the nematode worm, Ascaris lumbricoides, may cause cholecystitis by blockage of the cystic duct. AC can occur in the neonatal period, although it is usually misdiagnosed as necrotizing enterocolitis and diagnosed at laparotomy. Septicemia and fever are typically found and a mass in the right hypochondrium may be palpable. Complications may be more frequent in this type of gallbladder inflammation. Thus perforation due to necrosis and gangrene are not uncommon sequelae of untreated disease. Jaundice occurs in approximately one-third of the cases associated with another illness although it is not clear whether this is due to the effects of the sepsis or a mechanical obstruction to the adjacent common hepatic or bile duct.
A laparotomy may be indicated either because of difficulty in diagnosis, failure of resolution with antibiotic therapy or complications such as necrosis and abscess formation. A tube cholecystostomy is all that is needed for the majority of cases although on occasion cholecystectomy may be indicated, particularly for complicated disease. Interventional radiologists have described percutaneous techniques for drainage in adults.

A rare variant of gallbladder inflammation in children, xanthogranulomatous cholecystitis, has been described in a 10-year-old child who presented with a five month history of abdominal pain complicated by jaundice. The jaundice was secondary to involvement of the common bile duct in the inflammatory process. Cholecystectomy was performed and histological examination showed the typical features of a destructive inflammatory process, fibrosis and nodules of lipid-laden macrophages.

Acquired stenosis of the cystic duct may occur even in the absence of gallstones. We have recently treated a 14-year-old boy with sclerosing cholangitis who developed right upper quadrant pain with a palpable gallbladder (Fig. 82.2). At surgery he had a tense mucocele of the gallbladder with complete stenosis of the cystic duct, presumed to be due to the sclerosing process.

Cholelithiasis and Acute Cholecystitis

There are three types of gallstones, depending on their composition, which are generally termed cholesterol, pigment or mixed. Normally, cholesterol exists in a supersaturated form in bile and is kept in solution by lecithin, primary and secondary bile salts. Physiological alteration of this balance can render the bile lithogenic and cholesterol may precipitate as a consequence. Similarly, bilirubin is excreted in a water-soluble conjugated complex molecule by the biliary canalicular apparatus. The increased excretion of bilirubin which, for instance, occurs in chronic hemolysis increases the concentration of bilirubin and potential precipitation as calcium bilirubinate. Cholesterol stones tend to be large, smooth and solitary while pigment stones are multiple, black and spiky. The contribution of infection to the formation of stones in children is not known but in adults some bacteria present in bile may produce $\beta$-glucuronidase an enzyme known to hydrolyse bilirubin glucuronide to insoluble bilirubin and glucuronic acid.

INCIDENCE AND ETIOLOGY

Although compared with adults, cholelithiasis is unusual in children it is certainly not rare. One ultrasound screening program performed in children between 6 and 15 years of age showed a prevalence of 0.13%. For comparison, the prevalence among screened adults would be about 10%.

Table 82.1 lists a number of associated causes or predisposing factors in the development of gallstones in the pediatric population while Table 82.2 selectively illustrates some of the more recent large pediatric series of gallstones from around the world.

Pigment stones are certainly more prevalent in this age group than in comparable adult series and in these children, the sex ratio is the same. Common hemolytic disorders include congenital disorders of the red cell membrane such as spherocytosis, elliptocytosis and stomatocytosis and the more prevalent, thalassemia (α and β), hemoglobin C and sickle cell disease (SCD). Within each predisposing group, the prevalence of stones varies. Thus almost 60% of children and adolescents with congenital spherocytosis will have gallstones compared to a somewhat lower prevalence in homozygous sickle cell disease, ranging from 13–37% of cases. In one cohort study from Jamaica,
gallstones developed in 96 (57%) of 167 patients. Actual symptoms were however uncommon as only 7 children required a cholecystectomy. Biliary sludge has also been recognised as a predisposing feature to actual stones in children with SCD. In one study from Saudi Arabia, some 16% of a SCD population had sludge present, compared with 20% who had actual stones.

Cholelithiasis in the neonatal period has been noted with increasing frequency and has been attributed to the increased use of total parenteral nutrition (TPN) and perhaps to an increased availability of ultrasonography. The genesis of TPN-related gallstones is unclear but may include physiochemical alterations in bile due to amino acid infusion or to a lack of enteral stimulation. Biliary sludge also appears to predate true stones and has been identified in approximately 40% of neonates receiving TPN.

Heaton et al described 9 infants with an obstructed biliary tree caused by bile and sludge in seven infants aged 2-12 weeks and by gallstones in two infants aged four and six months. Underlying factors such as prematurity or hemolysis were not present in most of these infants but there was a high incidence of congenital anomalies of the biliary tree. Spontaneous resolution of "cholelithiasis" in infants has been reported particularly if the stones are not calcified and a conservative policy is probably justified although later complications can occur.

**CLINICAL FEATURES**

Gallstones may cause abdominal pain, and the diagnosis should certainly be considered in cases of recurrent abdominal pain, even in children. The typical relationship to meals may be established in older children and adolescents. Most can be localised to the right hypochondrium with a degree of tenderness even between attacks. Palpation of a mass in an otherwise well child implies the formation of a mucocele of the gallbladder due to complete obstruction of the cystic duct (Fig. 82.2).

Stones in the common bile duct (choledocholithiasis) (Fig. 82.3) will present as a conjugated jaundice with pale stools and dark urine and has been estimated to occur in from 2 - 6% of cases. Secondary infection and ascending cholangitis are uncommon complications in children but must be considered if there are features of jaundice, pyrexia and marked right-upper quadrant tenderness. Occasionally Mirizzi’s syndrome can occur where a gallstone impacts in Hartman’s pouch causing inflammation and obstructive jaundice due to narrowing of the adjacent common hepatic duct. Small gallstones particularly may pass through the sphincter of Oddi temporarily obstructing the main pancreatic duct to cause acute pancreatitis. This occurred in up to 8% of an unselected series of children with gallstones in one American series. Such children may well present with pancreatitis and hyperamylasemia, having otherwise asymptomatic gallstones. If the symptoms do not subside quickly on conservative management then an ERCP is indicated in the acute phase with stone removal and sphincterotomy.

The diagnosis of gallstones is easily established by ultrasonography (Fig. 82.4) although in children with sickle cell disease for instance, it can be difficult to determine their relationship to symptoms. Recurrent jaundice, fever and leucocytosis and abdominal pain occurs in sickling crises and the concomitant changes in liver function are often similar to those seen with biliary tract obstruction. The combination of

ultrasonography and biliary tract scintigraphy can be useful for differentiating sickling crises from gallstone induced abdominal pain although Serafini et al found a low predictive value for either test when used alone.35

The management of gallstones in children is straightforward if they are symptomatic-elective cholecystectomy. However, where they are asymptomatic or indeed if symptoms are atypical then a more conservative approach may be indicated. This is true whether the stones are pigmented or not. For instance, Bruch et al prospectively studied 74 children with gallstones where 33 (45%) required cholecystectomy and 41 were followed without intervention.19 In the follow-up only group, 34 (83%) remained symptom-free or had responded to dietary manipulation.

**CHOLECYSTECTOMY**

Cholecystectomy through a right subcostal muscle-cutting incision was the standard procedure until relatively recently. In many centers however, this has been replaced by the technique of laparoscopic cholecystectomy with excellent results reported. This minimally invasive procedure has proved beneficial particularly to the children with sickle cell disease because of a reduced morbidity from respiratory complications.36,37

Sometimes the question of an incidental cholecystectomy is raised. Thus a preoperative ultrasound scan of the gallbladder should be performed if splenectomy is being considered for hemolytic disorders to detect gallstones in these children and concomitant cholecystectomy has been recommended even for asymptomatic stones.38

**LAPAROSCOPIC CHOLECYSTECTOMY IN CHILDREN**

Laparoscopic cholecystectomy (LC) was initially performed by French surgeons at the end of the 1980’s.39 Since then it has become the procedure of choice for cholecystectomy in adults with low morbidity and mortality in several large series.40 Nevertheless it may be prone to occasional complications which can be life-threatening such as common bile duct damage and biliary leaks. Many authors have emphasised that there is a "learning curve" in the acquisition of the necessary manual skills and techniques. It is a debatable point whether the general pediatric surgeon will acquire enough expertise to be able to remove the occasional gallbladder laparoscopically in the same way that they had once removed gallbladders at open operation.

Pediatric-specific series have been reported.41,42 Although there is no technical reason why even infants cannot undergo LC, for instance Sanada et al.43 have described its use in an eight-month-old girl with gallstones, a common-sense approach should be adopted as the actual benefits of such a challenging procedure in an infant are marginal.

Typically four ports will be used: Umbilical, epigastric and two lateral ports placed in the right lower quadrant in smaller children or in the flank in the older child or adolescent (Figs 82.5 and 82.6). Although all these ports can be 5 mm in diameter, if a 10 mm port is used through the umbilicus it facilitates final removal of the gallbladder. Most surgeons would now place the initial port by open dissection at the umbilicus (Hassan approach) although the alternative using a Veress-type needle is still widely performed. A CO₂ pneumoperitoneum is then induced with a maximum pressure of about 10-12 mm Hg. At this point the anesthetist may well have to increase the inspired minute volume to reduce the tendency to hypercarbia. Some authors describe gasless laparoscopic procedures using devices designed to "tent" the abdominal wall and this may be particularly useful in very small children and infants.43

![Fig. 82.5: Typical appearance of laparoscopic ports (x4) required for cholecystectomy. The uppermost is a 10 mm disposable port sited at the umbilicus with camera in place. The two in the foreground are 5 mm disposable ports used for grasping the gallbladder. The epigastric port (left and unfocused in picture) is used for dissection and diathermy](image-url)
Dissection of the cystic artery and duct is exactly the same as the open procedure and once identified these may be clipped or ligated. The gallbladder is taken off its bed by diathermy (bipolar or monopolar) and removed through the largest available point using heavy grasping forceps.

Perioperative Medical Preparation

The commonest single group requiring cholecystectomy in many centers will be children with homozygous sickle cell disease. Careful preoperative preparation of these children is important to minimise medical and hematological complications and must include hydration, antibiotic administration, avoidance of anemia and pre- and perioperative oxygen saturation monitoring.

Formerly an aggressive preoperative transfusion regimen was advocated in order to reduce the sickle percentage (to < 30%) and increase the hemoglobin levels (to > 10 g/dl).\(^4\) Recently this approach has changed and currently in many centers a more conservative approach is taken with blood transfusion being undertaken only to the level required to raise the hemoglobin to > 10 g/dl.\(^5\) This has been associated without change in perioperative morbidity and with much less transfusion-related problems.

There are specific medical complications peculiar to sickle cell disease which may be precipitated by surgery. For instance, the acute chest syndrome (ACS) is a post-operative phenomenon where there is sickling and sequestration of red cells in the pulmonary vasculature. In children this presents as fever, cough and respiratory distress with hypoxia. The mortality ranges from 10 - 25% and laparoscopic procedures do not appear to offer much protection. In one recent series, ACS occurred in 6 (10%) of 59 children with SCD undergoing a surgical procedure.\(^6\) Although in the surgical population, risk factors have been hard to define, in other studies ACS appears more commonly in children aged 2-4 years of age and in those with the SS genotype.

MISCELLANEOUS CONDITIONS OF THE GALLBLADDER

Biliary Dyskinesia

This is a poorly defined condition that has been described in detail in only a single pediatric series.\(^7\) The key features are chronic right-upper quadrant pain without gallstones, an absence of other causes of pain and objective delayed gallbladder emptying. The later feature may be difficult to satisfy outside of a specialised center but involves a cholecystokinin (CCK)-stimulated gallbladder ejection fraction as assessed using a radionuclide hepatobiliary isotope (e.g. Technetium labelled -imino-diacetic acid). Normally 90-100% emptying should be achieved following CCK administration; in biliary dyskinesia, < 40% is all that should be achieved. Gollin et al described 29 children with a median age of 13 years who fulfilled these criteria and who were subjected to cholecystectomy.\(^7\) Symptoms were relieved in 23 (79%) suggesting the validity of this entity.

Gallbladder Torsion

Daux reported the first case of torsion of the gallbladder identified at postmortem in 1925.\(^8\) Although the condition is typically found in elderly women, a few cases have been reported in children.\(^9\) About 50 cases have been documented in the literature with about 14 of those being in children. Invariably it is related to a mobile gallbladder with its own mesentery and pedicle consisting of cystic artery and duct.

In children it presents as an acute-onset right-sided pain with features of right upper quadrant peritonism.
A single case of torsion following blunt abdominal trauma has also been reported. A palpable mass may be found in about 10% of cases. It is possible to diagnose the condition on ultrasound or CT scan although this is uncommon. Kitagawa et al have suggested the following ultrasonographic signs (1) a collection of fluid between gallbladder and fossa, (2) horizontal rather than vertical appearance of gallbladder, (3) edema and wall-thickening. In addition there is often marked enhancement of the cystic duct, lying to the right of the gallbladder which can be apparent on CT or ultrasonography.

Cholecystectomy is usually required as the gallbladder is typically gangrenous at laparotomy. Percutaneous cholecystostomy has also been suggested by Quinn et al although perhaps only as a temporising measure.

**Polypoid Lesions and Adenomyomatosis of the Gallbladder**

Hyperplastic mucosal polyps occur either singly (Fig. 82.7) or multiple. Adenomyomatosis is a benign neoplastic condition which occasionally occurs in children. It may be defined as localised or diffuse hyperplastic extensions of the mucosa into the muscular layer and beyond. In adults it has been reported to be premalignant. The youngest such case in the pediatric literature appears to be a five-year-old child reported by Alberti et al.

**ACKNOWLEDGEMENTS**

Figures 82.2, 82.4 and 82.7 were kindly supplied by Mrs Pat Farrant and Figure 82.3 by Dr J Karani, both of the Department of Radiology at Kings College Hospital.

**REFERENCES**

Although the precise figure can never be known with certainty perhaps 10% of all liver masses are of vascular origin. These are mostly benign vascular tumors termed hemangioma or hemangioendothelioma (HAE). Such lesions can present in many ways; from being entirely asymptomatic, incidental lesions to multiple tumors almost entirely replacing liver tissue and causing life-threatening cardiac failure. As with hemangiomas in other parts of the body, the natural history of most lesions in the liver is to undergo initial rapid proliferation within the first 6-12 month of life and then spontaneous involution over the next 5-10 years. Hepatic angiosarcoma, not covered in this chapter, is the malignant counterpart of a hemangioma, which in adults is associated with environmental exposure to vinyl chloride monomer and rarely presents in childhood.

**HISTORICAL ASPECTS**

Isolated reports of hemangiomatous lesions of the liver appearing in infancy exist in the 19th century literature although they were often referred to as angiosarcoma or hemangioendotheliosarcoma. Kundstadler in a classic review of hepatic hemangiomatous lesions during childhood reported a case and reviewed the literature up to 1933, identifying 14 other cases. Anemia was frequently mentioned by early authors as one manifestation, although it was not directly related to red cell destruction within the liver lesions. The association of thrombocytopenic purpura and a giant capillary hemangioma of the skin was first reported by Haig Kasabach and Katharine Merritt in 1940 of New York and applied by later authors to a similar phenomenon in extensive liver hemangiomas.2

**EPIDEMIOLOGY AND PREVALENCE**

Cavernous hemangiomas of the liver are considered the second most common hepatic tumor, in the general population, exceeded only by hepatic metastases. Most, however, are clearly incidental lesions usually presenting in later life. In these, there is a female predominance although this seems to be less marked in children.

**HISTOLOGICAL AND IMMUNOHISTOCHEMICAL FEATURES**

Although there is a broad histological division between the predominantly solitary cavernous hemangioma and the often multifocal and bilobar hemangioendotheliomas, this may mean little in clinical practice. There can be histological overlap and commonly, no actual tissue is ever obtained for histological analysis. In most reports, there is no particularly precision to either of the two terms. Hemangiomas and hemangioendotheliomas (HAE’s) are histologically benign tumors arising from the hepatic mesenchyme. Their cut surface varies from grey to reddish brown with a spongy consistency. There may be areas of fibrosis, calcification, cystic degeneration and overt hemorrhage.

Hemangioendotheliomas may be isolated or multiple and tend to have smaller vascular spaces than hemangiomas. Dehner and Ishak subdivided them into two histological types with the most common, Type
Hepatic Hemangiomas

1, being composed of multiple small vascular channels lined by immature endothelial cells and separated by a fibrous stroma that may contain biliary ductules (Fig. 83.1). Type 2 HAE’s are less common lesions where the vascular spaces are lined by more pleomorphic and even frankly malignant-looking endothelial cells. These tend to form papillary-like structures budding into the vascular spaces and are without stromal bile ductules. Type 2 HAE’s tend to present outside of the neonatal period and there is a definite tendency for malignant transformation into overt angiosarcoma.

The immunohistochemical characteristics of HAE’s have been reported by Selby et al in a large series of 91 cases. In this series, about 20% were Type 2. Immunohistochemical staining for factor VIII was usually present. Bile ducts demonstrable by cytokeratin staining, were present in all cases, although largely confined to the periphery of the tumor. Other vascular cell receptors may be expressed such as vimentin, intercellular adhesion molecule (ICAM-1) and PECAM/CD31 but interestingly not vascular cell adhesion molecule (VCAM) or e-selectin. The underlying stromal cells can express α-smooth muscle actin (α-SMA) and vimentin had no aortic disparity, whereas this was almost invariably observed in those who had percutaneous angiograms some weeks later. Nevertheless, the reports from the obstetric literature detailed above do show definite prenatal examples of cardiac failure.

Rupture of a liver hemangioma and hemothorax has been reported rarely, both in children and adults, and usually with fatal consequences.

Jaundice may occur in up to 50% of cases and is multifactorial in origin. Commonly it is caused by increased hemolysis and a reduced erythrocyte life, span consequent upon "sumping" in the dilated tortuous vascular channels of the hemangioma. Occasionally, hemangiomas at the hilum appear to be a direct cause of obstructive jaundice. For instance, Hase et al described a four-month-old boy who presented with conjugated jaundice who had a 4 cm tumor arising in the hepatoduodenal ligament extending to the hepatic hilum, which had caused biliary obstruction. This was unresectable and treated by internal biliary stenting. Spontaneous resolution of the tumor occurred by 20 months, allowing stent removal and an excellent outcome.

Occasionally, gastrointestinal symptoms such as diarrhea and even malabsorption may be apparent although the mechanism of this in the absence of arterioporal hypertension is obscure.

Liver hemangiomas may be part of a multiple hemangioma syndrome. The commonest sites aside from the skin, are the lungs and the central nervous system. Other rarer sites have been the small bowel, larynx and trachea, vertebral column and spleen.

Table 83.1 illustrates the occurrence of liver hemangiomas that have been reported as part of a recognised malformation syndrome. Isolated cases have been reported of liver hemangiomas in association with congenital heart defects.

It has been recently recognized that hemangiomatous tissue may also secrete protein, hormones or hormone-like substances. Clinical manifestations of this phenomenon are however rare. The commonest example of this is the secretion of α-fetoprotein and abnormally high serum levels may cause diagnostic confusion between hepatoblastomas and solitary hemangiomas. A definite association with thyroid hormone abnormalities has recently been identified.

A recent analysis at our institution identified seven infants with multifocal liver HAE who had abnormal biochemical thyroid function. In seven, this was characterised by a raised TSH with otherwise variable plasma thyroxine levels. Autopsy liver material from one child showed positive immuno-
histochemical staining for TSH thought to be evidence for secretion of a TSH-like substance by the hemangiomatous tissue capable of causing inappropriate stimulation of the thyroid gland.

**CLINICAL FEATURES**

**Antenatal**

The antenatal liver hemangiomas have been reported although with markedly different clinical outcomes. For instance, Dreyfus et al identified a large markedly vascular, septated liver mass in a fetus.\(^\text{15}\) No intervention was necessary and indeed postnatal investigations showed spontaneous regression of the tumor. In contrast, Morris et al reported a fetus initially diagnosed at 17 weeks gestation to have a liver hemangioma with later antenatal ultrasound evidence of heart failure.\(^\text{13}\) This was treated with maternal and later postnatal corticosteroids with ultimate resolution.

Fetal liver hemangiomas may have effects upon the mother. Certainly, associated vascular anomalies of the placenta such as chorionangiomas have been reported.\(^\text{14}\)

**Postnatal**

Hemangiomas may well be entirely asymptomatic, particularly if small. Increasing size and vascularity make symptoms more likely and typically these can include a palpable abdominal mass hepatomegaly, failure to thrive, respiratory distress, cardiac failure, jaundice, anemia, thrombocytopenia and disseminated intravascular coagulation. Often the specific diagnostic clue is the presence of cutaneous hemangiomas, which have been described in up to 60% of cases.\(^\text{9}\)

Cardiac failure is high-output in nature and due to the huge, yet futile, hepatic artery to hepatic vein shunt through the liver. This can account for up to 50% of cardiac output in some cases and will be manifest as cardiomegaly, systolic cardiac murmurs, an abdominal bruit and marked aortic disparity above and below the origin of the relevant hepatic artery. It is not uncommon for the cardiac features to be so prominent that the actual cause of the failure is sometimes disregarded leading to a delay in diagnosis.

The hemodynamic changes, which accompany the rapid enlargement of the lesions, are usually considered as a postnatal phenomenon. Thus Stanley et al showed that all those infants who had angiography via the umbilical artery within one week of life has usually been ineffective.\(^\text{9}\) Holcomb et al described liver irradiation in five children who received from 350-2000 rads, apparently with reasonable tumor control in three.\(^\text{15}\) They also noted that an early case died later at the age of 12 years of leukemia.

**DIAGNOSIS**

Although the diagnosis of hemangiomatous lesions may not be straightforward. For most symptomatic lesions presenting in infancy a combination of ultrasonography, Doppler flow studies and dynamic contrast CT scanning should be adequate. Occasionally, plain radiographs may show hepatomegaly and intratumoral calcification with features such as cardiac enlargement and pulmonary plethora due to cardiac failure.\(^\text{8}\)

Ultrasonography and Doppler flow studies are not in themselves characteristic and may show hypoechoic, complex or even hyperechoic lesions.\(^\text{8}\) Dilatation of the draining hepatic veins may be seen and is consistent evidence of increased vascularity and a high flow shunt.

The characteristic CT appearance of hemangiomas is of a mass of lower attenuation than surrounding
Hepatic Hemangiomas

liver with an immediate intense peripheral enhancement and centripetal frond-like extensions following intravenous contrast administration (Fig. 83.2). More delayed scans will show contrast retained within periphery although there may be sequential central enhancement. Magnetic resonance imaging (MRI) shows decreased signal on T1-weighted images and increased signal on T2-weighted. Most are usually discrete and best seen on T2-weighted images as high intensity lesions (Figs 83.3A and B). Functionally they exhibit fast flow, which are seen as flow voids on spin-echo images and high signal intensity on gradient recalled echo images. Hepatic angiography has been used extensively to study the vascular nature of these tumors. The blood supply may be very variable although typically it is predominantly from the hepatic arteries and may be manifest as hypertrophy of the right and left hepatic arteries. The development of both collaterals and accessory arteries (e.g., phrenic arteries) is also common. Most lesions exhibit a rapid homogenous capillary blush, while others show peripheral eggshell opacification. Some hemangiomas may have predominantly a portal venous rather than arterial blood supply—which is angiographically apparent as late re-opacification of hepatic lesions. Occasionally direct portal vein to hepatic vein communications can be demonstrated with a minimal systemic arterial collateral circulation. Clearly, attempts at therapeutic embolization or arterial ligation will be completely ineffective for this latter type.

MANAGEMENT

The management of both symptomatic hemangiomas and HAE's is controversial and there is widespread disagreement between authors as to the most appropriate choice of therapy. Figure 83.4 illustrates a suitable management algorithm developed at our institution for hepatic hemangiomas/HAE's. Most asymptomatic lesions can simply be managed expectantly perhaps using serial ultrasonography to
document the expected pattern of resolution. However, at the other end of the symptom scale, those infants who present with catastrophic cardiac and respiratory failure will need emergency therapy effective immediately. This usually implies interventional strategies such as hepatic resection, hepatic arterial ligation or embolization.

The medical treatment for liver HAE and hemangiomas has not been standardized but in addition to the specific agents detailed below infants with clinical signs of cardiac failure will also require fluid restriction, digitalization and diuretics as supportive therapy. Occasionally epsilonaminocaproic acid (EACA) has also been suggested as supportive therapy to counter the intravascular coagulation seen in multiple HAE’s.

**Hepatic Arterial Ligation**

Early reports of successful hepatic arterial ligation (HAL) by De Lorimier et al. in 1967 in infants with cardiac failure and multiple liver hemangiomas showed the value of selective arterial devascularization. At that time there was 80-90% mortality in infants who were conservatively treated and this was the first effective treatment for the high-output cardiac failure due to shunting through typically unresectable, bilobar lesions. Further reports have confirmed its value in the management of multiple lesions particularly when associated with cardiac failure.

The effectiveness of HAL arises from the biological observation that liver hemangiomas and HAE are preferentially supplied by hepatic arterial rather than portal venous sources. Consequently, dearterialization causes selective ischemia in abnormal hemangiomatous tissue sparing normal hepatic parenchyma. In humans, and unlike dogs, hepatic necrosis is not a consequence of HAL provided that sepsis and shock can be avoided.

The largest experience of HAL in symptomatic RAE is from our institution, which described eight infants who had presented at a median age of four weeks with symptomatic cardiac failure. HAL was extremely
successful in controlling the high flow shunt and cardiac failure in six.

At operation it is important to look for all possible arterial sources in order to dearterialise the liver effectively including accessory arteries in the lesser omentum from the right gastric artery and an aberrant right hepatic artery from the superior mesenteric artery. A cholecystectomy should also be performed, as the cystic artery will be ligated. Bile duct ischemia due to devascularization is a possible sequel and we have had one child who developed a spontaneous duodeno-biliary fistula manifest some years after HAL as recurrent cholangitis.

**Hepatic Artery Embolization**

Transcatheter arterial embolization of the feeding vessels was introduced in the 1980's to control the high-output cardiac failure in infants with RAE. Numerous materials have since been used to achieve thrombosis including gelatin sponge particles (Gelfoam), polyvinyl alcohol particles (Ivalon), silicone balloons, cyanoacrylate and coils.

The procedure requires a high degree of skill and experience in pediatric angiography is essential. A variety of technique-related complications have been reported including hepatic necrosis, renal infarction and pulmonary embolism. Femoral artery damage is common although fortunately this does not usually lead to clinical sequelae due to collateral formation. Nevertheless, a possible late manifestation of femoral artery damage is inequality of lower limb growth.

The effectiveness of dearterialization (either HAL or embolization) procedures will depend upon the scale of the arterial input, the type of arteriovenous shunt and its contribution to symptoms. If the blood supply to the hemangiomatous tissue is predominantly from the portal vein then arterial embolization will not be helpful and is contraindicated. Dearterialization is also unlikely to be of benefit in infants where the clinical manifestations are more characteristic of low-flow "sumping" (e.g. consumption coagulopathy and anemia) rather than a high-flow arteriovenous shunt (e.g. cardiac failure).

**Hepatic Resection**

Unilobar tumors may be effectively treated by partial hepatectomy (right, left or non-anatomical). Nevertheless, resection of a large hemangioma can be formidable as the liver is soft and friable in the early weeks of life coupled with the difficult dissection necessary to control the invariably dilated hepatic veins. Resection is usually the most suitable treatment for the late-presenting solitary tumor, particularly if there is doubt about its histological nature. In some centers, liver resection has been the only alternative to medical treatment. For instance, Luks et al. in Montreal described 7 of 16 cases where resection was carried out without morbidity or mortality, the other cases being managed entirely medically.

Some novel techniques have been used to aid safe resection surgery. For instance, Ranne et al. reported the use of hypothermic circulatory arrest and liver resection in two infants with cardiac failure and liver hemangiomas. The first, a four-day-old infant, underwent closure of an atrial septal defect and a left partial hepectomy for hemangioma and the second, a 12 day-old infant, an extended right hepectomy for HAE.

**Transplantation**

The option of complete liver excision and transplantation arrived with the advent of successful liver transplant programs in the early 1990's. However, real evidence of its value is still lacking and there are still considerable logistical problems related to lack of suitable size-matched donor organs and the urgency in which therapy is often needed.

The first successful liver excision and orthotopic liver transplantation (OLT) was reported in a child with RAE in 1994 by Egawa et al. At the time of transplant she was six months old and had required ventilation due to the massive size of her tumor. Daller et al from the Thomas Starzl Transplant Institute in Pittsburgh, USA have recently reported their experience with infantile HAE. Thirteen infants and children were referred for treatment for symptomatic HAE and giant hemangiomas at a median age of 14 days. Aside from the range of medical therapies, a variety of interventional techniques were used including resection (n = 5), embolization (n = 6), HAL (n = 2) and OLT (n = 3). However, the overall results were not good and only six (46%) children survived. Of the three infants who underwent OLT, one was for bilobar disease and the other two for Budd-Chiari syndrome following attempted resections. Only one remains alive, the others have died from transplant-related complications.
CAVERNOUS HEMANGIOMAS IN ADOLESCENTS AND ADULTS

Although the majority of cavernous hemangiomas will be incidental findings, some of the larger examples may become symptomatic, usually causing a dull ache or feelings of dragging. Cardiac failure is not seen and consumption coagulopathy is exceptional. A relationship with estrogens use has been suggested although with the female predominance this may well be incidental. Most surgical series concentrate on those > 4 cm in diameter and anything smaller tends to be ignored as trivial. For instance, Trastek et al.22 reported the Mayo Clinic experience of 118 adult patients with cavernous hemangiomas. Of these 49 (41%) were > 4 cms in diameter and 12 (10%) were resected. No complications occurred in 35 who were followed expectantly for an average of five years. Reading et al reported the Kings College Hospital experience of 24 adults (mean age 43 years) with cavernous hemangiomas of which 15 were symptomatic.23 Resection and/or gelfoam embolization were performed in cases. The later treatment was usually associated with reduction in symptoms but seldom with a reduction in size and furthermore in two of the larger examples multiple liver abscesses occurred.

REFERENCES

Liver abscess is a relatively rare but life-threatening condition in childhood. Failure to diagnose and treat the abscess(es) promptly and appropriately may cause serious morbidity or death. Accounts of the condition date back to Hippocrates (460-375 BC) who included abscesses in his accounts of liver disease and stated that they were least dangerous when opened externally. In modern times, it was not until 1938 that the first detailed study was published. Most liver abscesses are either pyogenic or amebic.

ETIOLOGY

Pyogenic liver abscess may develop in apparently healthy children, particularly in developing communities where protein calorie malnutrition and worm infestation are probable predisposing factors. In developed communities, liver abscess is more often seen in immunocompromized children, especially those with chronic granulomatous disease (see below).

Several pathways of infection may result in a liver abscess:
- **Biliary tract:** Ascending bacterial infection via the biliary tract or directly from the gallbladder
- **Portal vein:** From acute appendicitis or intra-abdominal sepsis
- **Hepatic artery:** From septicemia originating from a distant source, or bacteremia resulting in infection of a pre-existing hepatic lesion such as a hematoma or focal infarction
- **Direct:** From penetrating trauma or spread from contiguous intra-abdominal sepsis.

In the immunocompetent child, biliary tract disease is the commonest overall source. There still remains a substantial group of patients with cryptogenic abscess. Potential predisposing factors to pyogenic liver abscess are shown in Table 84.1.

**Biliary Tract Diseases**

This includes a wide variety of pathologies which can cause ascending bacterial cholangitis and intrahepatic abscess formation. Choleodocholithiasis, cholecystitis
cause liver abscess by obstruction of the biliary tree and ascending bacterial cholangitis. In addition, several authors have suggested that helminthic infestations such as ascariasis and toxocariasis, in which larvae migrate through the liver, may indirectly predispose to pyogenic liver abscess. Helminths can reduce the microbicidal activity of phagocytes and promote a granulomatous reaction encouraging trapping of bacteria in the liver.

### Intra-abdominal Sepsis

Acute appendicitis may be complicated by portal pyemia and liver abscess. In a literature review, Sorensen et al (1983) identified acute appendicitis as the cause of pyogenic liver abscess in only 8% of reported cases. This complication may present with nonspecific symptoms and signs either before or after a diagnosis of acute appendicitis but should be suspected in a persistently unwell child with signs of sepsis and hypoalbuminemia. In such children, an abdominal ultrasound scan may reveal a focal liver mass of low-to-mixed echogenicity and/or evidence of portal vein inflammation (Fig. 84.1). Portal vein thrombosis is a potential complication of portal pyemia.

Bacteria can be isolated from portal venous blood samples in up to one-third of patients undergoing surgery but the hepatic reticuloendothelial system normally prevents these pathogens from causing disease. In acute appendicitis, portal bacteremia occurs more frequently. In one study, bacteria were isolated from superior mesenteric venous blood samples in at least 40% of patients with appendicitis. Bacteroides spp. and *Escherichia coli* were most frequently identified. When the liver is compromised as a result of poor perfusion or disease or when the hepatic defence systems become overwhelmed by excessive numbers of bacteria, as in some cases of intra-abdominal sepsis, suppurative infection may supervene. In addition to appendicitis, other sources of intra-abdominal sepsis may be complicated by a pyogenic liver abscess. These include inflammatory bowel disease, necrotizing enterocolitis, and foreign body perforation of the gut.

---

**Table 84.1: Potential predisposing factors to pyogenic liver abscess**

- Biliary tract diseases, e.g. calculi, choledochal cyst, Caroli’s, cholecystitis, biliary atresia, etc.
- Intra-abdominal sepsis, e.g. appendicitis, NEC, Crohn’s disease, foreign body perforation, etc.
- Distant sepsis/septicemia, e.g. osteomyelitis, pneumonia, bacterial endocarditis
- Structural liver lesions, e.g. cysts (parasitic or simple)
- Blunt or penetrating liver trauma
- Hepatic artery thrombosis, e.g. after liver transplantation
- Sickle cell anemia
- Chronic granulomatous disease
- Immunosuppression
- Recent measles infection
- Protein energy malnutrition
- Ascariasis
- Toxocariasis
- Papillon-Lefèvre syndrome
- Venticulo-peritoneal shunts
- Cirrhosis (adults)
- Underlying hepatic malignancy (adults)
Liver Abscess in Children

Distant Sepsis

Septicemia from a distant site of infection may cause the development of a pyogenic liver abscess. For example, bacterial endocarditis, osteomyelitis and pneumonia may be complicated in this way; multiple small hepatic abscesses are more common than solitary lesions.

Trauma

An intrahepatic abscess may form after blunt or penetrating liver trauma. Penetrating wounds may lead to direct contamination of injured liver and after blunt trauma, hematogenous infection of a hematoma may result in abscess formation.

Structural Liver Lesions

A variety of structural abnormalities in the liver, both congenital, and acquired, may be complicated by infection and hepatic abscess formation. Caroli’s disease is a congenital segmental saccular dilatation of the intrahepatic bile ducts with intervening ducts of near normal caliber. It may affect the liver diffusely or be localized to one lobe, more often the left. The condition typically causes recurrent cholangitis which may present with fever, jaundice or abdominal pain.

Hepatosplenomegaly is common and intrahepatic abscess and/or stone formation may complicate the disease. Most cases present as young adults but pediatric examples have been reported. Simple liver cysts rarely become infected unless there have been attempts to drain them. In endemic regions, hydatid cysts may be complicated by pyogenic infection. Mesenchymal hamartoma may rarely become infected but, unlike adults, liver abscess in children is almost never the presenting feature of an underlying hepatic malignancy. In adults, cirrhosis of the liver is associated with a higher incidence of pyogenic liver abscess because of impaired immunity and macrophage function, and the potential for abdominal infection but this association has not been documented in children.

Other Causes of Pyogenic Liver Abscess

Children with chronic granulomatous disease, an inherited disorder of neutrophil function, are particularly susceptible to infection with catalase-positive organisms such as *Staphylococcus aureus*, gram negative bacteria such as *Escherichia coli* and *Serratia marascens*, and fungi such as *aspergillus* and *candida* species. These children typically present in early childhood with recurrent pyogenic abscesses which may involve the liver.

Hepatic allografts which are retained after hepatic artery thrombosis following liver transplantation are often complicated by focal infarction and/or biliary complications, both of which predispose to hepatic abscess formation. Liver abscess may also complicate sickle cell disease either as a consequence of biliary tract pathology (including choledocholithiasis) or after a vaso-occlusive crisis with segmental hepatic infarction.

Rarely, pyogenic liver abscess has been reported as a complication of ventriculoperitoneal shunting for hydrocephalus. The shunt partially erodes into the liver resulting in the formation of an intrahepatic cyst which becomes secondarily infected. Along with treatment of the abscess, the peritoneal part of the shunt must be externalized.

Papillon-Lefevre syndrome is an autosomal recessive condition characterized by palmoplantar keratosis and severe periodontopathy. The disease is related to defects in cell-mediated immunity and neutrophil function which, together with possible
bacteremia from dental disease, are responsible for infections at other sites, including liver abscesses.\textsuperscript{32}

**PATHOLOGY**

Abscesses may be single or multiple, unilocular or multilocular. Multiple abscesses are more often associated with biliary tract diseases. The right lobe is the site of abscess formation in more than two-thirds of patients.

*Staph. aureus* and *E. coli* account for most cases of pyogenic liver abscess (Table 84.2).\textsuperscript{5,7,33} In the Western Cape Province of South Africa, *Staph. aureus* was identified in 85\% of children with a pyogenic liver abscess.\textsuperscript{6} The *Streptococcus milleri* group of bacteria (which includes *Str. intermedius* and *Str. anginosus*) are important pathogens in adults with a liver abscess and may be the causative organism in some children. An occult hepatic abscess should be suspected if blood cultures are positive for *Streptococcus milleri*.\textsuperscript{34} These bacteria may be mistaken for anaerobes but are resistant to metronidazole and usually sensitive to penicillin. However, anaerobic organisms should always be suspected if the abscess contains gas. Hemophilus influenzae and other haemophilus species may rarely cause pyogenic liver abscess in unvaccinated children.\textsuperscript{35} Cat-scratch disease is an infection caused by a gram-negative bacillus, Bartonella henselae, and is another rare cause of liver and spleen abscesses in children.\textsuperscript{36}

**CLINICAL FEATURES**

Pyogenic liver abscess usually presents with fever and general malaise. Most school age children complain of upper abdominal pain. The duration of symptoms is variable but usually less than 3 weeks. Other symptoms may include anorexia, nausea and vomiting, weight loss, cough, and abdominal distension. Clinical signs include fever, tender hepatomegaly, and jaundice especially in those with biliary tract diseases and/or multiple liver abscesses. A right-sided pleural effusion may be present.

Routine laboratory investigations typically show anemia and leucocytosis with elevated inflammatory indices (C-reactive protein, plasma viscosity, and erythrocyte sedimentation rate) and hypoalbuminemia. Abnormalities of biochemical liver function are found in half the patients and include raised serum alkaline phosphatase and, to a lesser extent, bilirubin and transaminase levels. Blood cultures may be positive in up to 50\% of patients.\textsuperscript{7} Suspicion of chronic granulomatous disease may be confirmed by nitroblue tetrazolium test.

**DIAGNOSIS**

A pyogenic liver abscess should be suspected in any child with fever, abdominal pain and hepatomegaly. A plain chest radiograph may show an elevated right hemidiaphragm or pleural effusion or, rarely, gas or a fluid level within the abscess. Ultrasonography has proved to be sensitive method of detecting liver abscesses but may miss smaller lesions and those in the dome of the liver.\textsuperscript{37-39,41} Lesions are typically hypoechoic and round to oval with ill-defined margins and variable internal echoes (Figs 84.2A and 84.3A). A ring of hypoechoic liver edema often surrounds the lesion. Computed tomography (CT) is the most sensitive imaging modality for liver abscess.\textsuperscript{40,41} (Figs 84.2B and 84.3B). Appearances are variable and include low-density areas, cavities and more complex images. US and CT also provide other useful information about the cause of the pyogenic liver abscess. It has been suggested that, unlike fungal or mycobacterial microabscesses, small pyogenic abscesses tend to cluster, or aggregate, in a pattern that suggests the beginning of coalescence into a single, larger abscess cavity.\textsuperscript{42}

Conventional radionuclide scans are of limited diagnostic value but gallium scanning and labelled white cell scans may have a role in selected cases.\textsuperscript{41,43,44} With any imaging technique, pyogenic liver abscesses must be distinguished from liver cysts, tumors, pseudotumor, vascular malformations, and hematomas.

TREATMENT

This is guided by three basic principles:

- Confirm the diagnosis and determine the anatomy of the abscess(es).
- Treat with broad-spectrum intravenous antibiotics.
- Drain the abscess if there is no prompt clinical response to therapy.

The success of an initial non-operative approach has been verified by many authors in recent years.\(^7\)\(^4\)\(^5\)

In addition to the above measures, the patient will require correction of severe anemia and any fluid and electrolyte imbalance. Any underlying condition and associated diseases will require specific treatment.

Antibiotic Therapy

These must be an appropriate antibiotic given for an adequate duration. A penicillinase-resistant penicillin with an aminoglycoside and metronidazole is a...
suitable initial antibiotic regimen but a third generation cephalosporin and aminoglycoside is a reasonable alternative. In patients not responding promptly, percutaneous drainage will help to establish bacterial profiles and antibiotic sensitivities. Antibiotics are usually administered for 6-8 weeks but this is somewhat empirical. Symptomatic improvement is usually swift but complete sonographic resolution may take up to 8 weeks. In children with chronic granulomatous disease, antibiotic therapy may need to be supplemented with interferon gamma therapy to achieve abscess resolution.27

**Percutaneous Drainage**

Ultrasound-guided percutaneous needle aspiration/drainage should be considered in patients not responding to conservative therapy within 48 hours, i.e. those with persistent toxemia, tenderness and/or peritonism, and also in patients where the abscess is deemed to be at risk of imminent rupture.29 Some have recommended earlier drainage for left-sided liver abscesses which may be more prone to rupture.45 An anterior subcostal approach rather than a mid-axillary transpleural approach avoids the risk of empyema.29 Lavage may increase the risk of septicemia and is not routinely used but drainage catheters should be flushed with sterile saline 4-6 times daily.46

Although simple aspiration can be therapeutic it is generally less effective than catheter drainage. Rajak et al (1998), compared the efficacy of repeated sonographically guided percutaneous needle aspiration and percutaneous catheter drainage (both with appropriate antimicrobial therapy) in the treatment of liver abscesses larger than 3 cm in adults and found the latter to be superior.47 With catheter drainage, 8-12 French pigtail or sump catheters are introduced into the abscess cavity under ultrasound or CT guidance using a Seldinger’s technique. Percutaneous catheter drainage is now the procedure of choice in the drainage of pyogenic abscesses.29,48,49 Drainage is continued until abscess resolution is evidenced by defervescence, cessation of catheter drainage and ultrasound scan.50

**Open Surgical Drainage**

This is applicable in children with larger abscesses not responding to more conservative measures and in those undergoing laparotomy to treat a primary source of infection. A large perforated tube drain (18-24 Fr) is inserted into the abscess cavity, the wall of which should be biopsied to exclude amebic infection.

Rarely, hepatic resection is required. Indications include a chronically infected fibrotic cavity and focal hepatic involvement in Caroli’s disease. For oriental cholangiohepatitis and biliary ascariasis, interventional endoscopic procedures may also be necessary.

**RESULTS AND COMPLICATIONS**

The most serious complications of a pyogenic liver abscess are septicemia and rupture, both of which may be fatal. Rupture may lead to a subphrenic abscess, empyema or peritonitis.44,45 Liver abscess may rarely cause hemobilia manifesting as gastrointestinal bleeding this should be managed by angiography and selective arterial embolization. Metastatic septic endophthalmitis has also been reported in patients with Klebsiella liver abscess.51-53

Mortality from pyogenic liver abscess is now less than 10%.6,45 In a series of 98 pyogenic and 26 amebic abscesses in children from South Africa, Moore et al (1994) reported no fatalities in those treated by an initial nonoperative approach. Kumar et al (1998) recorded an 11% mortality in 18 children with pyogenic liver abscess from Southern India, but one of the two deaths in this series presented with septic shock.7,15 At greater risk of mortality and morbidity are immunodeficient children and those with other underlying diseases, patients with multiple abscesses, and those experiencing treatment complications.54

**AMOEBIC LIVER ABSCESS**

Amoebic liver abscess is the commonest extraintestinal manifestation of amebiasis and affects up to 10% of infected adults. The disease is less common in children but is associated with significant morbidity and mortality.55,56

**EPIDEMIOLOGY**

Amebiasis is endemic in much of Asia, Africa, Central and South America and is frequently associated with poor sanitation, malnutrition, and concomitant infectious diseases. Amebic liver abscess is most common in India, Pakistan and the Far East.56,57
is a slight male preponderance in children with amoebic liver abscess. The mean age of affected children was 2 years in the Cape Town series and three-quarters of patients were less than 10 years in a report from Karachi, Pakistan.

**PATHOLOGY**

Hepatic amoebiasis originates from intestinal infection by the protozoan parasite, *Entamoeba histolytica*. Amoebic liver abscesses develop after the trophozoites enter the portal venous system via the gut. Thrombosis of small portal venous radicles results in foci of liquefactive necrosis and the formation of characteristic “anchovy sauce” pus. Small abscesses coalesce to form large abscesses which expand and may rupture. Multiple abscesses occur more often in children than adults but in some series solitary lesions predominate. As with pyogenic abscesses, right lobe lesions are more common. A solitary left lobe abscess is present in approximately 10% of patients.

**CLINICAL FEATURES**

The typical presentation is a young debilitated child with a fever, right upper quadrant abdominal pain, and tender hepatomegaly. A previous history of bloody diarrhea is common but evidence of active amoebic colitis is unusual. Jaundice is uncommon. Some patients present with a pyrexia of unknown origin or with the consequences of abscess rupture. In some cases, acute abdominal signs may cause confusion by suggesting perforated appendicitis.

**DIAGNOSIS**

The key elements to diagnosis are imaging and serology. Investigations frequently show anemia and hypoalbuminemia and there may be a leucocytosis. Biochemical liver function tests are often normal or only minimally deranged. Cysts or trophozoites in the stool can only be isolated in one-third of patients. There exists a wide variety of serologic tests for invasive amoebiasis but they cannot differentiate between previous and current infection. They depend on the detection of anti-amoebic antibodies. In children with amoebic liver abscess serology is almost invariably positive but these tests are less reliable in affected infants.

A chest radiograph may show an elevated right hemidiaphragm, right pleural effusion, or right lower lobe changes. As with pyogenic liver abscess, ultrasound scanning and CT are sensitive imaging techniques. Ultrasound provides excellent anatomical information and demonstrates a characteristic peripheral halo with central liquefication. However, it does not reliably distinguish between amoebic and pyogenic liver abscess. Both ultrasound and CT are useful in detecting transdiaphragmatic pleural involvement. Magnetic resonance imaging shows no specific image or intensity pattern and is comparable to ultrasound and CT in the detection of amoebic abscess.

Diagnostic percutaneous aspiration of the abscess may be used in diagnosis; the aspirate is odorless and bacteriologically sterile (unless complicated by secondary bacterial infection) and may contain trophozoites. The characteristic “anchovy sauce” appearance is a variable finding. Recently, polymerase chain reaction technology has been successfully used to identify *E. histolytica* DNA in liver abscess pus.

**TREATMENT**

This consists of antimicrobial therapy with or without abscess drainage.

**Antimicrobial Therapy**

Small uncomplicated amebic liver abscesses can be successfully managed by antimicrobial therapy alone. Metronidazole is effective against both liver and intestinal parasites and is the drug of choice for amoebic liver abscess. The recommended doses are age related, ranging from 100 mg orally tds for children aged 1-3 years to 200 mg orally qds for 7-10 year old. The duration of treatment is 10-14 day. Most patients will respond clinically within 48-72 hours. Some authors recommend initial treatment with intravenous metronidazole and broad-spectrum antibiotics, discontinuing the later once the diagnosis of amoebic liver abscess is confirmed. This has the merit of treating co-existent secondary bacterial infection of the abscess.

Clinical response is the major determinant of successful treatment. Clinical and hematologic parameters return to normal within days and weeks, respectively but sonographic resolution takes
months. This delay in sonographic resolution does not warrant additional or prolonged therapy.

**Abscess Drainage**

Ultrasound guided percutaneous aspiration or catheter drainage of amoebic liver abscess may be indicated for the following reasons:

1. To distinguish pyogenic from amoebic abscess in nonendemic areas.
2. In cases failing to respond to metronidazole (lack of clinical and sonographic improvement within 48 hours).
3. For abscesses with signs of impending rupture (e.g. lesions >7cm diameter).
4. For large left lobe abscesses.

Percutaneous needle aspiration has yielded excellent results. In a series of 48 consecutive children with amoebic liver abscesses from Pakistan, 28 required aspiration, and 9 required repeat aspiration. No patient required open surgical drainage and all recovered without relapse.

Open surgical drainage is now reserved for the treatment of complications.

**RESULTS AND COMPLICATIONS**

The commonest complication is rupture into the pleural cavity and lung which results in pleural effusion, empyema and bronchopleural fistula. Chest tube drainage is required in addition to treatment of the liver abscess. The most serious complication is pericardial erosion from a left lobe abscess; this may lead to cardiac tamponade which requires urgent drainage of the liver abscess with or without pericardiocentesis. Intraperitoneal rupture causes peritonitis and intra-abdominal abscess formation, erosion of adjacent viscera such as the stomach can cause hematemesis, and rarely, hemobilia may develop. Many of these complications require laparotomy but localized intraperitoneal rupture can be treated by percutaneous drainage of the abscess and intravenous metronidazole. In recent years, patients with ruptured amebic liver abscesses have been increasingly managed successfully by percutaneous catheter drainage irrespective of the extent of extrahepatic contamination.

Morbidity and mortality from amoebic liver abscess have declined as a result of improved public health, earlier and more accurate diagnosis, and effective antimicrobial therapy. Overall mortality is significantly increased if the abscess ruptures or if it occurs in infancy.

Although hepatic amoebiasis can be treated effectively, it remains an important cause of morbidity and mortality in endemic regions. The future lies in prevention which demands socioeconomic interventions to improve public health and, hopefully, the development of a vaccine.

**NEONATAL LIVER ABSCESS**

Liver abscess is rarely encountered in neonates. Moss and Pysher (1981) identified only 24 cases in the literature prior to their report of 13 autopsy cases seen over a 20 year period. Infection may occur through several routes: following umbilical vein cannulation via the portal vein after intra-abdominal infection or surgery for necrotizing enterocolitis via the hepatic artery as part of a generalized septicemia, when abscesses are more often multiple; and as a complication of catheter migration and infusion of parenteral nutrition into the hepatic vein. Infusion of hypertonic solutions (such as 8.4% sodium bicarbonate or parenteral nutrition) and direct bacterial contamination may be significant factors with umbilical venous catheter sepsis. Given the frequency of portal vein gas in necrotizing enterocolitis, it is perhaps surprising that liver abscess does not occur more often in this setting. In endemic areas, amebic liver abscess may also occur in the neonatal period.

Clinical presentation and laboratory findings are frequently non-specific but indicative of sepsis. Hepatomegaly, abdominal tenderness and distension, with or without respiratory symptoms and signs may suggest the diagnosis. Leucocytosis, thrombocytopenia and abnormal liver enzymes are common. Sonography may show a solitary abscess but multiple, small abscesses are more commonly found. The causative organism is usually Staph. aureus, gram negative bacteria such as Klebsiella, Pseudomonas and E. coli, or Candida sp. Most cases can be managed medically with appropriate intravenous antibiotic therapy. Solitary abscesses may require percutaneous catheter drainage.
OTHER CAUSES OF LIVER ABSCESSES

Other rare causes of liver abscess include candidiasis (particularly immunocompromised children and neonates), actinomycosis, tuberculosis, listeriosis, brucellosis, and echinococcal disease.77,78

REFERENCES

HISTORY

The word "Echinococcosis" is of Greek origin and means "hedgehog berry". It was first used by "Rudolphi" in the period between 1801 and 1808. It is clear that human cystic hydatid disease was already known to Hippocrates and Galen and that the parasitic nature of this disease was strongly suspected in the 17th century. It was first noted in Talmud and was known to Hippocrates as "livers full of water". "Hydatid" is also of Greek origin and means "drop of water" or a "water vesicle". Siebolt in 1853 and Haubner in 1855 experimentally confirmed the cycle of the parasite. Hydatid cysts was demonstrated to be a zoonosis in 1862. It was only during the present century, however, that significant advances were made in accurate diagnosis and effective treatment of hydatid disease in the human. After World War II, enormous advances were achieved in surgical techniques and organ imaging techniques, as well as in immunologic diagnosis, so that the stage has been reached when both the diagnosis and treatment of human hydatid disease is at a most effective and sophisticated level. During the past 50 years an increasing understanding of the surgical pathology of human-hydatid disease and innovative developments in surgical technique have resulted in a very marked decrease in the mortality of human hydatid disease and, even more importantly, a very significant decrease in the morbidity that, in the past, often followed surgery for hydatid disease.

EPIDEMIOLOGY

E. granulosus thrives in environments as diverse as Arctic tundra and the deserts of North Africa. Cysts have been detected in up to 10% of the population in Northern Kenya and Western China. Among developed countries, the disease is well known in Italy, Greece and Australia. In the United States there is transmission in Alsaka, as well as foci in sheep herding areas of the Western States and Isle Royale on Lake Superior, where there is a wolf/moose cycle.

The disease is common in several Mediterranean countries and in a continuous belt eastwards up to the Indian subcontinent. In India, it is mainly reported amongst the south Indians and Indian Tamils. It is most frequently reported in the states of Tamilnadu, Andhra Pradesh, Gujarat. It is also common in Maharashtra, Madhya Pradesh, West Bengal, Himachal Pradesh and Punjab.

LIFE CYCLE (FIG. 85.1)

E. granulosus has a well established life cycle, which is shown in the following cycle:

Host Range

Definitive Hosts
Dog, wolf, dingo, and other canidae.

Intermediate Host
Herbivore (sheep, bovines, swine, goats, equine, camelids) and man.

Infectious Dose
Not known.
Mode of Transmission
Hand to mouth transfer of eggs from dog feces; fecally contaminated food and water; in Northwest Canada, disease is maintained by wolf-Moose cycle, from which the dog bring the parasite to people.

Incubation Period
It is variable, from 12 months to years, depending on the site and number of cysts.

Communicability
It is not directly transmitted from person to person, Dogs begin to pass eggs 7 weeks after infection.
Though most infections subside after 6 months; adult worms may survive for 2-3 years.

**Morphology**

- **Adults:** 2-7 mm long; usually has only 3-4 segments; scolex has 4 suckers and the rostellum has 2 rows of hooks.
- **Eggs:** (Fig. 85.2) Typical of taeniids, 32-36 × 25-30 microns.
- **Hydatid cyst (unilocular):** Usually 5-10 cm, but up to 50 cm in diameter, fluid filled; consisting of an outer laminated membrane and an inner germinal membrane from which multiple brood capsules containing many protoscolices develop (Figs 85.3 and 85.4). It is highly infective.

The ova, which are ingested by the human from the feces of the tapeworm-infected dog, reach the stomach, where they hatch, then penetrate the wall of the intestine and pass to the liver through a portal vein radicle. Some are destroyed in the liver, some develop into a hydatid cyst, and others pass through the hepatic veins into the systemic circulation to develop as hydatid cysts anywhere else in the body. In any of these sites, the development of cysts in the human is very slow but appears to be variable in its rate, possibly related to the immunologic interplay between the human and the hydatid parasite. It is emphasized that in the human, within the abdominal cavity, extrahepatic hydatids can also develop following either extrusion from the liver of a hydatid cyst or rupture of a hydatid cyst through the liver capsule and dissemination within the abdominal cavity, either spontaneously or, more commonly, during hepatic hydatid cyst surgery.

**PATHOLOGY**

The most common unilocular hydatid cyst is caused by *Echinococcus granulosus*, while the alveolar type is caused by *E. multilocularis*. Approximately 70% of hydatid cysts are located in the liver, and in one-quarter to one-third of these cases there are multiple cysts. The right lobe is affected in 85% of patients. Cysts are usually superficial and are composed of three layers.

1. **The adventitia (pseudocyst),** consisting of fibrous tissue, is the result of reaction of the liver to the parasite, is grey in color and blended intimately with the liver, from which it is inseparable.
Hydatid Disease

2. The laminated membrane (ectocyst) (Fig. 85.5) formed of the parasite itself is whitish and elastic, and contains the hydatid fluid. Indeed, this membrane closely resembles a child’s uncolored balloon filled with water, and unless bacterial infection has occurred it peels readily from the adventitia. Hydatid fluid is crystal-clear; it registers a specific gravity of 1.005-1.009, has a high pressure of approximately 300 mm of water. It is slightly alkaline, contains no albumin, and when not too old, also has hooklets and scolices. The cyst grows very slowly.

3. The only living part of a hydatid cyst is a single layer of cells (germinal epithelium) lining the cyst (endocyst); This secretes: (a) internally: the hydatid fluid; (b) externally: the laminated membrane. Brood capsules within the cyst develop from the germinal epithelium and are attached by pedicles to its innermost wall. Within the brood capsules, scolices (heads of future worms develop. Should the laminated membrane become damaged, it disintegrate, and the brood capsules, becoming free, grow into daughter cysts. In this event the mother cyst ceases to exist as such, the hydatid fluid and its content being confined by the adventitia only.

   Extension is commonly into the peritoneal cavity, but progressive intrahepatic expansion may result in the replacement of liver parenchyma. In contrast to the unilocular hydatid cysts, the alveolar hydatid is a growth without a capsule and with a tendency toward multiple metastases. As growth progresses, the center becomes necrotic, and the periphery invades the blood vessels and lymphatic channels.

**CLINICAL FEATURES**

The clinical features of hydatid disease depends on the site, size, stage of development, whether the cyst is alive or dead and whether the cyst is infected or not.

Clinically hydatid cyst may present as an asymptomatic cyst or symptomatic cyst due to infection, pressure effects, rupture and bile duct communication.

**Asymptomatic Presentation**

The outstanding feature of a simple, uncomplicated, liver hydatid cyst is its clinical latency. The hydatid produces few symptoms until complications occur.

Symptomless unsuspected, cysts can be detected during routine examinations, or at operations or autopsy. In the absence of complications and with an annual growth rate of 1-2 cm, the cyst may be as old as the patient. the only complaint may be a dull ache in the right upper quadrant, and a feeling of abdominal distention associated with hepatomegaly. An exception is 'hydatid cachexia', when an infected child, harboring a large cyst, becomes cachectic.

**Symptomatic Presentation**

**Infection**

An asymptomatic hydatid cyst may become infected. Leakage of the cyst is an essential preliminary to infection, as entry of serum into the cyst makes it an excellent medium for rapid bacterial growth. Secondary invasion by pyogenic organisms follows rupture into the biliary passage. The clinical presentation is as a pyogenic abscess and the parasite dies. The most frequently isolated organism is Escherichia coli.

**Pressure**

A viable liver hydatid cyst is a space-occupying lesion with a tendency to grow. In confined areas, such as
the central nervous system, small cysts cause serious
symptoms. In less restricted areas the symptoms
depend on the site and size of the cyst. Symptoms may
result from direct pressure or distortion of neighboring
structures or viscera. An enlarging liver cyst causes
compression atrophy of surrounding hepatocytes and
fibrosis. This can lead to compensatory hypertrophy
of the remaining liver tissue. Frequently an entire liver
lobe can be replaced by an enormous cyst. The cyst
grows in the direction of the least resistance.

Rupture

It may be of various forms,
- Obscure – as a result of rupture of the endocyst
  only, content is retained by the pericyst.
- Communicant – where the content enters the
  biliary or bronchial tree.
- Free – the hydatid contents disseminate throughout
  the peritoneal pleural and pericardial cavity.

Live hydatid cysts can rupture into:
- Physiologic channels—e.g. biliary or bronchial tree.
- Free body cavities—peritoneal, pleural or
  pericardial cavities.
- Adjacent organs—digestive tract.

Intraperitoneal rupture can present in several forms.9
- As acute abdominal symptoms due to peritoneal
  irritation by the cyst.
- As anaphylactic shock with severe circulatory
  collapse which may be fatal, tends to mask the
  abdominal manifestations.
- It may be totally silent with the patient presenting
  years later with disseminated abdominal
  hydatidosis.
- Rarely as herniation of the laminated membrane
  through the adventitial pericyst presenting as a
  ‘dumb-bell hepato-peritoneal cyst’. This condition
  mimics ascites and aspiration can lead to allergic
  manifestations.

The cyst can rupture into adjacent organs, e.g. into
the stomach, duodenum or small intestine.

These patients develop hydatidemesis (hydatid
cysts and membranes in the vomitus) and hyda-
tidenteria (passage of hydatid membranes in the
stools) with diminishing of clinical symptoms
Hydatiduria has been described.10,11 Rupture into the
aorta, the inferior vena cava into pericystic blood
vessels, the gallbladder, and into the heart with
subsequent embolism has been described.12-16

Hydatid cysts located in the dome of the liver close
to the diaphragm tend to generate intrathoracic
complications. A sympathetic pleural effusion occurs
which is sterile on culture. Infection and continued
expansion of the cyst causes pressure erosion and
adhesion to the diaphragm. Expansion of the cyst
stretches and ruptures the diaphragm and the cyst
eventually becomes contiguous with the pleural space.
In time, with increasing intracystic pressure, the cyst
ruptures into the pleural cavity. Empyema forms and
the pus (hydatopiothorax) contains necrotic hydatid
debris and innumerable daughter cysts.

Upward extension of a subdiaphragmatic cyst can
cause dry cough, dyspnea, chest pain and toxemia.
Rupture into the lumen of a bronchiole may lead to
the appearance of daughter cysts in the sputum.
Expectoration of bile tinged sputum is a sign of
bronchobiliary fistula.

Compression and displacement of biliary ducts is
frequent. A triad of symptoms characterizes rupture
into the bile ducts:
  a. Biliary colic
  b. Partial intermittent or complete ductal
     obstruction with cholangitis and jaundice
  c. Germinative membranes in the feces.

A cyst developing close to the porta hepatitis can
cause obstruction by compressing the common bile
duct or the hepatic ducts, thus not all patients with
biliary tract obstruction have intrabiliary rupture.

DIAGNOSIS

Imaging Techniques

Plain Radiograph

a. Abdomen: A calcified ring may be seen in the liver
zone which may indicate that a hydatid cyst is
present in the liver. It does not necessarily mean
that the hydatid cyst is dead.
b. **Chest:** It may reveal an elevated right hemidiaphragm or Concurrent hydatid cyst or lung pleurisy.

**Radionuclide Scanning**

A dynamic radionuclide scan, using agents such as technetium, show a hydatid cyst as filling defect, distinguishing it from solid vascular masses such as malignant tumors of the liver. Small cysts situated peripherally in the liver can be missed.

**Ultrasonography (Figs 85.6 and 85.7)**

Ultrasonography can demonstrate the cystic nature of the lesion and will sometimes show the presence of unmistakable daughter cysts within the main cyst cavity thus providing a definitive diagnosis.

**CT Scan**

CT probably yields the most information regarding the position and the extent of intrabdominal hydatid disease. CT, however is the method of choice to accurately diagnose extrahepatic intra-abdominal or extra-abdominal (Brain and thorax) hydatid cyst.

**MRI**

The real value of MRI in hydatid disease is in monitoring skeletal and vertebral disease and in cardiac hydatidosis.

**Immunologic Techniques**

Immunologic diagnosis using hydatid serology has become extremely sophisticated in the last few years and has assumed an increasing role, not only in primary diagnosis of hydatid disease but also in the screening of susceptible populations as well as in the post-surgical follow-up of hydatid cases for recurrent hydatid disease.

It is emphasised that the Casoni or intradermal test, though time honored, now has no place in diagnosis and because of its high rate of false-positives, its persistence after successful treatment and the occasional problem of anaphylaxis.

A number of laboratory tests have been used in recent years, these are described below.

**Immunoelectrophoresis**

This investigation depends on its positivity, upon the formation of a specific arc of precipitation (called "Arc 5") produced by the interaction of the serum from the hydatid patient with the antigen, compared to a control. It is highly specific.

**Indirect Hemagglutination Test**

This is a simple and sensitive test. It gives a positive reaction for *E.granulosus* and also for other parasitic...
infestation. This limits its usefulness in primary diagnosis in those countries in which these infestations are common.

**Latex Agglutination Test**

This is a reasonably specific, sensitive, and simple test and has no cross-reactions with other parasitic infestations, so that its very useful for large-scale screening of susceptible populations. Positive titers often persists for long periods after treatment and therefore it is not useful for post-surgical follow up: However, it is more sensitive than the immuno-electrophoresis test and does produce a number of false positives.

**Complement Fixation Test**

This was the first hydatid immunologic investigation and has been used since the beginning of this century. The test is extremely sensitive and therefore has a limited value in the primary diagnosis of human hydatid disease because of an unacceptably high positive reaction in other diseases. However, it returns to negative and is therefore useful in postoperative follow-up of hydatid patients.

**Enzyme-linked Immunosorbent Assay (ELISA)**

This investigation is automated, giving it a great advantage in large scale screening or in epidemiologic studies of hydatid disease. Only small amounts of hydatid antigen are required, which again makes it most useful for screening of susceptible populations. ELISA is a most valuable investigation in primary diagnosis. As the titer do not revert to normal for some years, ELISA is not useful in follow-up.

**TREATMENT**

Primary prevention is the most important step in the control this disease. The control measures are as follows,
- Decontamination of all wastes before disposal; steam sterilization, clinical disinfection, incineration
- Avoid feeding offal to dogs
- Periodically treat dogs with cestocides
- Humans must use good sanitary habits
- Laboratory staff must wear coat with gloves when skin contact with infectious material is unavoidable. Working with this parasite should be conducted in a biosafety cabinet or its equivalent
- Allow aerosols to settle; wearing protective clothing gently cover the spill with absorbent paper towel and apply 1% sodium hypochlorite starting at the perimeter and working toward the center; allow sufficient contact time (30 min) before clean up.

Secondary prevention includes the drug treatment or the surgical treatment depending upon the indication.

**DRUG THERAPY**

**Indications**
- Unusual site,
- multiple cysts (e.g. disseminated peritoneal disease),
- or other diseases in the patient, making operation and anesthesia hazardous.

**Contraindications**
- Pregnant and lactating mothers,
- Large hepatic cysts with cyst/biliary communications as chemotherapy will not prevent the discharge of cyst debris into the biliary system,
- Debris causing biliary obstruction or cholangitis.

Antimony, arsenic, thymol derivatives, iodides and mercury have been tried without concrete evidence of success. Variable success of mebendazole was first demonstrated in 1977. Mebendazole kills the larval stage by limiting their cellular glucose uptake and lowering the glycogen levels. The drug causes death of the germinal membrane cells and the cyst looses its ability to maintain homeostasis and integrity. Parasites undergo senile degeneration and death. However, the drug has to be given in high doses for longer periods. 20-50 mg/kg body weight divided into three equal doses per day for 21-30 days cycles for 3-12 months. Brandimarte et al (1980) and Morris and Gould (1982) showed limited absorption of mebendazole leading to low blood concentration and even lower cyst fluid concentrations.

Albendazole is the only drug that is oxicidal, larvicidal, and vermicidal. Albendazole studies have
been encouraging. It is the preferred drug for the treatment of cystic hydatidosis. It is given in the dosage of 15 mg/kg/day in three divided doses for 28 days and taken with a fatty meal to improve the absorption. The absorption of albendazole is far better than mebendazole. The course is usually repeated three to four times with 15 days drug free intervals. Careful monitoring of the white blood cells and the liver function tests during therapy are mandatory. A positive response is seen in 40-60% patients. Side effects of Albendazole includes, elevation in transaminase, jaundice, pyrexia, alopecia and leucopenia.

Praziquantel has much less dramatic effect on the germinal layer than on the protoscolices and it appears to be less effective than albendazole. It is probably the best prophylactic agent for prevention of implantation of spilled protoscolices, and a dose of 50 mg/kg day would certainly achieve active concentrations.

Medical therapy slows the progression of alveolar hydatid. It can be effective in approximately 30% of patients with E. granulosus infestation. It is most effective for pulmonary hydatid, less so for liver infections. Success is progressive shrinkage and solidification of the cyst.

Ultrasound indications for successful therapy are change in shape from spherical to elliptical or flat, progressive increase in echogenicity, and detachment of membranes from the capsule (Water lily sign); another CT criteria are reduction in diameter and augmented density of cyst fluid up to that of other tissues.

**SURGICAL MANAGEMENT**

**Indications for Operation**

The decision to operate for hepatic hydatidosis depends on the condition of the patient and the cyst characteristics. Surgery offers the only consistently effective treatment for living abdominal hydatid cysts of the E.granulosus; and it is recommended for both symptomatic as well as asymptomatic cases. Some cysts are reported to die without ever being symptomatic; however the natural history of the disease is of growth; complications of rupture into adjacent organs with serious, life threatening complications. The consensus dictates that uncomplicated, large peripherally located, viable hydatid cysts require operation, as do all complicated cysts.20,21

A small, deep parenchymal cysts measuring no more than 4 cms can be managed conservatively for several reasons. Hydatid cysts grow peripherally and will eventually reach the liver capsule if they survive. Small deep located cysts are difficult to manage and radical operation can cause unnecessary damage to the liver parenchyma. Such cysts should be monitored by repeated ultrasound. Once the cyst reaches subcapsular position, the risk of complication increases and the justification for operation is obvious.

Asymptomatic calcified cysts at a younger age require special consideration. The chances of major complications from the presence of a calcified dead, hydatid cyst are minimal and are less than the risks of surgery. Once the semisolid contents of the cyst are drained and the redundant portion of the roof resected; the rigid; calcified cyst wall does not collapse and biliary leaks may become persistent. Subphrenic abscesses, secondary infection in the cyst and sloughing of calcified adventitia are morbid complications, which may occur after the surgery of a calcified hydatid cyst. Segmental resection may become necessary in the case of a large calcified hydatid cyst.

Surgical treatment over the years has become progressively safer with a minimal mortality.22 The points in the evolution of surgical technique are oversimplification of operation, near complete elimination of postoperative biliary fistulae in liver hydatids, minimization of postsurgical major sepsis, decrease in recurrent cystic hydatid disease and reducing the disabling complications.

This should be achieved by:
1. Preventing spillage of living hydatid material
2.Removing all cyst elements
3. Sterilization of the residual hydatid cavity
4. Using an appropriate non-toxic scolicidal agent.
5. Intraoperative and postoperative complications can be avoided by the use of hydatid cones. Saidi and Nazarian (1971) first described the use of a cryogenic cone, which they adhered to the cyst surface by freezing.23 They were also the first to advocate the use of freshly prepared 0.5% silver nitrate solution as a good scolicidal agent.
In 1983 subsequently Aarons of Kune described a suction cone that adheres to the cyst wall. This instrument is simpler, safer and more effective than the cryogenic cone. In the recent past laparoscopy has offered minimally invasive option to treat hepatic hydatidosis.

**Preparation for Operation**

Antibiotic prophylaxis (single dose of cephalosporin) is administered to all patients with uncomplicated hydatid cysts. Septic patients are started on broad-spectrum antibiotic regimen. One may even add an antihistaminic and a steroid in premedication. A preoperative course of mebendazole (50 mg/kg/day) for a period of 1-8 wk is recommended.

The anesthetist should have adrenaline and steroid on the trolley and operating room personnel should adhere to strict regulations for contaminated procedures. Bronchospasm needs to be treated with conventional intravenous bronchodilators. In the event of a hypotension due to anaphylaxis, blood transfusion, plasma expanders and IV drug therapy is of significance. Protective goggles are recommended.

**Operative Procedures**

- Marsupialization
- Closed total cystectomy
- Partial pericystectomy
- Partial pericystectomy with capitonnage
- Partial pericystectomy with omentoplasty
- Liver resection - Typical, atypical, anatomic
- Laparoscopic methods.

**Inscision and Exploration**

The usual preference is for a long subcostal incision. An upward extension in the midline is sometimes necessary. On exploring the peritoneal cavity, spleen, pancreas, retroperitoneal areas, pelvis, inguinal canals must be looked carefully. Adhesions must be separated with great care since they might be overlying an unidentified abdominal cyst. The liver should be completely mobilized and bimanual palpation and inspection of both lobes is necessary.

The diaphragm should be dissected away from the superficially located cyst and full mobility restored. A large posterior cyst in the liver is dangerous and the liver must be mobilized adequately before handling such a cyst. If available, intraoperative ultrasound should be employed at this stage to note the intrahepatic extent, associated cysts and the relationship cyst to the inferior vena cava and the hepatic veins, and the complete patency of the CBD.

Right lobe is more commonly affected. In a series described by Al-Bassam et al of 21 patients over a period of 11 yrs, 11 children had a single cyst, 8 of which were in the right lobe. Ten children had multiple cysts occupying both liver lobes. Khoury et al report a series of 108 hydatid cysts of liver and spleen in 83 patients treated laparoscopically. In 42 patients (53%) the liver cysts were located in the right lobe; 21 patients (26%) in the left lobe and in both lobes in 16 patients (21%). The most frequently involved segment is; segments V, segment VI and segment VII.

**Conservative Operation**

**Aim: Safe Decompression of the Cyst**

**Salient Features**

a. Protect the skin around the entire space around the mobilized liver with packs and drapes soaked in 10% saline (green or blue drapes).
b. Put a pack behind the right lobe.
c. Treat all cysts as if they are viable and infectious.
d. A cyst will have contents under high pressure, therefore determine the point of entry and make actual working area as small as possible with additional packing.
e. 2 drains with a powerful suction must be available. Use a sump type cannula. The suction reservoirs should have a large capacity avoiding frequent changing.
f. Penetrate the cyst with a large gauge needle connected by a transparent plastic tubing to one of the drain. Observe the color of the hydatid fluid.
g. Aspirate at least 50 ml; then the cyst pressures lower and then take three stay sutures close to the inserted needle. Remove the needle. Hold the stay with upward traction. Incise the cyst with electrocautery and insert large gauge sump drain inside.
h. Incise the cyst further to about 3 cm; to allow direct vision inside and sump suck freely within the cavity. Inject warm saline solution intermittently
to keep the suction working and to evacuate the hydatid sand.

i. Evaluation of the cyst contents is important. The typical contents of a viable cyst are clear, containing sand and debris of brood capsules. Sometimes the contents may be stained with bile. Bile duct communications should always be looked for. Cyst may contain viable daughter cysts and the fluid may be infective.

j. The appearance of toothpaste-like material blocking the suction cannula is a sign that the cyst is dead. Once all the liquid has been drained the laminated membrane collapses into the cavity and the cyst contents can be evacuated. The laminated membrane can be best managed with a Babcock's forceps and progressive screwing type of movements with gentle traction. Daughter cysts should be sucked with wide bore suction. It is sometimes necessary to use a spoon to evacuate daughter cysts. When all the visible daughter cysts have been evacuated, the cavity is rinsed with 3-5% warm saline.

k. The redundant portion of the cyst roof is excised (Fig. 85.8). The adventitia and thinned out liver are cut with electrocautery or ultrasonic shears. The cut edges are oversewn using a reabsorbable suture material.

A careful search for daughter cysts is essential. Exogenic cyst can be incised and evacuated. The interior of the cyst should be carefully scrapped with sponges soaked in 5% sodium chloride. Curettage with sharp instruments is dangerous as it may injure adjacent hepatic veins. 3-5% of saline is left in the cystic cavity for 10 mins. To sterilize the cyst. Use a sponge immersed in formalin to gently scrub the interiors of the cyst cavity.

### Scolicidal Agents

Protoscolicidal agents are no substitute for meticulous surgical technique. Even the most effective agents may not kill all the protoscolices or the germinal layer. Inadequate sterilization usually results from lack of contact with all the daughter cysts or low concentration of the protoscolicidal agent in large volume cysts. Protoscolicides cannot penetrate the wall of the cysts. During operation, a protoscolicidal agent should not be injected into an unopened hydatid cyst.

### Complications of Protoscolicidal Agents

1. Acute toxic reactions
2. Anaphylactic shock
3. Hypernatremia
4. Gas embolism
5. Immediate postoperative death
6. Sclerosing cholangitis
7. Abscess formation.

### Management of Bile Duct Communications

Diagnosis of bile duct communications

1. Large cysts > 10 cm
2. Cysts occupying several liver segments
3. Episodes of cholangitis
4. Intraoperative cholangiography
5. Intraoperative ultrasound
6. Endoscopic retrograde cholangiopancreatography
7. Fill the cyst with saline, inject air and watch for bubbles at the site of leak
8. Appearance of bile stains in a cavity packed with hypertonic saline packs.
   Type of procedures on bile ducts in patients with cyst bile duct communications.
   1. Suture
   2. Suture + tube
   3. Roux-en-Y jejunostomy
   4. Intracavitary reconstruction (Roux-en-Y intracystic hepaticojejunostomy)
   5. Liver resection
   6. Choledochoduodenostomy.

   Gahukamble DB (2000) has analyzed 30 children with hydatid cysts of the liver who were treated by partial pericystectomy and external tube drainage. In 21% of cases in which clear hydatid fluid was observed during surgery developed biliary leakage in spite of appropriate precautions taken during surgery. Histological examination of the pericyst wall confirmed the presence of openings of small bile ducts in the cyst, which probably caused the biliary leak. The series also emphasizes on the fact that in children; the leak is likely to cease spontaneously, providing distal biliary duct obstruction is ruled out and external tube drainage is used to prevent accumulation of bile in the pericyst cavity.

Management of Residual Cavity

Methods of obliterating the residual cyst cavity:
1. Simple cyst closure
2. Leave the cyst open
3. Marsupialization
4. External drainage
5. Introflexion
6. Capitonage
7. Omentoplasty
8. Roux-en-Y cystojejunostomy

Omentoplasty as described by Papadimitiou and Mandrakas (1970), involves suturing of omentum into place, and if the cavity has a large volume, a drain is also placed. If the omentum is not available the cyst cavity can frequently be obliterated by capitonnage. This technique involves infolding the redundant cyst wall into the depths of the cyst with successive layers of sutures. Capitonnage is not possible when the volume the cyst is large and when the walls are calcified and rigid. Care should be taken not to place sutures deep into the cyst wall since hepatic veins can be injured. Marsupialization consists of suturing the adventitia to the parietes thereby allowing free and direct drainage of the cavity into the exterior.

An infected cyst should be treated like a liver abscess.

Radical Operation

Radical operation includes the procedure of closed cyst pericystectomy, anatomic liver resection, typical liver resection and liver transplantation. Resection is reserved for peripherally placed cysts, usually in the left lateral segment, for pedunculated lesions extrahepatic intra-abdominal cysts. It is to be avoided for cysts impinging upon the major hepatic veins; IVC and close to the liver hilum. It is an ideal procedure for multivesicular cysts and for calcified cyst. In atypical liver resection the cyst is dissected en-bloc with a thin layer of hepatic tissue disregarding the anatomy of the liver. Hepatic resection should be done only if there is no other surgical alternative.

Laparoscopic Treatment of Hepatic Hydatidosis

The technical development in laparoscopic instruments and increasing skill of surgeons has encouraged them to attempt a laparoscopic approach. 4-6 ports may be required. Cyst puncture and initial decompression is important and can be done by a special 10/12 mm cannula with aspirator.

The trocar cannula have a wider lumen, more force of suction and 2 side channels one for gas insufflation and one for suction. The special cannula is introduced perpendicularly into the cyst under supraventricularly inserted laparoscopic guidance. Cetrimide soaked pad is used to protect the trocar wound externally. Constant suction on the side suction cannula prevents spillage while introducing the trocar. Continuous irrigation and simultaneous suction removes fragments. Confirmation of extraction of entire cyst is checked by introducing operating laparoscope onto the cyst through the trocar. The wall of the cyst is carefully inspected for biliary leak and biliary communication can be sutured using vicryl. More than one hydatid cyst can be managed by multiple introduction of trocars.
Management of Extrahepatic Intraperitoneal Hydatid Cysts

These cysts may be either in a solid organ such as the spleen, pancreas or the kidney, or ovary. The other forms of extrahepatic peritoneal hydatidosis is usually the result of spillage of living hydatid material during surgery on a liver hydatid. Peritoneal hydatids need to be each individually removed with its host capsule intact. When part of the host capsule forms from the bladder, bowel or some viscus the cyst should then be treated in a fashion similar to primary liver cysts. When they are in the spleen the usual surgical treatment is splenectomy. Bhatnagar et al have reported successful enucleation of a deep seated splenic hydatid cyst and preservation of the spleen. Cysts located in the pancreas should be evacuated using a hydatid cone. Ismail K in his series of pancreatic hydatids has performed distal pancreatectomies, cystectomy and marsupialization in others. Hydatid cyst of the kidney has also been reported. It is possible to excise a small cyst. Partial or total nephrectomy is generally advisable.

Apart from the kidney, hydatid cyst may develop in retroperitoneal tissues. They arise in psoas sheath and progressively enlarge. It is difficult to excise the retroperitoneal cysts. They are densely adherent to adjacent structures and cannot be enucleated. Incision into the cyst after injecting 10% of formalin; evacuation of all the contents of the cyst and the laminated membrane and marsupialization are only possible.

Pulmonary Hydatidosis

Symptoms produced by hydatid cyst may not be severe, surgical treatment is always necessary to prevent a complication of rupture. Cyst may rupture into a bronchus or into the pleura. This may lead to anaphylactic reactions. The patient may develop aspiration pneumonia, disseminated disease, abscess or an empyema.

Thoracotomy is indicated in all cases of hydatid disease in lungs

1. Barrets maneuver – For a closed cyst which is not infected and which is situated near the surface of the lungs, it is possible to incise the thin adventitia and allow the cyst to separate itself from the adventitia while the anesthetist blows the lungs intermittently.

2. Removal of cyst (Fig. 85.9) – After preliminary aspiration of the cyst the laminated membrane is dissected away from the pericyst. Any openings of the minor bronchi are carefully closed and purse string sutures are taken to carefully obliterate the cavity.

3. Pulmonary resection – Pulmonary resection is indicated when the cyst is infected; when it is too large or when it arises from the middle lobe.

   The anatomical site of the lesion determines whether the resection be lobectomy, segmental resection or only a wedge resection. Results of pulmonary resection and other conservative measures are generally good and rewarding.

4. Pneumonostomy – After excision of the cyst a separate catheter is fixed within the residual lung cavity and brought through the adjacent chest wall; effectively marsupializing the residual cavity to the atmosphere.

Other Sites

Hydatids at the hip bone, lower third of tibia/femur calf, psoas, sternomastoid, in the diploic layer of skull bones, intracranial, temperoparietal, and periorbital region may need excision. Spinal hydatids may be intra or extra dural, vertebral or paravertebral, and may lead to progressive weakening of the lower limbs. Laminectomy is required to relieve the compression of the cord. The cavities have to be freely opened and curetted. Early decompression has good results.
REFERENCES

Liver resection in childhood is required for a variety of reasons but the commonest indication is for the treatment of liver tumors. All pediatric surgeons should be familiar with the principles and practice of the more basic techniques. Anatomically or pathologically complex lesions are best dealt with in an experienced center by a multidisciplinary team consisting of a specialist hepatobiliary surgeon and radiologist, supported by pediatric anesthesia, hepatology, oncology, intensive care, and nursing. This approach should minimize the risk of mortality and morbidity and yield the optimum long-term results from what is a potentially major undertaking.

HISTORICAL ASPECTS

The regenerative powers of the liver have been recognized since ancient times. They were hinted at in the legend of Prometheus who was bound to a rock in the Caucasus mountains because he stole fire to give to man. Every day, eagles came to devour his liver which then regrew each night. The study of liver anatomy began in earnest with Leonardo da Vinci’s observations gleaned from anatomical dissections. However, it was Francis Glisson’s *Anatomia Hepatis* published in 1654 that marked the beginnings of modern liver anatomy and surgery. In the late 1880s, after the introduction of anesthesia and antisepsis, adult liver resections were first performed by pioneers such as Langenbuch, Loreta, and others. Further advances in anatomy were made by Rex in Germany and Cantlie in England and in the early 1900s Pringle developed his maneuver for controlling hemorrhage.

The subsequent revolution in liver resectional surgery began in the 1950s and was inspired by Couinaud’s studies of segmental liver anatomy. The first right hepatectomy was undertaken by Lortat-jacob in Paris in 1952. It was not until the 1980’s that advanced techniques of liver resection became available, pioneered by surgeons such as Bengmark, Bismuth, and Blumgart. In particular, the different types of anatomical liver resection were refined and the problem of hemorrhage was successfully addressed. Liver transplantation ushered in the next wave of advances in resectional liver surgery and most recent progress has largely come from centers specializing in both fields.

In recent times, the three major advances in liver resectional surgery have been the definition of hepatic anatomy, the application of accurate imaging techniques, and the development of liver transplantation. It is against this background that pediatric hepatobiliary surgery has emerged as a specialist discipline.

INDICATIONS FOR LIVER RESECTION

Although liver tumors are the commonest reason for liver resection in childhood, there are a variety of other indications (Table 86.1).

Tumors

There is a wide spectrum of pediatric liver tumors (Table 86.2) but only the more common lesions requiring hepatic resection are described in this section. The rarity and complexity of these tumors indicates that they should be managed in centers with appropriate oncological and surgical expertise.

Malignant liver tumors

In Western societies, primary malignant liver tumors have an incidence of approximately 1-1.6 per million children per year and account for just over 1% of all childhood cancers.2,3 Hepatoblastoma (HB) and hepatocellular carcinoma (HCC) comprise more than two-thirds of childhood primary liver malignancies.

Hepatoblastoma

HB is the commonest primary malignant liver tumor in infants and children, with a peak incidence in the first 3 years of life. Presentation is usually with a combination of abdominal distension, pain or a mass. Rarely, the tumor ruptures and causes intraperitoneal bleeding. Most cases of HB are sporadic but familial cases associated with Beckwith-Wiedemann syndrome or familial adenomatous polyposis are described. Serum alpha-fetoprotein is elevated in more than 90% of cases and is a valuable diagnostic and prognostic marker. Biopsy is advisable for histological confirmation. Ultrasound scan (US) and computerized tomography (CT) are useful in assessing the primary tumor but chest radiography and CT are required to exclude metastases.

In the USA and Germany, the staging system for HB and HCC is based on operative findings and histological features, i.e. postsurgical. In Europe, the staging system adopted by the Societe Internationale d’Oncologie Pediatrique (SIOP) is a pretreatment grouping based on the results of imaging studies.4 In the latter, the liver is divided into four sections comprising the left lateral section (segments 2 and 3), a left medial section (segment 4 and part of 1), a right medial section (segments 5 and 8 and part of 1) and a right posterior section (segments 6 and 7). The number of liver sections involved by the tumor, and the presence of tumor involving the portal vein, vena cava, or extrahepatic sites are recorded.

Effective chemotherapy and complete surgical resection of the tumor are the mainstays of therapy. Various chemotherapy regimes have been advocated.5 In the USA, the traditional focus has been on initial laparotomy, surgical resection where possible, and postoperative chemotherapy (e.g. cisplatin, vincristine and 5-fluorouracil). Neoadjuvant chemotherapy is given for initially unresectable
Liver Resections and Allograft Preparation

The SIOP studies have concentrated on preoperative chemotherapy. In SIOPEL-1, all patients except those with small peripheral tumors were treated by preoperative chemotherapy with cisplatin and doxorubicin (PLADO) which induced tumor necrosis and shrinkage.6,7

The presence of multifocal tumor, involvement of more than three liver sectors, evidence of caval or main portal vein invasion, or distant metastases are the usual reasons for unresectable disease. However, HB resectability has progressively improved since the introduction of chemotherapy for unresectable disease.8-12 After PLADO cytotoxic therapy, 70-85% of unresectable tumors become operable. Preoperative chemotherapy renders most tumors smaller, better demarcated from the surrounding liver, and more likely to be completely resected.13

Patients who respond to chemotherapy but have unresectable tumors with no evidence of persistent metastases should be considered for orthotopic liver transplantation (OLT). A careful search for extrahepatic disease prior to OLT is important and chemotherapy should be continued until the time of transplant. Published experience is limited but the indications are that this approach offers a greater than 50% chance of disease-free survival if patients are carefully selected, despite the need for long-term immunosuppression.14-16

During the last 30 years, there has been a progressive improvement in survival after treatment of HB. In SIOPEL-1 overall 5 year survival was 75% and in the German Cooperative Liver Tumor Study 82% at 3 years.8,17 Results from SIOPEL-1 indicate that tumor extent at presentation (pretreatment grouping) and presence of distant metastases are possibly the most important prognostic variables.18

Hepatocellular Carcinoma

HCC (hepatoma) accounts for less than a quarter of all pediatric malignant liver tumors in Western societies but is much more frequent in parts of Asia, South America and Africa where hepatitis B infection is endemic.19 HCC typically occurs in older children (10-14 years) and more commonly affects boys. Presenting features include an abdominal mass, weight loss and fever.

Fewer than 10% of tumors in Western children are associated with cirrhosis or underlying liver disease.5 This is not the case in the Far East, where vertical transmission of Hepatitis B is an important cause of HCC and almost all affected children are infected with the virus and have chronic liver disease.20 A national hepatitis B vaccination program in Taiwan has significantly reduced the incidence of HCC in recent years.21

HCC spreads by lymphatic and vascular invasion. Bilobar, multifocal disease is common and at least half the patients have metastases or extrahepatic spread at presentation.22 Serum AFP is elevated in two-thirds or more of cases but not in the fibrolamellar variant of HCC which occurs in adolescents and young adults in the absence of underlying cirrhosis and is associated with elevated serum levels of the vitamin B12 binding protein, transcobalamin (Fig. 86.1).

The tumor is much more resistant to chemotherapy than HB. If possible, complete excision of HCC should be attempted but the presence of multifocal tumor or underlying cirrhosis may preclude resection. Children with unresectable tumors and no evidence of extrahepatic spread should be assessed for transplant.16

Children with HCC had a 41% 2 year survival in SIOPEL-1 but disease-free survival was only 27% in the German studies with longer follow-up.23,24 Currently, the role of chemoembolization, intra-arterial chemotherapy, ultrasound guided percutaneous intralesional injection of ethanol, intraoperative cryotherapy and radiofrequency ablation, all of which have their advocates in adult practice, remains uncertain in children and, where possible, liver resection offers the best chance of survival.

Fig. 86.1: Operative appearance of a fibrolamellar hepatocellular carcinoma in a 15-year-old boy just prior to left hemihepatectomy. Adherent omentum (previous biopsy site) was excised with the liver tumor.
Other Malignant Liver Tumors

Undifferentiated (embryonal) sarcoma usually occurs in school age children (Fig. 86.2). Treatment is by chemotherapy and liver resection but local recurrence is common and the prognosis generally poor.25

Rhabdomyosarcomas are mostly found in the extrahepatic biliary tree of pre-school children and presentation is with obstructive jaundice and abdominal pain. Histologically they are locally invasive embryonal or botryoid rhabdomyosarcomas. Approximately 20% of children have metastases at presentation. Surgical excision (assisted by intraoperative cholangiography and frozen section histology), multiagent chemotherapy, and in some cases radiotherapy have resulted in a significantly improved survival. The Intergroup Rhabdomyosarcoma Study Group reported their experience of 25 children with biliary rhabdomyosarcoma treated by chemotherapy and surgery.26 They concluded that (i) surgical exploration is required to accurately identify regional non-nodal metastases, and (ii) surgery should be used principally to determine histological diagnosis and extent of disease; if possible, endoscopic stent placement should be used to achieve biliary drainage. Estimated 5 year overall survival was 66% but was better in children without distant metastases at diagnosis.

A variety of other rare malignant liver tumors may be encountered in children (Table 86.2) and with the exception of lymphoma, may require resection. Surgical excision may also be indicated for isolated liver metastases from Wilms’ tumor.

Benign Liver Tumors

Several benign liver tumors are best treated by complete excision.

Mesenchymal Hamartoma

These are large, multicystic liver tumors usually found in infants and pre-school children but occasionally presenting in older persons.27,28 After hemangiomas, mesenchymal hamartomas are the second commonest benign hepatic tumor in childhood. They typically present with an abdominal mass or distension from progressive accumulation of serous or mucoid fluid within the cysts. Tumors may be very large, sometimes exceeding a diameter of 20 cm and weighing up to 3 kg.

Mesenchymal hamartomas are best treated by complete excision, either by conventional hepatic resection or non-anatomical excision with a rim of normal liver. An excellent prognosis can be anticipated after complete excision.27 Incomplete resection should be avoided because of the long-term risk of malignant change, namely the development of an undifferentiated (embryonal) sarcoma, and the possibility of late symptomatic recurrence.28,29 Marsupialization may lead to intractable local complications.

Focal Nodular Hyperplasia

This benign liver tumor is most often seen in young women; children account for only 7% of reported cases.30 It most commonly presents as an asymptomatic solitary liver mass but may cause discomfort. The lesion is not premalignant, and asymptomatic patients with a confirmed diagnosis can be managed conservatively. In children, the lesion often remains static in size and asymptomatic for many years.31 Symptomatic cases have been treated by resection, embolization or hepatic artery ligation.

Hemangiomas

These are the commonest liver tumors in children ranging from small asymptomatic lesions to large life-
threatening tumors. Most hemangiomas and many hemangioendotheliomas regress spontaneously but treatment is indicated for cardiac failure, respiratory symptoms, or abdominal pain and distension. Specific measures to control the hemangioma may be required. Corticosteroids or alpha-interferon can induce gradual regression in some but not all cases. For bilobar disease complicated by cardiac failure, hepatic artery ligation or embolization may be effective.32,33 Large symptomatic hemangiomas localized to one or other half of the liver can be resected.32 Buttressed compression sutures may be a useful adjunctive surgical treatment in unresectable cases.34 Rarely, liver transplantation is the only therapeutic option.

**Adenoma**

Although rare, hepatic adenomas may affect children of any age and either sex. They are usually single and well circumscribed with a thin fibrous capsule. In young women, there is a well established association between hepatic adenomas and the combined oral contraceptive pill. In children, hepatic adenomas may be idiopathic, associated with exogenous sex steroid therapy, or linked to various rare disorders.5,35 Symptomatic or large hepatic adenomas generally require resection to control pain or avert potential complications such as hemorrhage, rupture, and the small risk of malignant transformation.

Other pediatric liver ‘tumors’ which may occasionally require liver resection include large or symptomatic non-parasitic cysts, inflammatory pseudotumors (usually only if symptomatic or if there is diagnostic uncertainty), and rarely, chronic abscesses and parasitic cysts.36

**Trauma**

Most pediatric liver trauma is successfully managed non-operatively. Nevertheless, a child with a liver injury who is hemodynamically unstable after basic resuscitation (at least 40 ml/kg of intravenous fluid) requires an urgent laparotomy and control of intra-abdominal bleeding. Direct suture ligation and perihepatic packing are frequently sufficient to control ongoing hemorrhage. Anatomical resection following acute liver trauma has a high mortality rate when performed in the presence of coagulopathy, acidosis, and associated injuries which often complicate major liver injury. In contrast, non-anatomical resectional debridement, i.e. the removal of devitalized liver parenchyma along lines of injury rather than anatomical planes (after inflow occlusion) is valuable.37 However, formal hepatic resection can be useful for more delayed complications of liver trauma such as in the child with localized hepatic necrosis or in those with biliary complications not amenable to biliary reconstruction.

**SURGICAL ANATOMY AND IMAGING**

Any surgeon operating on the liver must be thoroughly familiar with normal hepatic anatomy and common variants. Unfortunately, the nomenclature for describing normal hepatic anatomy and the common types of hepatic resection is often confusing. In recent years, Strasberg has attempted to introduce a more consistent terminology.38

The right and left liver lobes are the classic lobes of surface anatomy separated by the attachment of the falciform ligament superiorly and the umbilical fissure and ligamentum venosum inferiorly. The internal anatomy of the whole organ can be subdivided on three levels:

1. The right and left hemilivers are divided by the midplane that lies between the medial margin of the gallbladder fossa and the left side of inferior vena cava (previously known as Cantlie’s line).
2. Each hemiliver is divided into two sections based on the internal anatomy of the hepatic artery and bile duct. Thus the right hemiliver has anterior (segments 5 and 8) and posterior (segments 6 and 7) sections and the left hemiliver has medial (segment 4) and lateral (segments 2 and 3) sections.
3. Segmental anatomy is based on Couinaud’s 8 segments which relate to the intrahepatic divisions of the portal vein but each segment is also subserved by branches of the hepatic artery and bile duct. The caudate lobe is segment 1 and is based on surface anatomy (Fig. 86.3).

There are three main hepatic veins—right, middle and left. The venous drainage of segment 2 is always solitary. Segment 3 has a single vein in 30%, two veins in 50%, and three veins in 20%. Segment 4 drains to the middle hepatic vein in 50% of cases, to the left hepatic vein in 10%, and to both in 40%. Almost 20% of adults have a sizeable right inferior hepatic vein (> 5 mm) which usually drains segment 4 but has good
collateral flow to other segments. The left and middle veins usually unite to form a short common trunk before entering the inferior vena cava. Consequently, the left hepatic vein is potentially vulnerable during a right trisectionectomy and the middle hepatic vein during left hemihepatectomy. The middle hepatic vein occupies the midplane of the liver and the right vein lies in the right intersectional plane. Only the terminal portion of the left hepatic vein occupies the left intersectional plane. During liver resection, the hepatic veins can be approached and ligated prior to parenchymal dissection or they may be controlled from within the liver substance.

The left branch of the portal vein and the left hepatic duct have a longer, more horizontal extrahepatic course (Fig. 86.4). The anatomy of the left portal vein is more constant than the right; the right portal vein trifurcates in about 15% of individuals. Common variations in the anatomy of the hepatic duct confluence are shown in (Fig. 86.5). It is also important to note that the right posterior sectional duct (draining segments 6 and 7) typically loops around the medial sectional branch of the portal structures ('Hjortsjo's crook') (Fig. 86.6) where it is vulnerable to injury during a left trisectionectomy.

Anatomical variations in the origin and course of the hepatic artery/arteries are common and the more frequent variations are shown in (Fig. 86.7). The arterial supply of the common bile duct has been studied in detail by Northover and Terblanche (1979) and is of relevance to liver resection and transplantation because of the need to avoid bile duct injuries.

Fig. 86.3: Segmental anatomy of the liver

Fig. 86.4: The bifurcation of the portal triad. Note the longer and relatively horizontal course of the left portal vein and left hepatic duct

Fig. 86.5: Common variations in the anatomy of the hepatic duct confluence (Couinaud 1981)
small arterial branches on the duct run in an axial direction and are mainly located at 3 and 9 o’clock.

Most liver tumors present with abdominal distension and/or a mass. Initial investigation using ultrasonography (US) will confirm whether the mass is hepatic, cystic or solid, and single or multiple. Doppler ultrasound studies provide information about its vascularity. Computerized tomography (CT) with intravenous contrast enhancement defines the anatomy of the lesion as a guide to surgical resection. Definition can be improved further by using faster scanners, CT arteriopportography, or spiral CT.

Additional investigations prior to surgery may include hepatic angiography but in our experience this has been largely supplanted by a combination of imaging using duplex ultrasonography and gadolinium-enhanced magnetic resonance angiography (MRA). The latter is particularly good at demonstrating vascular anatomy, including the vena cava and hepatic veins (Fig. 86.8). Hepatic masses are well characterized by magnetic resonance imaging after obtaining both T1 and T2 weighted images. MR cholangiography offers the ability to non-invasively assess the biliary tree and is particularly useful prior to a planned trisectionectomy.

**RESECTABILITY OF LIVER TUMORS**

CT, MR and sonography are all capable of providing images in the transaxial, sagittal and coronal planes which affords the surgeon considerable confidence when assessing hepatic vascular anatomy and tumor ischemia. The supraduodenal duct receives arterial blood from the right hepatic artery above and the retroduodenal and gastroduodenal arteries below; the
Prior to surgical resection of any liver tumor it is essential to determine the presence and extent of extrahepatic disease. The resectability of a liver tumor can generally be determined by accurate preoperative imaging but it is only finally possible to be sure at laparotomy. The greatest difficulty arises with tumors adjacent to the hilar structures or to the hepatic vein confluence or inferior vena cava. The size of the tumor *per se* is not a contraindication to resection. Intraoperative US can be extremely useful in defining the extent of a tumor adjacent to the cava or major hepatic veins; application of a high frequency transducer directly to the surface of the liver increases the sensitivity of conventional transabdominal ultrasound examination (Fig. 86.9).

Laparoscopy may also have a role in assessing the resectability of some liver tumors but there is little experience of using the technique for this purpose in children. Caval/hepatic vein assessment is best performed using other methods. In adults, laparoscopic liver resection with ‘hand port’ assistance has been described.

**TECHNIQUES OF LIVER RESECTION**

With tumors, the aim of surgery is complete excision of the mass leaving the remaining liver with an adequate arterial and portal supply, intact biliary drainage and satisfactory venous outflow.

**Preparation**

Preoperative coagulopathy should be corrected and prophylactic antibiotics given on induction. Epidural analgesia can produce effective postoperative pain relief and help to minimize respiratory complications. Intraoperative maintenance of body temperature is important and can be achieved in a variety of ways (e.g. warming mattress, warm air devices and ambient temperature control). A central venous line is inserted for pressure monitoring and rapid transfusion. Cross-matched blood and fresh frozen plasma should be available.

**Exposure**

Good surgical access is achieved via a curved bilateral subcostal incision with or without a midline xiphoid extension. Rarely, a thoracoabdominal approach may be indicated for paracaval tumors. A roll or gel pad may be placed under the thoracolumbar spine to facilitate exposure. After preliminary laparotomy, the liver is mobilized by division of the falciform, triangular and coronary ligaments and the retrohepatic cava exposed. A versatile self-retaining retractor attached to the operating table such as the Omni-Tract® (Minnesota Scientific, Inc., USA) enables the costal margins to be retracted in a superior, lateral and anterior direction (Fig. 86.10). Intraoperative US imaging is useful at this stage in selected cases.

**Inflow Occlusion**

The portal triad is slung to allow subsequent inflow occlusion (Pringle maneuver) which reduces blood loss during subsequent parenchymal transection. A warm ischemic period of up to one hour is well tolerated by the normal adult liver and intermittent portal triad clamping is safe up to two hours. Prolonged periods of ischemia may be better tolerated after a brief period of ischemia followed by temporary reperfusion and then sustained inflow occlusion, so called ischemic preconditioning. The underlying mechanism may be related to downregulation of apoptotic pathways in hepatocytes. Venous congestion of the gut can be a problem with temporary portal vein occlusion, especially in those patients with no pre-existing portal hypertension.
Parenchymal Transection

A variety of techniques can be used to transect the liver parenchyma and control vascular and biliary radicles (Table 86.3).\(^{55-56}\)

The author uses a combination of bipolar diathermy, ultrasonic aspiration, suture ligation, argon beam and fibrin glue but any technique which safely minimizes blood loss and prevents bile leakage is acceptable. The Cavitron ultrasonic surgical aspirator contains a transducer that oscillates longitudinally at high frequency and to which a hollow conical titanium tip is attached (Fig. 86.10). Irrigation and suction channels are incorporated. The hepatic parenchyma, with its high water content, is cavitated and fragmented but blood vessels and bile ducts are relatively spare.\(^{59,60}\) Hepatic veins, however, are more vulnerable. The harmonic scalpel operates at a higher frequency than the ultrasonic surgical aspirator and tissue dissection is achieved more by compression and sawing than cavitation.

Once surgical bleeding points have been controlled, the raw surface of the liver should be carefully inspected for bleeding and bile leaks. Oozing from small vessels on the cut-surface of the liver can be controlled in various ways. The argon beam coagulator is particularly good; the non-combustible argon gas provides a safe medium for the transmission of electrosurgical current leading to less smoke, non-contact coagulation, and reduced tissue adhesion. Suture sites should be avoided since the argon beam may damage these. Fibrin sealant is also valuable; fibrinogen and thrombin are sprayed on to the raw surface of the liver using compressed air interacting rapidly to produce a stable fibrin clot. There is a theoretical risk of viral transmission with current products. Other topical hemostatic agents include oxidized regenerated cellulose, gelatin sponge, and collagen fleece.

A vascular stapler (Endo GIA\(^{®}\)) can be used to control large hepatic veins in older children.

Central Venous Pressure

Maintenance of a low central venous pressure (0-4cms H\(_2\)O) helps to minimize blood loss during the phase of parenchymal transection and this is facilitated by a slight head down tilt.\(^{51}\) The CVP should be above 0 cm H\(_2\)O to avoid the risk of air embolism when hepatic veins are opened.

Total Vascular Exclusion

Normothermic total vascular exclusion (TVE) is occasionally necessary for lesions adjacent to the hepatic veins or inferior vena cava; the non-cirrhotic liver will tolerate up to one hour of warm ischemia.\(^{62,63,64}\) This technique requires complete mobilization of the liver with vascular inflow occlusion (Pringle manœuvre), supra and infrahepatic caval clamping and control of the right adrenal vein and

any accessory hepatic arteries. Hemodynamic disturbances, particularly a fall in cardiac output, must be anticipated by appropriate expansion of the intravascular volume. Hemodynamic changes may be minimized by synchronous portosystemic venovenous bypass. The addition of supraceliac aortic clamping has been largely abandoned. In situ perfusion of the isolated liver with cold preservative solution has been used in adults to extend the period of total vascular exclusion.

Cardiopulmonary bypass with hypothermic circulatory arrest has been advocated in special circumstances but is not without hazard.

Abdominal Drainage
After straightforward hemihepatectomy, abdominal drainage may not be required but after more extensive hepatic resections, drainage with a soft, perforated, wide-bore silicone drain is advisable.

TYPES OF LIVER RESECTION
Standard liver resections are based on segmental hepatic anatomy. The currently recommended nomenclature for such resections is shown in (Fig. 86.11). Upto 85% of the liver may be safely resected in children provided that the remaining parenchyma

![Diagram of liver resections](mebooksfree.com)
Liver Resections and Allograft Preparation

is healthy and the arterial and portal inflow and hepatic venous outflow are safeguarded. Major resections are better tolerated if there has been compensatory hypertrophy of remaining healthy liver as a result of the disease process. A right trisectectomy leaves a remnant volume of between 15 and 35% (median 20%).

The approach to liver resection is illustrated by consideration of two "standard" resections.

**Right Hemihepatectomy**

The liver is mobilized by division of its ligamentous attachments and the portal triad is slung. The retrohepatic cava is exposed by dividing the venous branches from the caudate lobe. Superiorly, the hepatocaval ligament is divided to expose the right hepatic vein. This vein can be divided between vascular clamps and oversewn with a non-absorbable suture at this stage or from within the liver parenchyma at a later stage of the operation, depending on ease and preference.

After cholecystectomy, the right hepatic artery is dissected and divided close to the hilum of the liver, usually to the right of the common hepatic duct. Left hepatic arterial pulsation should be confirmed prior to ligation. The right portal vein is mobilized by dividing any posterior caudate branches; it is then divided and oversewn. The hilar plate is lowered by incising Glisson's capsule anteriorly at the base of segment 4 to expose the common hepatic duct bifurcation. The right hepatic duct is usually divided well away from the bifurcation at a later stage, after hepatic transection. The plane of hepatic transection lies just to the right of the midplane, proceeding along the right margin of the middle hepatic vein (Fig. 86.12). This is initially outlined by diathermy on the liver surface. If the caudate lobe is retained, the portal structures must be divided distal to their caudate branches. Positioning packs behind the right lobe brings it anteriorly and medially and renders the transection plane close to the sagittal.

**Left Trisectionectomy**

Previously known as extended left hepatectomy or left trisegmentectomy, this resection involves the excision of segments 2, 3, 4, 5 and 8. Occasionally, the caudate lobe (segment 1) is also removed. This resection was first described in detail by Starzl et al (1982) and Blumgart et al (1993) and has been utilized in the treatment of extensive pediatric liver tumors by others. More recently, a specific description of the technique applied to children has been reported.

Vascular structures are controlled outside the liver before dividing the hepatic parenchyma. The left hepatic artery and left branch of the portal vein are dissected by incising Glisson's capsule and lowering the hilar plate; both vessels are then ligated. The obliterated ductus venosus is identified by retracting segments 2 and 3 anteriorly and division of this fibrous band exposes a recess at its upper limit which runs under the confluence of the middle and left hepatic veins. The suprahepatic cava is exposed by incising the falciform ligament posteriorly and careful dissection now enables the confluence of the middle and left hepatic veins to be isolated and slung. The confluence is then divided between vascular clamps and oversewn with a non-absorbable monofilament suture. A vascular stapler can be used in teenagers.

Control of the vascular inflow to segments 5 and 8 is achieved by dissecting the hepatic parenchyma surrounding the right portal vein and right hepatic artery as far as the right anterior sectional pedicle. This is initially clamped to demarcate segments 5 and 8 after which it is ligated. If segment 1 is to be retained, the left portal vein and left hepatic artery should be ligated...
distal to their caudate branches. The hepatic parenchyma is then transected in a coronal plane with or without temporary inflow occlusion.

Thus, in hemihepatectomy and trisectionectomy procedures, preliminary hilar dissection is necessary prior to hemihepatic vascular occlusion. If the relevant hepatic vein can be safely clamped extrahepatically, this allows a form of localized total vascular exclusion which helps to reduce the need for blood transfusion.

Liver tumors should be excised en bloc with any localized area of tumor adherence, such as the diaphragm or omentum, to ensure complete tumor excision. Caudate lobe hepatoblastomas are uncommon but typically adherent to the cava and/or porta hepatis, show signs of early vascular invasion and dissemination and are technically difficult to resect. An understanding of segmental hepatic anatomy also renders atypical liver resections possible such as central or transverse hepatectomies. For more detailed accounts of hepatic resections and a description of individual segmentectomy procedures, the reader is advised to consult Blumgart (2000).

**Non-anatomic Hepatic Resection**

Despite the advantage of anatomical resections there are indications for non-anatomical procedures such as removal of small benign tumours, excision of a small hepatocellular carcinoma in liver cirrhosis, re-resection following a previous major hepatectomy, and liver trauma.

Pledgetted sutures can be useful for dealing with cut surface bleeding after resection or after reduced-size transplantation; it is important that such sutures are placed superficially on the cut surface and tied to produce compression. Strangulation and necrosis of deeper areas of parenchyma must be avoided. This technique has been extended by Sandler et al (2001) to non-anatomical liver resection in small children by prior placement of Teflon felt pledgetted sutures. It may be particularly advantageous in small children who have a relatively soft liver parenchyma and in whom a non-anatomical resection is planned.

Most hepatic resections are relatively straightforward but tumors which are complex, either because of size or location, should be managed in centers with hepatobiliary surgical expertise. These include large central tumors and those involving the hepatic vein confluence or IVC. Innovative techniques have been used to treat tumors of borderline resectability, thus avoiding the need for liver transplantation.

**Extending the Limits of Hepatic Resection**

i. **Neoadjuvant chemotherapy** or transarterial chemoembolization have effectively extended the limits of resection for hepatoblastoma. Between one and two-thirds of patients present with unresectable primary tumors or distant metastases and after PLADO cytotoxic therapy, 70-85% of unresectable tumors become operable.

ii. **Preoperative portal vein embolization.** This may encourage growth of an anticipated liver remnant consequently permitting a more extensive hepatic resection to be performed. Kaneko et al 2001 reported preoperative portal embolization of the right hemiliver and caudate lobe one month before right trisectionectomy for an inflammatory pseudotumor involving the hepatic hilum in a 6 year old boy. The volume of the left lateral segment assessed by CT increased from 217 cm$^3$ to 250 cm$^3$ prior to resection. A similar although spontaneous process enabled Shuto et al (1993) to perform a massive liver resection for a giant mesenchymal hamartoma, leaving only the hypertrophied caudate lobe behind.

iii. **Caval repair/reconstruction.** Minimal tumour involvement of the inferior vena cava is best dealt with by local resection and repair, with or without an autologous vein patch. More extensive involvement has been treated in adults by prosthetic replacement which requires hypothermic hepatic perfusion with preservative solution and ex-vivo bench surgery. Takayama et al 1991 reported excision of the retrohepatic cava en bloc with a left trisectionectomy for a hepatoblastoma in the caudate lobe which had invaded the cava. The retrohepatic cava was not reconstructed because it had been chronically occluded by tumor and fibrosis and the patient already had well established collateral venous pathways.

iv. **Liver transplantation.** This is the ultimate hepatic resection for an otherwise unresectable liver tumor where there is no evidence of persistent extrahepatic disease. The results are critically dependent on the type of tumor and case selection.
Liver Resections and Allograft Preparation

5 Extended hepatic resection with transplant back-up has been proposed for tumors of borderline resectability by the Cape Town group.77 This innovative strategy may encourage a more aggressive attempt at tumor resection in the knowledge that transplantation is an option but the logistics are potentially problematic.

v. **Resection of the hepatic vein confluence.** Liver tumors that surround the three major hepatic veins are generally considered unresectable. Superina et al (2000) have described a new technique: the left hepatic artery, left branch of the portal vein, and the three hepatic veins are occluded with vascular clamps.67 Perfusion of the remaining liver is through the right hepatic artery and portal vein. An extensive resection of segments 2, 3, 4, 7 and 8 is possible if there is adequate venous drainage of the right hemiliver via the retro-hepatic veins (most likely if there is a sizeable accessory right inferior hepatic vein). If the liver remains soft and does not become tense or mottled, the three major hepatic veins can be divided and the tumor resected. If venous drainage is inadequate, the procedure must be abandoned and the patient considered for liver transplantation.

vi. **Staged resection** of multiple tumors has been recommended as a means of allowing intervening parenchymal regeneration in cases where residual hepatic sufficiency is in doubt but this would probably only be applicable to benign tumors in children.84

vii. **Ex-vivo dissection and auto-transplantation** involves total hepatectomy, placing the patient on caval and portal veno-venous bypass, and, after extracorporeal bench surgery, transplanting the healthy liver remnant back into the patient.85,65 Such an approach has not yet been used in children.

Before any liver tumor resection, close liaison with the pathologist is important so that resection margins can be adequately assessed and the tumor appropriately characterized. This will often mean submitting the liver resection specimen in the intact, fresh, and unfixed state.86

**POSTOPERATIVE MANAGEMENT**

The patient is supported with dextrose saline and albumin infusions for two or three days after a major hepatic resection; vitamin K and fresh frozen plasma may be necessary to correct coagulopathy.80 After major resection, gastric hyperacidity and temporary portal hypertension predispose to bleeding from gastric erosions and gastric protection with H2 blockers or Sucralfate is advisable until enteral feeding is re-established. A fever above 38°C is commonly seen for a few days after an uncomplicated major hepatic resection. Prophylactic antibiotics are usually given for 24 hours.

*Includes 7 patients with "incidental" HCC discovered within the explanted liver
Standard biochemical liver function tests are initially abnormal after hepatic resection because of loss of functioning hepatocytes and relative portal hypertension secondary to reduced hepatic mass and venous outflow. Typically, the prothrombin time returns to normal by the fourth postoperative day and liver enzymes and bilirubin within 10-14 days, but albumin levels may take 6 weeks to normalize.57,87 Hepatic regeneration is particularly rapid in children and, despite perioperative chemotherapy, liver volume is restored within 90 days in most cases and remains almost normal for age with continued growth.88,89 Cisplatin interferes little with hepatic regeneration but chemotherapy is best avoided 10 days either side of surgery.90

An injured or fatty liver shows slower and/or incomplete regeneration and liver regeneration is slowed by extrahepatic complications such as sepsis. Cirrhotic livers have a significantly impaired capacity to regenerate and postoperative liver function is disturbed more and for longer. Biliary obstruction also impedes hepatic repair.88 In the vast majority of cases, liver function is restored and continues to be normal years later.88

COMPLICATIONS

Major intraoperative risks are hemorrhage, air embolism, tumor embolus, hyperkalemia from tumor lysis and primary or secondary (ischemic) bile duct injury.9,11,91-95 Excessive blood loss during surgery correlates with increased postoperative morbidity. Median intraoperative blood loss is very variable but is generally less for hemihepatectomy compared to trisectionectomy.11,58 With modern techniques, hepatic resection is associated with a substantially reduced blood loss. Indeed, blood transfusion may be unnecessary in some standard hemihepatectomies.

Postoperative complications include hemorrhage, bile leak, subphrenic abscess, pulmonary complications, hepatic insufficiency, adhesive bowel obstruction, catheter-related blood stream infection, and wound problems. A bile leak is usually from the parenchymal cut-surface and tends to resolve spontaneously with drainage but major duct injury or ischemia are possible causes. Persistent or large volume bile leaks require investigation by radionuclide scan and/or endoscopic retrograde cholangiography. Temporary stenting of the common bile duct encourages transduodenal bile flow which may accelerate resolution. Persistent or infected fluid collections can be successfully treated by percutaneous catheter drainage. Hepatic insufficiency and ascites is rare except in patients with cirrhosis.

The mortality from elective liver resection in children has progressively fallen and is now below 5%. Most patients recover rapidly and can be discharged home within 7-10 days.

LIVER RESECTION IN PEDIATRIC LIVER TRANSPLANTATION

Liver transplantation is the treatment of choice for end-stage liver disease in children. The commonest indication for pediatric liver transplantation is biliary atresia and the majority of these patients are infants. A shortage of size-matched pediatric donors stimulated the development of innovative surgical techniques to produce smaller allografts from adult donors. Many of these techniques and associated aspects of liver function are relevant to liver resection.

The theoretical liver volume of an individual is related to body weight and in children corresponds to 2.5 ml per 100 g (i.e. 2.5% of body weight). When procuring liver grafts from living donors, the aim is to obtain a minimum graft to recipient body weight ratio of 1%.96 Clearly, the function of the graft depends not only on this critical liver mass but also on a wide variety of other graft and host factors. Small-for-size grafts (< 0.8% graft to recipient body weight ratio) are associated with lower graft survival, and reduced metabolic and synthetic capacity.

The adult liver mass is somewhere between 1300 and 1700 g and is reached at 15-20 years of age. The weight of the adult organ depends not only on age and sex (M > F) but also on body mass, alcohol consumption and steatosis. The left lateral segment (segments 2 and 3) comprises approximately 20-25% of the liver weight and the left lobe 40%. Implantation of a large for size graft is also associated with an increased morbidity and a greater risk of graft failure. Table 86.5 provides a guide to the maximum donor:recipient weight mismatch which is usually tolerated in liver transplantation in children.
TYPES OF LIVER GRAFT

- Full-size or whole liver graft
- Reduced-size graft (=cut-down or partial graft)

In a reduced-size graft, a single smaller liver graft is prepared from a larger donor by excision of part of the liver. Reduced or split livers now account for more than 50% of all pediatric grafts.97,98

The first successful reduced-size graft was reported by Bismuth and Houssin in 1984 but these allografts only gained wide acceptance when methods of graft preservation improved to allow an adequate cold ischemic time for the necessary graft dissection.99

Further technical refinements led to the development of both right (segments 5-8 ± 4) and left (2-4) lobe grafts and the left lateral segment (2 and 3) graft. For a reduced right or left lobe graft the retrohepatic cava is usually retained with the lobe but for the left lateral segment graft (Fig. 86.13) the left hepatic vein of the donor graft is anastomosed to the recipient's retrohepatic inferior vena cava.100,101

Split-liver Graft

In a split-liver graft, the donor liver is divided for implantation into two recipients, either as a left lateral segment and a right lobe graft (Fig. 86.14) or as right and left lobe grafts. In 1988, Pichlmayr in Germany and Bismuth in France simultaneously performed the first split-liver transplant.102,63,64 For optimum results in split-liver transplantation, a graft must be prepared from a hemodynamically stable donor aged between 10 and 50 years with normal biochemical liver function and a macroscopically healthy liver with minimal steatosis.

Most liver splits are performed on the back table after cadaveric organ retrieval (ex-situ splitting) but, where logistic and organizational aspects permit, in situ splitting in the donor has some advantages.103 These include better cut-surface hemostasis and a potentially shorter cold ischemic time.

Living Donor Liver Graft

The liver graft is procured from a living donor, usually a close relative. The left lateral segment graft for children was popularized at first but adult to adult right lobe transplantation has since become increasingly common.104 Donors require an intensive physical and psychological work up to assess their suitability. The first successful pediatric living donor liver transplant was performed by Strong et al (1990) who implanted a left lobe graft from the pediatric.
recipient’s mother. Broelsch et al subsequently reported the first successful series.

**Monosegmental Grafts**

The left lateral segment graft (segments 2 and 3) can be used to overcome a size discrepancy from donor to recipient of up to 10:1. Monosegmental grafts (segment 2 or 3) from pediatric donors have been used successfully to transplant small infants weighing as little as 2.9 kg (Fig. 86.15). Long, thin left lateral segments are more suitable than short, thick grafts.

**GRAFT PREPARATION**

Most split-liver grafts are prepared on the bench and this process may take 2-3 hours. Close communication with the recipient hepatectomy team is important to make adjustments according to liver size and vessel allocation in split procedures. The donor liver must be kept immersed in preservative solution (e.g. University of Wisconsin solution) at a temperature of 4°C throughout the dissection. After conventional preparation of the liver and major vessels, an early assessment of vascular and biliary anatomy is important to ensure that there is no anatomical contraindication to splitting, such as an absent portal vein bifurcation, a segment 3 vein draining directly into the middle hepatic vein, atrophy of the left lobe, or an accessory right hepatic artery arising from the left hepatic artery. Many of the commoner arterial anomalies are not a bar to splitting.

The plane of parenchymal transection is dictated by the type of graft being prepared—this is close to the midplane with right and left lobe grafts and about 1 cm to the right of the falciform ligament in left lateral segment grafts. The middle hepatic vein is retained with left lobe grafts. The liver parenchyma may be divided with forceps, an ultrasonic dissector, and/or diathermy. Individual vessels and bile ducts are ligated and divided within the parenchyma. On the cut surface, superficial circular monofilament purse string sutures from the liver capsule are useful in securing hemostasis. The integrity of the cut surface can be tested by gentle injection of preservative solution into the hepatic artery, portal vein and bile duct. After implantation of the graft, argon beam coagulation and fibrin sealant are helpful.

In right/left lobe splits, preliminary back-table cholangiography is valuable. The vessels and bile ducts are divided from within the parenchyma, leaving the division of porta hepatis structures until later. In contrast, the extrahepatic vessels are divided early in the preparation of the left lateral segment graft (usually the portal vein trunk remains with the right lobe but the common hepatic artery may be allocated to either graft depending on recipient vessels); the left hepatic duct is divided well away from the porta hepatis adjacent to the cut surface of the graft. After preparation of the left lateral segment graft, there is some controversy as to whether segment 4 should be preserved with the right lobe or removed. This is partly because the arterial supply to segment 4 is often divided when dissecting free the left lateral segment graft.

**CONCLUSIONS**

Liver resection is an uncommon procedure in children but potentially hazardous. The risks of surgery can be minimized by a thorough understanding of surgical anatomy, meticulous surgical technique, and familiarity with all aspects of hepatobiliary surgery. Occasionally, the surgeon must be prepared to be innovative. Many hepatic resections are relatively straightforward but lesions which are complex because of their size or location are best managed in centers with hepatobiliary surgical expertise.

Liver Resections and Allograft Preparation

The modern era of 'Omics' has heralded a new beginning in our understanding of the molecular aspects of Clinical Immunology with considerable impact on developing new perspectives in the field of organ transplantation. While proteomics and functional genomics have significantly enhanced our understanding of how genes, transcripts and proteins interact, the science of 'immunomics' has helped in identifying a variety of genes, involved in immune regulation. Of the 20-25,000 genes estimated to comprise the human genome, > 4000 are broadly associated with the immune system. Immune tolerance holds the key to controlling unwanted immunological attacks on self and transplanted tissues/ organs. The major determinant of acceptance or rejection of a technically perfect graft is the magnitude of immunologically mediated response against graft, based on the ability to differentiate 'self from nonself'. It has long been recognized that the specificity of antigens involved in graft rejection is under genetic control. Thus while grafts can be freely exchanged among genetically identical individuals, the same is not true in the highly outbreed human species.

The genetic difference between recipient and the donor is predominantly determined by a set of immune response genes clustered together as human leukocyte antigen (HLA) system, which is an analogue of the major histocompatibility complex (MHC) that exists in almost all species. These antigens play an important role in immune discrimination between self and non-self (foreign) and effectively promote detection and elimination of foreign macromolecules. Accordingly, immune mechanisms are associated with the recognition of alloantigens in allogeneic transplantation. This article attempts to provide a simplified review of basic features of the HLA system and its role in long and short-term survival of a renal allograft. Also discussed are other immunological factors that influence the graft outcome. Critical among these are the influence of de novo development of anti donor and lymphocytotoxic antibodies on the overall graft survival and protocols for their removal.

MAJOR HISTOCOMPATIBILITY COMPLEX (MHC)

This article attempts to provide a simplified review of basic features of the HLA system and its role in long and short-term survival of a renal allograft. Also discussed are other immunological factors that influence the graft outcome. Critical among these are the influence of de novo development of anti donor and lymphocytotoxic antibodies on the overall graft survival and protocols for their removal.

MAJOR HISTOCOMPATIBILITY COMPLEX (MHC)

Developments in the field of histocompatibility have largely been related to the progress in technology, computer aided programs of data storage and analysis. In the MHC region, a total of 224 genes have been identified, of which 128 are assumed to be functional genes and 96 are pseudogenes. More than 40% of the genes have one or more assigned immune functions. Four inherent features of the MHC, namely i) extraordinary polymorphism, ii) tight linkage among its various loci, iii) nonrandom association of alleles and iv) its multi-peptide binding ability make the system of particular interest in biology and medicine. The MHC molecules are the peptide-display molecules of the immune system that bind peptide fragments derived from protein antigens (e.g. viruses, bacterial peptides and mismatched transplant antigens) and display them on the surface of APCs, evoking effector responses upon recognition by the T-cell receptor (TCR). As the number of peptides that can be generated is very large, there is a biological need for an extensive MHC gene pool. Apart from being an invaluable tool in organ and bonemarrow
transplantation, MHC is specifically relevant with respect to its causative role as an important immunogenetic marker of 'risk prediction' for several diseases. In recent years, there has been an upsurge of information on MHC ligands, peptide motifs and structural requirements of their optimal binding. Knowledge on these lines has been utilized effectively for designing immune intervention therapies in autoimmune and infectious diseases.4,5

In the area of transplantation, experience of several centers suggests that a critical factor that determines the success of a renal allograft is through better understanding of the immunobiology of the human MHC and more precise and comprehensive immunogenetic matching between the donor and recipient. This is based on the notion that 'better' the matching, better the transplant outcome". In addition to this, other immunological factors also influence graft survival to a large extent. These include the presence of antibodies and sensitization status of the recipient, HLA versus non-HLA humoral immunity, involvement of the MHC class I A (MICA) antigen system and genetic constitution of the host.6-9 Although acute rejection episodes are important risk factors for the success of a renal allograft, the major challenge today remains in the area of chronic rejection.

**GENETICS OF HLA**

The human MHC gene cluster (HLA molecule) spans a region of approximately 4000 kb (4×10⁶ nucleotides) on chromosome 6 (position 6p21.1 to 21.3) and contains several genes, only some of which are related to histocompatibility. These genes are grouped into three distinct sets of molecules, each comprising of a cluster of immune response (Ir) genes (Fig. 87.1). The most centromeric segment is the class II region that spans around 1100 kb, and contains the HLA-DP, DQ and DR loci: The class I region, on the other hand lies at the telomeric end and contains the classical HLA-A,B,C and related loci spread over a region of approximately 2 MB. Both class I and II gene products show important differences in structure, function and tissue distribution. They represent the major transplantation antigen system. Matching donors and recipients for class I and class II antigens during organ and bone marrow transplantation is therefore critical to the survival of a graft.10,11 In contrast, the central 'non-HLA' or class III region contains genes whose products are involved in the complement cascade and various non-immunological functions.

**HLA Class I Genes**

HLA class I molecules are expressed on all nucleated cells. Upto 35 genes have been defined in this region
so far although HLA –A, –B and –C are most important since their products have been well defined as ‘classical transplantation antigens’. Several other human class I genes with less defined gene products have been identified and include HLA –E, –F, –G, –H and –J. All these genes are polymorphic. Using tools of molecular biology and DNA typing methods, 238 alleles have been identified in locus A, 451 in locus B, and 238 in locus Cw. Conventional serology, on the other hand, can define much less number of alleles in each of these loci (23 in locus A, 47 in B, and 8 in C locus).

Biochemically, HLA class I molecules are heterodimeric glycoproteins consisting of an MHC-encoded alpha or heavy chain of about 44,000 daltons molecular weight and non MHC encoded light chain (beta-2 microglobulin) of 12,000 dalton molecular weight. The alpha chain is about 350 amino acid residues long and can be divided into three functional regions: external, transmembrane and intracytoplasmic (Fig. 87.2). The extracellular portion of the heavy chain is folded into three globular domains, α1, α2 and α3, each of which contains stretches of about 90 amino acids long, and encoded on separate exons. The transmembrane region spans the lipid bilayer of the plasma membrane while the cytoplasmic region has elements of the cytoskeleton.

The β2 microglobulin (β2m) is a soluble protein encoded by a gene located on chromosome 15 in man and associates noncovalently with the heavy alpha chain. Cells lacking β2m are deficient in the expression of MHC class I molecules. The X-ray crystallography of class I molecule has provided an understanding of the three-dimensional structure of the MHC:12,13

a. The membrane proximal structures (α3 and β2m) are essentially conserved and folded to form immunoglobulin (Ig) like domains. The α3 and β2m are responsible for imparting general shape to the class I molecule by providing a platform to the top lying polymorphic domains.

b. The region distal from the membrane is formed by α1 and α2 domains which take part in antigen binding. Structurally, therefore, the peptide-binding groove of the MHC class I molecule is made up of only one polypeptide chain, while two chains contribute to the peptide-binding groove of the MHC class II molecule. The two alpha helices form the sides of a cleft whose floor is formed by a plane of eight anti parallel beta pleated sheets. The dimensions of this cleft (25Å×10Å×11Å) are sufficiently large as to accommodate foreign peptides which are about 9 amino acids long.

c. Most of the polymorphic residues of the MHC class I molecules are clustered in the cleft and those critical for recognition of class I molecules by T lymphocytes are located around it, accounting for the differential ability of different allelic forms of class I molecules to bind to a variety of peptides.

d. Functionally, MHC class I molecules bind to CD8 co-receptor molecules on the T-cells and therefore present antigen to CD8 T-cells. MHC class II molecules bind to CD4 co-receptors molecules on T-cells and hence they present antigen to CD4 helper T-cells.

**HLA Class II Genes**

The HLA-class II region of the human MHC extends over 1000-1200 kb with at least six subregions termed DR, DQ, DO, DN, DM and DP (Fig. 87.1). They are expressed as heterodimers on the cell surface and are composed of two genes that traverse the plasma membrane: an α (alpha) gene and a β (beta) gene (Fig. 87.2). The alpha genes encode glycoproteins of 34000 dalton molecular weight which are much less polymorphic compared to beta genes (mol. wt. 29000 daltons) which are highly polymorphic. The tissue distribution of class II molecules is relatively restricted. They are expressed on specific cells of the immune system involved in antigen presentation (APCs). These include B lymphocytes, macrophages, monocytes, epithelial cells, dendritic cells, Langerhan's cells and Kupffer cells. In addition, some other cell types such as keratinocytes, thyrocytes and human T lymphocytes are known to express class II molecules under certain situations, e.g. following viral infection and induction due to gamma interferon-like factors.

X-ray crystallographic studies have revealed overall similarity in the structure of class II HLA molecules with that of class I molecules.14 The alpha and beta chains consist of two extracellular domains of 90 amino acids each. The α2, β2 domains are close to the plasma membrane, whereas the α1, β1 domains are on the top of the molecule. Long peptides of at least
15 residues are seen to be bound on the class II molecule.

Currently, 438 DRB1, 71 DQB1 and 59 DPB1 alleles can be recognized using DNA typing methods of PCR and oligonucleotide probes. Of course, the number of alleles defined by serology remains very small (14 DR, 9 DQ and 6 DP).

**Non-MHC Genes in Human Class II Region**

In addition to the classical HLA class II genes, two groups of non-HLA genes have recently been identified in the MHC class II regions. There are two genes in the first group named as TAP-1 and TAP-2 genes for 'transporter associated with antigen processing'. These belong to a large family of transporters called ABC (ATP-binding cassette) transporters. The second group is proteasome-related low-molecular-mass polypeptide (LMP) complex that includes LMP2 and LMP7 genes. Both the LMP as well as TAP genes are polymorphic.

**Class III Genes (Central Genes)**

At least 39 genes have now been located in a 1000 kb stretch of DNA within the class III region interposed between class I and class II regions. This includes the complement genes C2, C4 and Bf (factor β), the TNF - α and TNF-β genes and the Hsp 70 (heat shock protein) genes. In addition, genes with no obvious association with the immune system have also been identified in this region. This includes G7α(valyl-tRNA synthetase) and CYP21B (steroid 21-hydroxylase).

**HLA Class I and Class II Molecules Differ in Antigen Presentation**

The determination of the crystal structure of the human MHC class I and class II molecules and the identification of the putative peptide binding cleft established that MHC molecules are the principal antigen binding and presenting molecules to the T-cells. Thus peptide antigens alter the HLA molecule by occupying the cleft to be scrutinized by the T-cell. This concept was first put forward by Zinkernagel and Doherty whose studies of anti-viral T-cell recognition led to their award of the Nobel Prize for Medicine in 1996.15

The fundamental difference in the above process is that whereas class I MHC molecules bind 'endogenous' peptides and eliminate them through the process of cytotoxic T-cell killing (inside out mechanisms), the class II molecules, on the other hand, bind peptides derived from 'external' sources (exogenous) and present them to CD4+ helper T-cells.
(outside in mechanism). The processing pathway in both situations utilizes highly specialized cell machinery that works most effectively. The endogenous proteins in the cytoplasm of the cells are digested into 9-10 amino acid peptides by the LMP complex, a distinct subset of the cellular pool of proteasome. Peptides in the cytoplasm may gain access to the TAP transporter on the membrane of the endoplasmic reticulum (ER) via a specific transporter. Peptides transported into the ER lumen bind to class I molecules, inducing a conformational change that may facilitate their export to the cell surface. The CD8+ cytotoxic T lymphocytes see this MHC-peptide complex through the T-cell receptor and other co-receptors, subsequently causing killing of the target T-cell.

In the class II pathway, antigens taken from outside the cell by endocytosis are digested by the proteolytic enzymes in the endosomal compartment into small peptide fragments. The MHC class II molecule with its α and β chains assembles in the ER with the invariant chain to form a stable trimolecular complex which inhibits the binding of endogenous or self-peptides in the ER. The trimolecular complex is efficiently transported out of the ER and is targeted to a post-Golgi compartment in the peripheral cytoplasm. The invariant chain is subsequently cleaved in endosomes, opening up the cleft for peptide occupancy.

The development of accurate and reproducible high-resolution DNA-based HLA typing methods have significantly improved our capabilities to define HLA alleles at a single nucleotide difference. Further advanced technologies based on sequencing, mass spectroscopy and DNA chips have now opened up a whole new dimension of studying SNPs, i.e. polymorphism at a single nucleotide level. Using these procedures, an appreciable number of ‘novel alleles’ and unique HLA haplotypes have been discovered in the Indian population.16,17

LEVEL OF HLA MATCHING IN TRANSPLANTATION

Owing to its inherent extreme polymorphic diversity, the MHC has proven to be a major barrier in selection of HLA matched donors for patients requiring organ transplantation. Theoretically, the likelihood of finding a match among any two unrelated individuals sharing the same genotype is less than 1 in 10 billion. Although the HLA system comprises multiple Class I and class II genes, most matching strategies for renal transplantation consider only HLA-A, HLA-B and HLA-DR loci. Because of the co-dominant expression of HLA genes, the degree of compatibility ranges from 0 to 6 matches (two for each locus).

The degree of HLA matching required for successful organ grafting depends upon the donor category and nature of the graft. In renal and other solid organ transplantation, a large body of data indicates a direct relationship between graft survival and the level of matching.18-20 As outlined in Table 87.1, four types of donors are generally available for renal transplantation. Family donors include parents, siblings and offspring and their match status is determined by the parental haplotype inheritance and whether they share one, both or no HLA haplotypes.

A haplotype refers to a set of HLA alleles on one chromosome inherited together from one parent and defined through family studies (Fig. 87.3). Accordingly biological parents and offspring always share at least one haplotype and such donors are referred to as 'haploidentical. On the other hand, as per the Mendelian segregation analysis, at least 25% of the siblings have an opportunity to share both haplotypes with each other and kidneys exchanged amongst them are called ‘HLA-identical’ sibling transplants. In bone marrow or hematopoietic stem cell transplantation (HSCT), the level of HLA matching is much more critical than solid organ transplants because of the risk of graft versus host diseases (GVHD) where T-cells in the stem cell graft react against allogeneic host HLA molecules expressed in all tissues. Thus while HSCT is limited to HLA-identical sibling donors, renal transplants with live related donors involves mostly haploidentical parental/sibling or offspring donors and very few are HLA-Id donors.

Most grafts from unrelated donors that include cadaver (or deceased), spousal or other unrelated donors are mismatched at one or more HLA loci. Thus it is not unusual to see patients transplanted with a graft bearing a 6/6 (HLA-A, B and DR loci) mismatch, even though, statistically, graft survival in these patients is significantly reduced compared with the survival in better matched (0/6 mismatch, or 1, 2/6 mismatch or family donors) patients.
Pediatric Surgery—Diagnosis and Management

Fig. 87.4 summarizes the results of long-term renal graft survival compiled by the University of California Los Angeles (UCLA) registry involving a large number of transplants. The ten year graft survival of 70% seen in the HLA identical sibling grafts is significantly reduced to 50% for the HLA haploidentical parental donor grafts and < 40% for those involving poorly matched cadaver donors. Further, the data is expressed as 'half-life' that indicates the period at which at least half the grafts are still functioning. While it is 25 years for well matched HLA-Id sibling grafts, it is 11.5 years for parental donors and only 7.8 years for cadaver donor grafts which are generally mismatched. Again, there is no significant difference in the half life of the latter grafts in the period between 1996-2006 despite introduction of highly effective immunosuppressive agents including Tacrolimus and Sirolimus.

It may be mentioned here that optimal HLA matching of renal grafts using cadaveric donors is greatly improved by organ sharing schemes such as within Europe, UK, North America, Japan and other developed countries. Systematic organ sharing involving HLA matching practiced by the Large Organ Transplant Organizations such as Eurotransplant Foundation (Netherlands), United Network of Organ Sharing (UNOS) USA, ScandiaTransplant, etc. have proven extremely useful in making available 6/6 or 5/6 matched donors for renal transplantation. HLA matching is logistically less achievable for heart/lung and liver transplantation which almost invariably results in some mismatching between the host and graft.

Since the passage of the Transplantation Act of Human organs by the Indian Parliament in 1994 (TAHO 1994), a large number of spousal transplants have been conducted in India. As expectedly, most of these are poorly matched and are from wives to the husband. The Act also has a provision of permitting unrelated voluntary donors provided they are motivated through altruistic reasons and are approved by the Hospital Authorization Committee. Again such donors are poorly matched and long-term graft survival with these is not very encouraging.

DIRECT AND INDIRECT ALLORECOGNITION

The term allorecognition refers to T-cell recognition of genetically encoded polymorphism between members of the same species. The immunological
event(s) that initiate graft rejection involves interaction between the donor derived peptides and major histocompatibility complex (MHC) molecules on antigen presenting cells (APCs) and the T-cell receptor on CD4+ recipient T-cells. The latter can recognize donor alloantigens through either of the two pathways of allorecognition. In the direct pathway, the host T lymphocytes recognize native MHC molecules expressed on graft-associated APCs. In the indirect pathway, on the other hand, the same cell recognizes donor alloantigen-derived peptides in the context of self MHC molecules expressed on recipient APCs (Figs 87.5A and B). Historically evidence favors a predominant role of the direct pathway especially during acute rejection. Host T cells primed through the direct pathway have the ability to engage the allograft directly and thus to efficiently mediate effector functions. Further, the proportion of host T-cells that can respond to native alloantigens is substantially greater than the proportion of host T-cells that can respond through the indirect pathway to donor-derived peptides presented in the context of self MHC. It is likely that the direct pathway predominates early post-transplant and is a major factor in acute rejection since donor derived APCs expressing donor alloantigens rapidly migrate from the graft and enter the secondary lymphoid tissues, where they can encounter and prime the allospecific T-cells.

On the other hand, indirect pathway of alloantigen recognition involves recipient T-cells that recognize allogenic peptides presented by MHC molecules on self-APCs. Donor MHC molecules are presumed to be shed off from the allograft into the recipients circulation, phagocytosed by the recipient APCs, processed into peptides and presented on the cell surface by self MHC Class II molecules. The recipient CD4+ T-cells recognize this foreign peptide-self MHC complex and get activated, proliferate, differentiate and secrete various cytokines from the effector cells which in turn destroy the graft. A variety of cell types, that include cytotoxic T lymphocytes, B cells, macrophages and natural killer cells are recruited in a graft undergoing rejection. The three main
mechanisms implicated for graft destruction are cell-mediated cytotoxicity, delayed type hypersensitivity and antibody-dependent-cellular cytotoxicity. Of these, direct antibody mediated damage and development of donor-specific alloantibodies that can cause rejection has been found to be the most critical and lends support to the importance of antibodies in graft rejection. It is now amply clear that the pre and post-transplant development of IgG antibodies against donor epithelium and/or endothelium may predict the risk of allograft rejection.24,25 Thus, humoral mechanisms appear to play the most critical role both in chronic as well as acute rejection.

PRE-TRANSPLANT EVALUATION OF ANTIBODIES

Anti-donor Antibodies

The most important factor in organ transplantation is the meticulous evaluation of the possible occurrence of antidonor antibodies before transplantation. This is referred to as the ‘cross-match test’ and is usually carried out by the complement dependent lymphocytotoxicity (CDC) assay. In this test, the donor lymphocytes are first incubated with the patient serum, followed by the rabbit complement and finally the lysis of lymphocytes is assessed by the uptake of an extravital dye like trypan blue or eosin red. A positive CDC crossmatch is generally a contraindication for organ transplantation because of the presence of IgG antibodies in the recipient leading to antibody-mediated (hyperacute) rejection. This applies particularly for kidney transplants whereas the liver allograft shows a relative resistance to antibody-mediated injury. In kidney transplantation, several cross match assays have been developed with the purpose of increasing the sensitivity and specificity of the test and depending upon the type specificity of the antibody to be detected. These include the anti human globulin (AHG), flow cytometry and ELISA based test systems. Serum treatment with dithiothreitol (DTT) is used to distinguish clinically less relevant IgM type antibodies.

Crossmatch assays detect different types of antibodies, some of which are deleterious while others
may be harmless or even beneficial for the graft. Generally, the auto reactive T and B cells detect IgM, cold reactive auto antibodies that are not harmful. Many investigators have reported that successful transplantation can be performed with a positive donor specific cross match due to IgM antibodies after their reduction using dithiothreitol.26,27 Also most centers agree that neither the short nor the long-term graft survival of deceased donor kidneys is influenced by a positive flow B-cell IgG cross match.28 Further transplantation can be performed in the presence of a negative cross match with a current serum sample and a historical positive serum sample particularly in the case of first grafts.29

The greatest drawback of the CDC test is that in addition to the HLA specific antibodies, it detects non-HLA auto antibodies. This can be circumvented by incubating the test at 37°C (and not at room temperature) to avoid reaction of cold auto antibodies and by the addition of dithiothreitol to the serum to inactivate IgM antibodies. It may be noted, however that some strong auto antibodies, present particularly in patients with systemic lupus erythematosus (SLE), are of IgG type and therefore DTT treatment in such situations does not completely solve the problem of excluding extraneous reactions. Ultimately a better technique with increased specificity and sensitivity is required to detect donor specific antibodies for meticulous evaluation of anti-donor antibodies.

Panel Reactive Antibodies

Transplant candidates often become sensitized due either to a prior transplant, pre-transplant blood transfusions or previous pregnancies/abortions. Serum screening for generalized lymphocytotoxic antibodies (not necessarily anti-donor) against a random cell panel derived from healthy volunteers (covering diverse HLA antigen specificities) provides an assessment of the degree of sensitization expressed as the percentage panel reactive antibody (PRA). Generally, a panel of up to 50 volunteers is sufficient to cover the known broad HLA specificities. The PRA test result is expressed as 0-10% (non-sensitized), 1-50% (moderately sensitized) and 51-100% indicating a high degree of sensitization. Patients with high PRA values are more likely to have anti-donor antibodies in addition and are therefore prone to graft rejection. These patients generally require longer time before a transplant can be planned on them since their antibody levels must come down to the threshold level. Meticulous evaluation of the recipient sensitization status both during pre- and post-transplant periods provides highly useful information on the state of allosensitization. Graft survival analyzed with respect to the post-transplant PRA at a 2 year follow up time indicates that the overall survival is significantly compromised in the highly sensitized group as compared to the non-sensitized patients, along with high incidence of acute and chronic rejection episodes.30 The PRA test is equally important both in live related as well as cadaver donor transplant situations. Most highly sensitized patients show persistence of the same pattern of antibody specificity against one or a few shared epitopes. A better understanding of the antibody specificity improves the selection of renal transplant donors with acceptable HLA mismatches, and significantly improved graft outcome.

Flow Cytometric Crossmatch (FCXM)

Flow cytometry is a more sensitive technology for the detection of anti-donor antibodies during renal transplantation. The assay detects the anti-donor antibodies with a 10 to 250 fold greater sensitivity than the CDC test and characterizes their isotype(s) using fluorescent labelled secondary anti-human antibodies. Further, it is possible to determine if these antibodies are directed against class I and/or class II HLA determinants. T and B lymphocytes are generally used as targets to distinguish anti-HLA class I from class II reactivity. By using fluorescent labeled anti-human globulin isotype-specific antibodies like, anti-human IgG or anti-human IgM, isotype of the antibody can be easily determined. Finally, the intensity of the reaction, which is related to the ratio of antibody molecules per target antigen, can be determined quantitatively by median channel shift or relative change in fluorescence ratio (Figs 87.6A to F). However, determining the HLA specificity of the anti-donor antibodies is generally difficult, mainly due to the requirement of lymphocytes derived from a diverse pool of donors.

Detection of anti-donor antibodies by flow-cytometry is of immense value for the clinicians in the
field of transplant immunology. Mismatched HLA antigens in the transplant may induce the formation of specific antibodies against the donor antigens. The conventional serological cytotoxic cross match (CTXM) is sometimes unable to detect sub threshold levels of donor specific antibodies (DS-Abs), which can be otherwise detected by flow cytometry. In the post-transplant scenario, FCXM is helpful in differentiating acute rejection episodes from other causes of declining graft function like cyclosporin-A (CsA) nephrotoxicity and acute tubular necrosis (ATN). Our data on the live related donor transplants carried out at the AIIMS center has shown that a comprehensive assessment of anti-donor antibody repertoire using both CDC as well as flow cytometry assays provides a more sensitive system of assessing sensitization status of the recipient and can prove to be of immense prognostic value in renal transplantation.31

Figs 87.6A to F: Representative samples of the flow cytometric cross match (FCXM) showing negative (shaded line) and positive (dotted line) control peaks as compared to patient (thick line) sample. A mean peak shift to the right of > 40 is taken as the positive result (A)
Enzyme Linked Immunosorbant Assay (ELISA)

Use of the ELISA based method for the determination of HLA antibodies was introduced in 1993 to detect IgG and IgA antibodies to HLA antigens. Purified HLA antigens are adhered to a microplate, and antibody reactivity is measured using a sandwich assay. Experience of several centers suggests that ELISA detects HLA antibodies with greater sensitivity than the CDC test. Although the conventional colorimetric substrates of ELISA are probably less sensitive than flow cytometry, fluorescent substrates may be as sensitive. The main advantage of the test is that ELISA readers are readily available and are far less expensive than flowcytometers. Moreover, many reactions can be examined in a 96-well plate, thus permitting determination of the specificity of HLA antibodies. As with flow cytometry, complement fixation is not required and the antibody isotype can be readily resolved. Nevertheless, a major disadvantage of the ELISA test is that it does not provide information on the presence of anti-donor antibodies. Indeed in most centers, the donor cells are often not available for the determination of donor-specific activity following transplantation. Therefore, most ELISA assays detect anti-HLA antibodies reactive against a panel of antigens. We have recently made a comparison of the CDC versus FCXM and ELISA based tests for determination of alloantibody development following renal transplantation. Our data indicate that while FCXM is a sensitive test for the detection of donor specific antibodies, ELISA offers the additional advantage of detecting anti-HLA antibodies, which are detrimental for the graft survival.

CLINICAL RELEVANCE OF POST-TRANSPLANT ANTI-HLA AND NON-HLA ANTIBODIES

In the previous section, we have observed that occurrence of pretransplant anti-HLA antibodies plays a central role in graft survival, particularly in kidney transplantation. The presence of such preformed donor specific anti-HLA antibodies is always excluded before transplantation by performing crossmatches using current and historic recipient serum samples. However, in recent years, it has become clear that several HLA antibodies that develop denovo post transplant and are not necessarily donor specific, are also associated with poor graft survival. It is therefore advisable to monitor routinely the post-transplant development of such antibodies, which could be a predictive marker for allograft function. Indeed the presence of circulating anti-HLA antibodies along with positive C4d staining on allograft biopsies has been reported to have strong correlation with the development of chronic rejection in kidney transplant recipients. Long-term follow-up of these patients is necessary to establish whether patients who subsequently reject their grafts come from the antibody-positive group. Our results are also consistent with those of others that renal transplant patients with anti-HLA antibodies, even though they are not donor specific (cross-match negative) have significantly poor graft survival as compared to the negative group.

Despite the availability of potent immunoregulatory drugs and other biologic agents, allograft rejection still remains a formidable challenge in renal transplantation. The presence of donor lymphocyte-reactive HLA-specific antibodies before and after transplantation is associated with rejection episodes and renal allograft loss. Nevertheless, rejections may still occur in the absence of detectable lymphocytotoxic antibodies, suggesting that non-HLA antigenic systems may also play a role in hyperacute and acute renal allograft rejections. Amongst these, the MHC class I related chain (MICA) is a locus situated on chromosome 6 linked to HLA and determines a polymorphic series of antigens similar to HLA. The MICA and MICB genes are located in close proximity to the HLA-B locus and encode for 62 kDa cell-surface glycoproteins. MICA is expressed on the cell surface of endothelial cells that makes this polymorphic molecule a target for both cellular and humoral immune responses. Indeed MICA has been reported to be an important polymorphic alloantigen capable of inducing synthesis of specific allo-antibodies in transplant patients and as a target for humoral immunity associated with irreversible rejection of kidney allograft. Recently, it has been reported that antibodies to MICA are produced in the course of immunization by pregnancy and kidney transplantation, and they occur more frequently in patients experiencing rejection episodes compared to those with well functioning grafts. Presensitization of kidney-transplant recipients against MICA antigens
is associated with an increased frequency of graft loss and this might contribute to allograft loss among recipients who are well matched for HLA and have otherwise no evidence of the presence of anti HLA antibodies.

Studies carried out by us on LRD renal transplants have revealed that MICA is an important antibody target towards graft destruction. Patients who develop both anti HLA and MICA antibodies reject their grafts more frequently than those having either of these antibodies. Thus, post-transplant monitoring of both these antibodies could not only be predictive of renal allograft failure, but also as an important prognostic marker in renal transplant subjects.

**GRAFT REJECTION**

Since transplant immunity leads to rejection primarily due to genetic disparity between donor and the recipient, it is plausible that the patient and donor are matched for HLA gene loci as completely as possible. Although full HLA compatibility is possible only among genetically identical twins (syngeneic grafts) and to a lesser extent between HLA-identical siblings, the vast majority of transplants come from HLA incompatible unrelated donors. These include parental and/or sibling donors, a majority of whom are HLA haploidentical (50% match grade). Deceased and spousal donors are likewise poorly matched. Accordingly, immunosuppressive drugs are given to control the host immunity steaming out of the HLA disparity so that rejection can be prevented or controlled and the recipient develops long-term acceptance (or tolerance) of the graft. Rejection can be mediated by antibodies, lymphocytes or both and can manifest itself in different ways: hyperacute rejection (during the early post-transplant period, within hours), acute rejection (may occur at any time) and chronic rejection (a slowly developing process causing a progressive decline in graft function).

**Hyper-acute Rejection**

Hyperacute rejection is mainly due to the presence of preformed donor specific alloantibodies in the presensitized recipients. Vascularized organs (especially kidney and heart) are at risk for hyperacute rejection if the patient has preformed donor-specific alloantibodies. This humoral presensitization (or alloimmunization) may be caused by a previous transplant, blood transfusions and pregnancy. The primary target of the donor-specific antibodies is the vascular endothelium of the grafted organ. The most common target antigens are HLA class I, and ABO, although other less-well defined antigens are also involved. HLA class II antigens seem less relevant in hyperacute rejection because they are not strongly expressed on the vascular endothelium. Antibodies mediating hyperacute rejection are almost always complement-fixing and could be of IgG or IgM type or both. Alloreactive T lymphocytes are rarely involved in hyperacute rejection. A critical step in alloantibody-mediated rejection is the initiation of the Complement cascade that involves binding and activation of C1q, which requires at least two Complement-fixing sites on the antigen/antibody complex. This requires close proximity between antigens and complement such that activation will not occur if the antigen density is too low on the cell surface. Activation of the Complement cascade leads to the release of various inflammatory mediators and the initiation of the coagulation and fibrinolytic systems. Hyperacute rejection is manifested by rapid vascular constriction, edema and thrombotic occlusion. Endothelium stimulation and exposure to sub-endothelial basement membrane proteins activate platelets which then adhere and aggregate in the vasculature. Soon afterwards, polymorphonuclear leukocytes (PMN) adhere to the vascular endothelium, leading to its damage.

**Acute Rejection**

Acute cellular rejection is mediated by lymphocytes which have become alloactivated against donor transplantation antigens. In vivo stimulation of alloreactive T-cells takes places primarily in the peripheral lymphoid tissues of the recipient although intragraft sensitization may also occur. The strongest stimulus is provided by donor dendritic cells in the allograft which enter the circulation and end up on the lymphoid tissues of the recipient. These dendritic cells function as antigen-presenting cells and provide a strong stimulus of HLA class II reactive CD4 cells, which can stimulate the growth and differentiation of HLA class I reactive CD8+ cytotoxic lymphocytes. Alloreactive lymphocytes enter the circulation and react with allograft vascular endothelium, which is the primary target of the initial stage of cellular rejection.
The lymphocyte-endothelial interactions depend on the expression of appropriate target antigens on the endothelium. HLA class I antigens are constitutively expressed at the cell surface whereas HLA class II antigen expression (with the exception of the APCs) must be induced by various cytokines, especially gamma interferon (IFN-γ). Furthermore, adhesion molecules like intercellular adhesion molecules (ICAMs), vascular cellular adhesion molecules (VCAMs), integrins, selectins, play an important role in the cell surface interaction between lymphocytes and endothelium, their activation and release of inflammatory mediators including cytokines and, chemokines. These processes lead to migration of lymphocytes through the vascular wall to the grafted tissues.

Graft-infiltrating lymphocytes can mediate various effector mechanisms of allograft immunity. Besides a direct cytotoxic effect on graft parenchymal cells, lymphocytes can mediate a delayed type hypersensitivity leading to graft rejection. The latter involves the recruitment of macrophages and release of various cytokines. Other inflammatory cells may also be seen during rejection, including neutrophils, eosinophils, B lymphocytes and NK cells. Varying proportions of CD4 and CD8 lymphocytes are found in cellular infiltrates of rejecting allografts. Many of them express T-cell activation markers, like IL-2 receptors and these activated T-cells, probably through release of IFN-γ and other cytokines, increase expression of HLA antigens (especially class II) on the vascular endothelium and other target cells in the graft parenchyma. Consideration must be given to additional immunological mechanisms of graft injury secondary to infection, especially by viruses. This means that other types of lymphocytes may infiltrate the graft and these could mediate effector immune responses against virus infected cells in the graft. Another possibility is that graft infiltrating lymphocytes mediate recurrent autoimmune disease processes.

**Chronic Rejection**

This major complication, affecting most long-term transplant survivors, is not completely understood. Chronic rejection is characterized by vasculopathy, fibrosis and a progressive loss of the organ function. Its pathogenesis probably involves both humoral as well as cellular immune mechanisms. Chronic rejection may be mediated by low-grade, persistent delayed type hypersensitivity response in which activated macrophages secrete mesenchymal cell growth factors leading to fibrosis. Of potential importance are persistent viral infections which induce cellular immune responses simultaneously along with the donor-specific alloreactive T-cells. Chronic rejection may also reflect chronic ischemia secondary to injury of the blood vessels by antibody or cell-mediated mechanisms. Vascular occlusion may occur as a result of smooth muscle cell proliferation in the intima of the arterial walls.

**IMMUNE PROFILING: PREDICTIVE VALUE OF HLA ANTIBODIES**

The humoral theory of transplantation states that antibodies cause allograft rejection, lead to C4d deposits associated with early kidney graft failure, are a good indicator of presensitization leading to early acute rejection, are present in a large majority of patients who reject a kidney graft, are associated with chronic rejection and appear in circulation well before rejection. One of the challenges for organ transplantation today is development of diagnostic criteria for humoral rejection, assess the relevance of immune profiling, develop potential immunologic paradigms and develop effective treatment protocols for removal of alloantibodies. A positive CDC or AHG cross match result poses a high risk of humoral rejection or early graft loss. A positive CDC cross match is a contraindication to transplantation particularly when antibody in the recipient cannot be reduced with desensitization protocols. A positive flow or historic CDC cross match result poses intermediate risk for early acute rejection that may require intensive immunosuppression. Recipients with a negative flow or AHG crossmatch have low risk of acute humoral rejection with conventional immunosuppression. Hence it is essential that antibody specificity and cross match should always be assessed prior to transplantation. Table 87.2 summarizes strategies for cross matching depending on the 'risk' status of the patients.

Diagnosis of acute and chronic humoral rejection is based on clinical, pathologic and serological criteria. When recipients have deteriorating function and other
potential causes such as cellular rejection or drug toxicity are ruled out, clinicians normally resort to allograft biopsy to make a definitive diagnosis. However, it is often difficult to distinguish humoral rejection from other forms of graft dysfunction, so current experience depends mainly on the results of the existence of circulating antibody for diagnosis.

Strategies to diagnose and treat acute humoral rejection involves four parameters: allograft dysfunction, circulating HLA or DSA antibody, C4d deposition in peritubular capillaries and other rejection morphology on allograft biopsy. These parameters help in defining four levels of rejection. Types 1-3 represent subclinical grades where there is evidence of humoral rejection but no measurable graft dysfunction Type 1 classification for patients with detectable antibody (DSA) indicates a biopsy would be informative to determine the severity of rejection. Type 2 indicates C4d staining is observed in the absence of other histologic parameters, while type 3 indicates both C4d and histologic evidence of humoral rejection is present. If type 4 dysfunction is observed with the other three parameters, treatment for antibody removal is recommended.

**TREATMENT OF HUMORAL REJECTION**

Two treatment protocols are currently being used to remove donor specific antibodies for patients awaiting renal transplant: i) one protocol uses high dose intravenous immunoglobulin (IVIG) to reduce or eliminate antibody reactivity. Desensitization is more durable with this protocol in comparison to the second protocol, although not all patients respond to treatment. ii) The second protocol uses plasmapheresis, and a lower dose of IVIG. Most patients respond to this treatment, but the procedure is expensive and rebound of antibody can occur if the patient does not undergo kidney transplantation immediately after completion of the protocol.

Terasaki and Ozawa through a large collaborative study of 2231 transplanted patients have concluded that regular screening of HLA antibodies post-transplantation is predictive of subsequent graft failure and this predictive value can be enhanced among patients with higher serum creatinine values. Thus if HLA antibody testing is to be used for monitoring, the value of testing will depend on serum creatinine value at any given time. If the creatinine is low, one can expect that the graft will function well for some years, and the antibody results will give a warning far in advance of failure. If Kidney damage develops, as shown by higher serum creatinine levels, then the results of the antibody screening will require rapid action, if graft failure is to be stopped.

**CYTOKINES AND CYTOKINE GENE POLYMORPHISMS IN RENAL GRAFT OUTCOME**

Cytokines are known to play a central role in directing both the magnitude and type of the immune response directed against the grafted tissue. Since immunologic processes like antigen recognition and proliferation of lymphoid cells, mark the beginning of graft dysfunction, their products (cytokines and antibodies) appear quite early in the circulation following transplantation.

Current immunologic protocols fail to detect acute rejection at an early stage before the onset of clinically observable rejection episode, a time point by which already certain level of irreversible damage to the graft tissue has take place. Since the cytokines produced by the alloactivated T-cells play an important role in the initiation and maintenance of alloimmune response,
an assessment of their profile could provide an important predictive marker of post-transplant immune activation and may provide useful clues for tailoring immunosuppressive regimen leading to improved clinical care.\textsuperscript{47-49} Our own data indicates that monitoring intracellular cytokine expression profile of primed peripheral T-cells is important and that estimation of circulating sIL-2 levels post transplantation provides not only a useful prognostic tool but also a better alternative for functional assessment of immune-suppression for follow up of transplant subjects.\textsuperscript{50}

Quantitative estimation of cytokines at the site of the allograft is a useful indicator of graft function and helps to determine accelerating or suppressing rejection. The level of cytokine production has been associated with polymorphisms in cytokine gene promoters.\textsuperscript{51-53} It is now accepted that promoter region polymorphisms can directly or indirectly affect the binding of transcription factors and consequently increase or decrease the production of mRNA, thus regulating cytokine production. Cytokines can be categorized into two broad groups: i) the so-called Th1-type cytokines, including interleukin-2 (IL-2), tumor necrosis factor-\(\alpha\) (TNF-\(\alpha\)), TNF-\(\beta\) and interferon-\(\gamma\) (IFN-\(\gamma\)), that mediate cellular immune responses and are proinflammatory ii) cytokines described as the Th2 type, which include IL-4, IL-5, and IL-10, that have been shown to inhibit the development and function of Th1 cells, suppress inflammation, and enhance humoral pathways of the immune response. These are designated as the anti-inflammatory cytokines.

The proinflamatory cytokine TNF-\(\alpha\), which stimulates macrophage function and increases MHC class II antigen expression, has been implicated both in acute as well as chronic rejection. It has been shown that a G to A polymorphism at position –308 on the TNF-\(\alpha\) gene promoter, giving alleles TNF1 and TNF2, respectively, is associated with a six to seven fold increase in transcription of the TNF-\(\alpha\) gene \textit{in vitro}.\textsuperscript{54} Similarly, the activation of endothelial cells and the subsequent expression of intercellular adhesion molecule-1 (ICAM-1) induced by TNF-\(\alpha\) can enhance vascular permeability and therefore augment the infiltration of proinflammatory granulocytes into the graft. The expression of ICAM-1 on the vascular endothelium has been associated with acute rejection in kidney transplants. Conversely, IL-10 has the ability to inhibit APC function, TNF-\(\alpha\) production, and ICAM-1 expression \textit{in vitro}. Evidence from animal transplant models has suggested a role for the immunoregulatory cytokine IL-10 in promoting graft survival. However, others have provided evidence supporting the role of IL-10 in rejection.\textsuperscript{55}

The exact relationship between transforming growth factor beta-1 (TGF\(\beta\)-1) and the development of chronic graft nephropathy remains uncertain. However, it appears that TGF\(\beta\)-1 is up-regulated at the protein and mRNA levels during the first year following cadaveric renal transplantation and the effect of 'high producer' gene polymorphism is important. This up-regulation of TGF\(\beta\)-1 in plasma may provide a novel noninvasive means of identifying early fibrotic damage before it becomes clinically apparent thus allowing an opportunity for intervention for grafts that may otherwise fail.

Infection remains a significant cause of morbidity and mortality after solid organ transplantation. Genetic background has an influence on the incidence of infection. Kidney transplant recipients with -511 IL-1\(\beta\) CC genotypes or with -1188 IL-12 CA and CC genotypes have been reported to be at higher risk of developing infections in the first year after transplantation. Such patients with genetic susceptibility to infection may therefore benefit from less potent immunosuppressive therapy and more intense preventive measures.\textsuperscript{56}

Quantitation of soluble interleukin receptor-2 (sIL-2R) has also been found to be useful in the detection of rejection in recipients of heart and liver allo-grafts. It has been suggested that sIL-2R assays offer a rapid, reliable and noninvasive indicator of allo-reactivity, response to therapy and prognosis in conditions associated with T and B cell activation. It may also reflect immune activation in other tissues or fluid compartments as the IL-2R generated in these sites may enter the circulation. Impaired renal function has been reported to show elevated serum sIL-2R as this molecule is likely to be actively transported into the urine. The preoperative and serial postoperative measurement of sIL-2R level has been used to distinguish rejection from cyclosporin A (CsA) nephrotoxicity in renal transplant recipients but not rejection from infection. Data generated from our group showed that sIL-2R levels are generally higher in patients undergoing acute rejection, chronic rejection cases and even those with infective
episodes. However, there was no difference in patients with CsA nephrotoxicity and those with ATN despite elevation of their serum creatinine levels.

Similarly, soluble CD30 (sCD30), a marker for T-helper 2-type cytokine-producing cells reflects on the immune state of the graft and could be used as a predictor for kidney graft survival. Elevated pre transplant serum sCD30 levels have been found to be detrimental for graft survival, hence could be a better predictor of allograft rejection. The permissible and immunogenic HLA mismatches reflected in cytotoxic T-lymphocyte precursor frequencies could be used in clinical settings, whereby significantly lower CTLp frequency is correlated with permissible HLA mismatches and better graft survival compared to immunogenic HLA mismatches. Therefore, use of multiple parameters for assessing recipient’s immune profile can predict graft outcome more accurately and help in subsequent individualization and optimization of immuno-suppression.

TRANSPLANT TOLERANCE AND MOLECULAR THERAPEUTICS

Although the goal of transplantation is to achieve long-term acceptance of the allograft, little is known about the mechanisms responsible for this successful outcome. Induction of immunological tolerance has long been thought to be the ultimate goal of research in the field. As graft rejection is the major cause and primarily mediated by immunological reactivity against the donor antigens, attempts to induce a state of tolerance as observed in case of self antigens seems most rational. Self tolerance is brought about mainly by central and peripheral mechanisms. Central mechanism relies on the deletion and/or functional incapacitation of self reactive T-cells during the ontogeny of the immune system and manipulating these mechanisms may not be directly relevant to the clinical induction of graft tolerance. However, studying the underlying mechanisms has greatly facilitated our knowledge on the immunological basis of tolerance. On the other hand, peripheral tolerance is mediated by mechanisms actively suppressing the auto and/or alloreactive T-cells and understanding of the cellular and molecular mechanism may contribute in the translational research leading to the development of effective protocols for tolerance induction following allografting.

Recent advances in the field of peripheral tolerance have paved the way for the induction of transplant tolerance. This is best exemplified by the standard immuno-suppressive regimen used in clinical management of organ transplant. Currently used immuno-suppressive drugs like cyclosporine, Tacrolimus, Sirolimus, etc. are all known to mediate their therapeutic action by inhibiting the clacineurin pathway of T-cells activation. However, they suffer from the major limitation of non-specifically suppressing T-cell function indiscriminately, thus compromising the function of T-cells involved in controlling the infections and immune surveillance. Therefore, alternate routes of specifically inhibiting the T-cells responsible for alloreactivity need to be developed. Recent findings suggest that donor specific hypo responsiveness induced by Foxp3+ T regulatory (Treg) cells or by manipulating the co-stimulatory pathway may be a potential approach to achieve a state of immune tolerance among transplant patients. Blocking the co-stimulatory pathways of T-cell activation namely CD28-CD80/86 and CD40-CD40L has met with considerable degree of success in various transplant models. However, their inclusion in the clinical protocols for use in humans still remains controversial. Similarly genetically engineered CTLA4-Ig fusion protein has been tried for effective blockage of the co-stimulatory pathway leading to induction of T-cell anergy with encouraging success. Many of these molecular approaches alone may offer an effective state of tolerance, but their use as adjunct molecular therapy seems quite promising and may offer more specific and effective immunosuppressive or tolerogenic regimen for therapeutic management of patients following renal transplantation.

CONCLUSION

Newer insights into the cellular and molecular basis of the allograft rejection have delineated novel targets for immunosuppressive therapy. Recent advances in the immunological techniques also promise improved management of transplant patients by developing newer assays to predict the pending rejection episodes before irreversible and terminal damage of the grafted tissue. HLA matching effect has been proven both for short as well as long-term survival of the renal allograft and involving live related or cadaver donors. Further, antibody development following transplantation has
been directly correlated with the HLA match status of the donor and recipient—the poor match status frequently associated with more vigorous antibody response. Molecular approaches for clinical monitoring of the post-transplant immune status and identifying the best functionally matched donor before the transplant procedures are among the key area of futuristic research in the area of clinical transplantation. Appreciation of the mechanisms underlying T-cell recognition of alloantigen has generated scopes for the use of synthetic peptides in prevention of graft rejection. Furthermore, a better understanding of the importance of adhesion molecules in transplant rejection has encouraged the introduction of clinical trials with anti-ICAM-1 monoclonal antibodies for the prevention of acute graft rejection. Hopefully, continuing progress in unraveling the molecular mechanisms of graft rejection will facilitate further refinements in immunosuppressive protocols and soon achieve the ultimate goal of long-term acceptance of organ allograft through tolerance induction.

INTRODUCTION

Until recently, treatment options for the debilitating effects of liver disease in children were limited to supportive therapy and immunosuppressive agents. With surgical conditions such as biliary atresia, some success has been achieved with timely diagnosis and early surgical intervention. However, in many cases even with expert management there is inevitable progression of liver disease. Liver transplantation offers the only chance of a cure for these unfortunate children. Early experimental studies were conducted in the 1950’s and early 60’s in Boston and Denver. Although the first attempted human transplant was performed in 1963, it was not until five years later that long-term success was achieved. In 1983, the National Institutes of Health Consensus Development Conference in the USA accepted liver transplantation in children and adults as deserving a wider clinical application. Advances in surgical technique, anesthetic management, pre- and postoperative care and refinements in immunosuppression over the last three decades have resulted in a much improved outcome and wide acceptance of liver transplantation among pediatricians with an ever-increasing list of indications being identified (Table 88.1).

The full story of liver transplantation for children has yet to be told but the current expected five-year survival is now greater than 85% in some centres. The longest survivor is well nearly 40 years after transplantation. Current anxieties over organ donor scarcity, long-term side effects of the immunosuppressive therapy, financial implications and some ethical issues remain. The focus of attention has now...
shifted from an initial target of early post-transplant survival to quality of life in the long-term. The transformation of a miserable jaundiced invalid into an active healthy child remains a powerful stimulant for pediatricians and transplant surgeons alike.

Shortage of donor organs has been tackled in an imaginative way with increasing use being made of size reduction of the donor liver for transplantation, splitting the liver into two functioning units for two recipients, as well as the use of segments of liver from living related donors. Transplantation in developing countries initially lagged behind, due mainly to inadequate resources and the unavailability of cadaver donors. However, many of these countries are now forging ahead with living donor transplantation.

**INDICATIONS**

Liver disease has been generally underestimated as a cause of death in children. This is probably because many liver conditions in children have led to rapid deterioration and death in the past. Almost all forms of liver disease in children can be complicated by hepatocellular failure. These would include acute and subacute liver failure from metabolic, toxic or viral insults and chronic parenchymal disease of varying causes of which biliary atresia, biliary hypoplasia, chronic active hepatitis, post-viral hepatitis and some metabolic diseases are the most common. In some metabolic diseases, the manifestation is as in hepatocellular disease and in others there may be more widespread effects such as tyrosinemia, Wilson’s disease, hyperglycoproteinemia, some glyco-storage diseases and hyperoxaluriable.

**Assessment**

In general, liver transplantation should be considered as a therapeutic option in all cases of chronic liver disease before the condition of end stage liver disease is realised. This allows for a thorough assessment of the child and the family and gives time for full and frank discussions of treatment options which can prepare all concerned as much as possible for the transplant procedure and afterwards. The family’s capacity to sustain long-term compliance after transplantation, so crucial to the success of this endeavour, must also be assessed. Transplant candidacy inevitably results in enormous emotional stress for parents while waiting for the appropriate donor as their child’s condition often deteriorates with bleeding from gastroesophageal varices and episodes of systemic infection. Family life may become disrupted. Those that live afar may feel constrained to relocate, which in itself could cause major domestic distressed families. The value of a sympathetic social worker to provide support cannot be overstated.

There are indeed few reasons for refusal for transplantation (Table 88.2). These include uncontrolled systemic bacterial, viral or fungal infections, malignancy outside the liver, cyanotic pulmonary arteriovenous shunting with pulmonary hypertension, active chronic hepatitis B, HIV/AIDS as well as other major cardiorespiratory, neurological or renal disease which would be incompatible with quality long-term survival. To a certain extent these are all relative contraindications. Psychosocial factors may be a reason for refusal. Parental substance abuse, severe psychiatric problems and poor preoperative compliance with therapy need to be factors carefully examined.

Compliance is more difficult to predict in children with acute hepatic failure, as time from presentation to decision to transplant is much shorter. As the outcome of the operation is so much better in recent years, indications for early transplant would be evidence of impaired synthetic function, including prolonged prothrombin time, reduced serum cholesterol levels and low serum albumin. Clinical indicators include presence of ascites, bleeding from esophageal varices not controlled by sclerotherapy and poor response to nutritional resuscitation. Those with acute hepatic failure who develop encephalopathy, hypoglycemia, a prothrombin time of greater than 50 seconds and a Factor V level of less than 20% should be considered for transplant, as almost all of these children die without transplantation.

**Table 88.2: Contraindications**

- Inadequate vascular supply
- Uncontrolled systemic infection
- Malignancy outside the liver
- Cyanotic pulmonary arteriovenous shunting
- Hepatitis B, HBeAg positive, HIV/AIDS
- Disease in other organs incompatible with quality survival
- Psychosocial factors
All patients require initial confirmation of the diagnosis, intensive medical investigation and nutritional resuscitation to treat the complications of the liver disease, portal hypertension and nutritional deprivation (Tables 88.3, 88.4). Immunization status must be reviewed and supplemented with hepatitis A and B immunization, Hemophilus influenzae, pneumococcal and meningococcal vaccine in most cases. Blood group identical or compatible donors are much preferred as the long-term survival with blood group incompatible donors is significantly less. Patients are generally listed according to urgency on a score from 1 to 4 with 1 being the most urgent.

**SURGICAL TECHNIQUE**

Donor organ suitability and function is difficult to predict. Increasingly marginal donors are being used with a surprisingly low incidence of primary poor or non-function. Age limits are being extended. However, stable donors from patients with a short intensive care unit stay (less than 3 days), little requirement for inotropic support and normal or near normal liver function are preferred, with an expected <5% incidence of impaired function after transplant. Liver biopsy is useful if steatosis is suspected. Greater than 50% fatty infiltration would preclude the use of the liver in most centers. Viral screening of the donors is essential. This would include Hepatitis A, B and C, CMV, EBV and HIV screening. Core HBV antibody and HCV positive donors would only be considered in selected viral infected recipients.

Surgical techniques used for donor retrieval and recipient liver removal and engraftment have evolved over the last 30 years. The majority of donor livers are removed as part of a multiorgan procurement procedure, which would include various combinations of kidneys, liver, heart or heart and lungs, small bowel and pancreas. University of Wisconsin solution is widely used as the preservation solution of choice.

The principle two techniques are a careful dissection and excision technique or the so-called rapid technique described by Starzl. A mid-line incision is made from the suprasternal notch to the pubis. The sternum is opened and spread with a sternal retractor. The subcostal diaphragm is incised on each side to obtain better exposure. The abdominal part of the operation includes control of the aorta above the celiac axis by incision of the right crus of the diaphragm, being careful to avoid entering esophagus. The aorta is encircled with tape to enable cross clamping prior to infusion of preservation solution. The inferior vena cava and aorta are identified, dissected and encircled with tapes below the renal vessels. The inferior mesenteric artery may be ligated in continuity to prevent loss of preservation fluid into the bowel. After a careful search for any vascular abnormalities, which would include most frequently, a left hepatic branch from the left gastric artery and an accessory or replaced

Liver Transplantation

right hepatic from the superior mesenteric artery, which may run through the head of the pancreas and behind the common bile duct, the liver is mobilized by division of the left coronary ligament. An appropriate sized cannula is placed in the inferior mesenteric or superior mesenteric vein so that the tip lies at the junction with the splenic vein. A large bore cannula may be placed in the inferior vena cava, which is connected to an away suction. The gallbladder and biliary tree are thoroughly irrigated with saline.

Procurement commences with infusion of preservation solution through both the portal vein and aorta after cross clamping the aorta at the level of the diaphragm and incising the suprahepatic vena cava within the pericardium. Normally one to two liters of preservation solution is infused through each cannula according to the size of the donor. If the superior mesenteric artery is not ligated the bowel will blanche and this will allow portal perfusion as well as arterial perfusion particularly if the inferior mesenteric vein

Supplements

Supplements need to be added to the formula, enteral feed or the food of the patient. They require 160 kcal/kg/d and 12-15% protein, or (± 4 g/kg/d if < 1yr.), and an ordinary daily intake would not allow them to reach such high caloric and protein intake. Failing to reach these requirements will result in failure to thrive. The supplements need to be added with detailed calculations, as the ratios and total percentages of the final product will determine tolerance and continual growth.

Vitamins (Daily)

- **Fat soluble:** A (15,000 units), 1 alpha vitamin D (1 µgm), E (300-1,000 units, K (2.5-5 mg)
- **Water Soluble:** B1, B6, C and folate as multivitamin syrup.
- **Micronutrients and minerals:** Zinc, Selenium, Manganese, Iron.
- **Calcium and phosphate:** Monitor serum Ca** and PO4 and urinary Ca** excretion.
is used for access. The porta hepatitis is divided distal to the gastroduodenal artery, which is ligated and the portal vein is divided at the junction with the splenic vein. The proximal part of the superior mesenteric artery is defined and is dissected down to the aorta on its left side preserving 2 to 3 cm if accessory or replaced right hepatic arteries are present.

The liver is now removed with a patch of aorta including the base of the superior mesenteric and the celiac axis particularly if abnormal arterial supply has been identified. The liver is then removed from above downwards. The resected liver includes a cuff of diaphragm around the bare area along with the retrohepatic cava and part of the right adrenal gland, which is cut through. The infrahepatic inferior vena cava is divided above the renal veins. Once the organs have been removed, they are placed in a plastic bag and the liver is further perfused with 500 ml of preservation solution via the portal vein, hepatic artery and through the bile ducts. The liver then is placed in a further two plastic bags and packed in ice for transportation. Once the kidneys are removed, the iliac arteries and veins are retrieved in case of subsequent vascular reconstructions.

The recipient operation is commenced so that the estimated hepatic graft ischemic time is less than 12 hours. Much longer preservation times have been recorded, but this leads to an increased incidence of cholestasis and graft dysfunction. The recipient operation commences with a laparotomy incision, which may be subcostal or extended in the midline to the xiphoid process for extra exposure. Self-retaining subcostal retractors are an essential aid in obtaining the necessary exposure. Careful suture ligation of large thin walled veins in the abdominal wall, adhesions and omentum are required to keep blood loss to a minimum. Once the infrahepatic and subcostal areas are freed from the surrounding structures and liver, the flaps of abdominal wall are sewn back over the costal margins and the subcostal self-retaining retractor such as is inserted. The porta hepatitis is dissected first and in children with biliary atresia, this requires the portoenterostomy to be taken down with preservation of the Roux-en-Y loop for later anastomosis.

It is useful at this stage to dissect out the hepatic artery at least as far back as the gastroduodenal in preparation for revascularization; this avoids unnecessary delay at the engraftment stage of the procedure. The portal vein is dissected and isolated. The rest of the liver is carefully mobilized. This includes the gastrohepatic ligament, the falciform and triangular ligaments together with the right retroperitoneal reflection. Mobilization of the liver off the inferior vena cava which is frequently preserved to facilitate reduced size transplantation or piggy-back engraftment should be done and is assisted by carefully dividing the vena cava ligament and right adrenal vein. The suprahepatic and infrahepatic vena cava are dissected and encircled with tape.

Backtable preparation of the donor liver would depend on whether a reduced size liver graft is to be used (Fig. 88.1). The liver is placed with the inferior surface uppermost within the inner plastic bag and is surrounded by packed sterile ice. Upper and lower cava are defined and redundant diaphragmatic muscle is excised, phrenic veins are ligated and sutured closed and the arterial and venous anatomy clearly dissected. The plane of transection when size reduction is planned is usually just to the right of the falciform ligament in left lateral segment transplants and in the median plane for left liver transplants (Fig. 88.2).

Even more careful dissection is required where split liver transplantation is being used; that is the liver is divided into two functional units for two recipients;
and decisions must be made as to which porta hepatis structures will go with which graft. To a certain extent, this depends on local preference but many centers opt to export the right-sided graft with the full compliment of structures of bile duct, portal vein and hepatic artery keeping the left lateral segment for the local graft in much the same way as a living donor transplant. Where a reduced size liver is used, the caudate lobe is always excised. The division of liver tissue may be performed using the standard forceps clamp or bipolar diathermy technique with suture and ligation of vascular and biliary structures. The ultrasonic dissector or harmonic scalpel may also be used. The cut edge of the liver is then sprayed with two layers of tissue glue. Once the recipient liver has been removed meticulously, hemostasis of the retroperitoneum must be ensured with a combination of suture ligation and cautery. If the recipient inferior vena cava is to be preserved, this is simplest done by carefully incising the diseased liver clear of the cava and when the liver has been removed individually suturing all small areas of leakage from divided direct caudate lobe hepatic veins. The IVC is prepared for the donor liver by dividing the bridges between the separate hepatic veins. This creates a wide orifice for the hepatic vein to cava anastomosis. The inferior vena cava should be incised distally for approximately 1-2 cm to make a triangular orifice for the ‘piggy-back’ graft.

**Engraftment** should begin with the upper caval anastomosis, which is usually performed with continuous posterior sutures of polypropylene and interrupted anterior sutures if a conventional transplant is being done. Prior to completion of the anastomosis, the liver is flushed of preservation solution via the portal vein with normal saline or a colloid solution. The lower cava anastomosis is then performed if required being sure not to cause any stricture or kinking, a growth factor of about a third of the diameter of the vessel is usually sufficient to prevent this occurring. The recipient portal vein is usually used for the anastomosis and in reduced size transplants where the donor liver is of large diameter, the bifurcation of the recipient portal vein is opened to create a trumpeted end for anastomosis. If the portal vein is hypoplastic, then the anastomosis is done at the level of the confluence the splenic vein after careful dissection under the head of the pancreas.

Another technique is to place a graft from the donor iliac vein onto this area first during the anhepatic phase. The portal vein anastomosis is carefully performed using continuous posterior and interrupted anterior sutures or the use of a generous growth factor.

Fig. 88.2: This shows a reduced size liver (segments 2 and 3) at transplantation with its vascular and biliary anastomoses. In this case the recipient vena cava has been preserved and the hepatic vein of the donor is sutured onto the IVC.
In reduced size grafts, plenty of portal vein length should be left to avoid having any tension on the vein, which may result in stretching thus compromising flow. The donor hepatic artery is flushed with heparin saline to remove air and blood clots and an anastomosis is done to the recipient common hepatic artery. End to end microvascular techniques are preferred and in our series, we have not required any vascular grafts even with retransplantation. Some centers have used vascular grafts to the infra-renal aorta or from the supra-celiac aorta with success. The donor liver is usually revascularized with removal of the suprahepatic clamp followed by the infrahepatic clamp portal vein and artery. There is some experimental evidence that there is less reperfusion injury with early arterial revascularization.

After careful hemostasis of bleeding areas, either from the free edge of a reduced size liver or from any of the other major bleeding points, the operation is completed, by performing the biliary reconstruction. The bile duct is trimmed back such that good bleeding from the edges is obtained. In biliary atresia patients and those with a reduced size graft, a Roux-en-Y choledochojejunostomy is performed with fine absorbable sutures.19-23

Occasionally in pediatric cases, a duct-to-duct anastomosis may be performed with a whole liver graft in a recipient with a normal extrahepatic biliary system. Stents or T tubes are optional with some evidence of increased biliary complications associated with their use. The only real advantage is access to the biliary system during the postoperative period. Finally hemostasis is obtained and the wound closed with drainage to the suprahepatic and infrahepatic spaces.

**LIVING RELATED DONORS**

Living related donation of the left lateral segment, first successfully performed by Strong, has become widely accepted as a method of acquiring a liver graft in the face of severe donor shortages, particularly in countries with cultural or religious reticence to accept brain death in a ventilated heart-beating donor.24 There are clear advantages in the planned nature of the procedure preferably before end stage liver disease in the recipient, the excellent quality of the graft and short ischemic time.

The use of a living donor also increases the availability of donor organs in general for other patients on the waiting list. The only advantage to the donor is a psychological one and there is a current morbidity of around 10% (wound sepsis, hernia, bile leak and adhesive bowel obstruction). There is also a reported mortality of around 0.2% although in Japan more than a 1000 of these operations have been done without donor mortality. There are ethical concerns, which appear justified, as with more widespread transplant activity increasing mortality and morbidity has been recorded. The donor should first undergo a thorough screening both clinical and psychological without coercion and be given an option to withdraw from the procedure at any time before the transplant.25-26

**SPLIT LIVER TRANSPLANTATION**

The liver of the donor is divided into two functional units thus making maximum use of this very scarce resource (Figs 88.3A and B). The procedure may be performed in situ, which has been associated with less post-reperfusion bleeding from the cut surfaces and improved graft function. However, this technique is time-consuming and may not be feasible in many cases. Early results with ex-situ dissection on the back table were poor and this was in part due to a technical learning curve, prolonged preservation times and the use of grafts, for only those recipients in the worst condition. Recent results are much improved. Clearly, the infrastructure must be in place to either perform two transplants simultaneously or alternatively one hemi-liver graft is exported to another center.

The in situ technique is similar to a living related transplant. Cholangiography is essential as there is considerable variety in the intrahepatic biliary anatomy.27 Angiography is desirable but not essential. Some centers leave the hepatic artery with the right lobe making it more acceptable as an ‘export’. The left lateral segment graft remaining is then used locally. Segment 4 should be used with the left graft if size is compatible, otherwise it is better to resect it prior to transplant as the segment 4 duct usually drains into the left hepatic duct. Likewise arterial anatomy is carefully examined and apportioned to each hemi-liver. There is usually a sufficient periductular vascular network to ensure adequate blood supply to the relevant ductal systems so long as the main hepatic artery branch to each hemi-liver is preserved. Accessory arteries can be ligated.
MEDICAL MANAGEMENT

Immunosuppression

Most protocols employ triple therapy with cyclosporin, azathioprine and methylprednisolone. Increasingly, particularly for small children, tacrolimus is used as primary immunosuppression. In addition, there are a number of other strategies in place to reduce the amount of nephrotoxicity, which is a toxic side effect to both calcineurin II inhibitors. Thus, mycophenolate mofetil, an inosine monophosphate dehydrogenase inhibitor may be used instead of azathioprine and a monoclonal interleukin-2 antibody may also be used with some steroid-sparing. 28,29

Rapamycin, a drug structurally similar to tacrolimus, which prevents proliferation of T cells but acts at a different stage of T cell activation than either cyclosporin or tacrolimus, has the advantage that it is not nephrotoxic and does not interfere with transcription and production of interleukin II, rather it antagonises the action of interleukin II on its receptor. It has no adverse effects on liver function and may be synergistic with cyclosporin.

With cyclosporin in the microemulsion formulation (Neoral) 5 mg/kg is given immediately before the operation and is continued in the postoperative period as an oral dose. In infants and small children, there is some advantage to giving it as a three times a day dose initially, aiming at a trough level of around 350 ng/ml initially or a C2 (2 hour post dose) peak level of greater than 800-1200 ng/ml. The C2 appears to be a more effective measure of dosing as it reflects the area under the pharmacodynamic curve more accurately than the trough level. The dose must be frequently adjusted in the postoperative period, as particularly in small children absorption is erratic. Azathioprine (1-2 mg/kg) and methylprednisolone (10 mg/kg) are given at the time of reperfusion of the graft. The methylprednisolone dosage is reduced over the first week to about 1 mg/kg/day for the first month and then reduced to a level of 0.3 mg/kg/day to 0.2 mg/kg as maintenance. This can be later reduced in some patients to alternate day therapy or even withdrawn completely.

The azathioprine dose of 1 to 0.5 mg/kg/day is monitored keeping the leucocyte count above 4000 per mm$^2$ and is continued for 3 to 6 months. Tacrolimus can be used as rescue therapy for an acute rejection that does not respond to three or four daily pulses of intravenous methylprednisolone (10 mg/kg per dose) or it can be used as primary immunotherapy with steroids. Both mycophenolate mofetil and rapamycin can be used as renal sparing should nephrotoxicity become evident. Use of humanised anti-CD25 monoclonal antibodies given before and during the first week of the transplant have reduced the incidence of acute rejection in the first three months by around 30% but long-term graft survival is
essentially the same as when these agents have not been used. The other polyclonal anti-lymphocyte immunoglobulins are rarely used.

**Anti-infection Agents**

Immunosuppression naturally leads to susceptibility to bacterial, fungal and viral infections. Fungal prophylaxis is given before the transplant as mycostatin orally to reduce *Candida* colonization of the gut and after transplant as amphotericin lozenges and continued for a period of several months.

From two to three weeks after the transplant, for at least the first year, trimethoprin-sulphamethoxazole is given at a dose of 6 mg/kg/day in two divided doses three days a week for prevention of *Pneumocystis carinii* infection. Intravenous ganciclovir 5 mg/kg/dose, 12 hourly is used as prophylaxis against cytomegalovirus (CMV) and Epstein-Barr virus (EBV) infection, initially for two weeks and this may be extended for up to three months in high-risk patients who have not previously been exposed to CMV or EBV but have received a donor graft with previous exposure. This considerably reduces the incidence of both cytomegalovirus disease and post-transplantation lymphoproliferative disorder. Either hyper-immune cytomegalovirus globulin or immunoglobulin is also given to assist viral prophylaxis. Leucocyte filtered blood products are used throughout to reduce CMV load.

Prophylactic antibiotics are given with induction of anesthesia and continued for three to five days. These are changed according to cultures taken of blood, secretions, sputum and urine. Anti-tuberculosis prophylaxis is given only if the reason for transplant is a reaction to anti-tuberculosis drugs with fulminant hepatic failure, where evidence of tuberculosis is found before surgery and if a close family contact has tuberculosis.

Ofloxacin, rifampicin and ethambutol or ethionamide may be used in addition to isoniazid but very careful monitoring of liver function tests is required because all of these drugs may be hepatotoxic and particularly rifampicin may result in a decrease in the levels of cyclosporin or tacrolimus levels due to enzyme P450 induction with increased drug metabolism.

**Postoperative care:** Patients are monitored intensively postoperatively and usually require ventilation for a period of 24-48 hours. Liver ultrasound with color flow Doppler is performed frequently to confirm vascular patency and the absence of biliary dilatation. Liver biopsies are performed if indicated by increasing serum liver enzyme activity or by bilirubin levels, using the Menghini technique (Hypafix needle (Braun), diameter 1.4 mm), unless biliary dilatation is observed on ultrasonography. Biopsies are routinely assayed for viral and bacterial activity.

Diagnosis of rejection can be made on the basis of clinical, biochemical and histologic changes and usually presents in the first few weeks after transplant with fever, malaise, a tender graft and loose stools. The grade of rejection is assessed according to established histological criteria on a scale of 0 to 4.

Acute rejection is treated with four doses of methyl prednisolone 10 mg/kg for the first three doses on successive days and the fourth on the fifth day after commencing treatment. Monoclonal antibodies and antilymphocyte globulin are very rarely used for steroid resistant rejection. If rejection persists, immunosuppressive protocols can be changed or the dosage increased. The tacrolimus starting dosage of 0.3 mg/kg/day in two divided doses is usually given to obtain a trough level of between 10 and 15 ng/ml initially. Once rejection is under control and liver function tests have returned to normal, the dosage can be reduced to a maintenance dose, obtaining trough levels of around 5 ng/ml. Hypertension is almost universal in pediatric transplantation and can be initially managed with nifedipine sublingually in conjunction with diuretic agents. Subsequently calcium channel blockers may be given in appropriate dosage. Aspirin 3 mg/kg given on alternate days is used as prophylaxis against arterial thrombosis and a proton pump inhibitor is given for gastric mucosal protection.

Nutritional and vitamin supplementation should be commenced within 72 hours of surgery and may be supplemented by nasogastric feeding or parenteral nutrition in the early phase if there is a delay in restoration of bowel function. Phosphate and magnesium deficiency is common and requires replacement therapy in nearly all patients.

**SURGICAL COMPLICATIONS (TABLE 88.5)**

Surgical complications may be reduced to an absolute minimum with meticulous technique.30-32 These may
Liver Transplantation

997

Present early and late. Biliary complications continue to be a significant problem with an overall incidence of between 10 and 20%, particularly in living related left lateral segment grafts. These complications include bile leak, anastomotic strictures, and non-anastomotic strictures of the donor bile duct with sludge formation.

It is imperative with all suspected biliary complications to ensure that the hepatic artery is patent using Doppler ultrasound or angiography, as hepatic artery thrombosis will cause ischemia and necrosis of the biliary tree.

Simple bile leaks are diagnosed in the early postoperative period by the presence of bile in drainage fluid or in percutaneous aspirate of fluid collections around the liver. Early biliary complications are best treated by immediate surgery and re-anastomosis if required. Late stricture formation may be satisfactorily dealt with by endoscopic or percutaneous balloon dilatation or stenting. Graft ischemia either from hepatic artery thrombosis or portal vein thrombosis can be a devastating complication. The incidence is much less frequent with the use of reduced size liver transplants and microsurgical techniques for living donor transplants. Nevertheless, when it occurs it may lead to graft necrosis, intrahepatic abscess, biliary necrosis and bile leakage. A massive rise in enzyme activity, particularly in the first few days after transplant, may be the first signs. Immediate intervention with thrombectomy and re-anastomosis is only occasionally successful. Bowel perforation is also a well recognized complication with predisposing factors, which include previous surgery (Kasai porto-enterostomy), steroid therapy and hypoxemia due to porto-pulmonary syndrome. Rarely, diaphragmatic hernia has also been reported.

Late presentations may be less acute and typically present with gram-negative sepsis, liver abscess or biliary complications. An early hepatic artery thrombosis usually means that the patient will require an urgent liver retransplant. Late thrombosis may be asymptomatic and if so can be ignored. Although technical factors usually account for most cases, it is advisable to maintain the hematocrit at around 30% to improve microvascular flow. Portal vein thrombosis usually presents with a degree of liver dysfunction with prolonged clotting and portal hypertension, which may be heralded by an esophageal variceal bleed. Immediate thrombectomy may be successful.

Where portal vein thrombosis is established, a meso-portal (Rex) shunt, with a vein graft taken from the internal jugular vein and interposed between the superior mesenteric vein and the left branch of the portal vein, may be curative. Inferior vena cava thrombosis or venous outflow obstructions are now rare, particularly since the triangular technique of caval anastomosis has been practiced. Thrombosis in the IVC may develop either in the immediate postoperative period presenting with ascites and lower body edema or later on due to regeneration of the graft

and twisting of the caval anastomosis. Thrombolytic therapy may be successful in late thromboses but should be avoided in early thromboses as uncontrollable bleeding may occur from raw surfaces particularly if a reduced size liver was transplanted. Hepatic venous outflow obstruction is suspected if there is persistence of ascites and is confirmed by liver biopsy findings of congestion, and ultrasound and red cell extravasation around central veins.

**MEDICAL FOLLOW-UP AND LATE COMPLICATIONS**

Most patients can be discharged from the intensive care unit within the first week after transplantation. The majority of infections can be prevented. However, should the patient require excessive immunosuppression for persistent rejection, almost inevitably they will develop some opportunistic infections.

In this situation, not only must specific therapy be directed at the pathogen but also immunosuppression must be reduced. Cytomegalovirus is best monitored with PP65 antigen and polymerase chain reaction (PCR) measurement of the virus.

Post-transplantation lymphoproliferative disorder (PTLPD) presents from the first few weeks after transplant to several years later with a mean time of onset around nine months. A typical presentation is initially with acute membranous tonsillitis and associated cervical lymphadenopathy, which is resistant to antibiotic therapy. However, the disease may be widespread and gastrointestinal and central nervous system involvement is common.

Management strategies include reduction of immunosuppression, which may require complete withdrawal along with standard anti-lymphoma chemotherapy, particularly with the monoclonal type. Mortality varies from 20 to 70% or more. Prophylactic intravenous ganciclovir given for a prolonged period may be effective in preventing EBV activation, which is the promoter of PTLD in most cases. Hepatitis B infection has been a problem particularly if hepatitis B core antibody positive donors are used where HBV in the graft occurs in up to 80% of cases. There is frequently progression to active hepatitis although antiviral therapy using famciclovir or lamivudine along with hepatitis B immunoglobulin may be effective in controlling the virus, which is monitored with regular DNA levels.

Most children are hypertensive and require some anti-hypertensive agent for a period of time post-transplant. A degree of renal impairment is almost inevitable in those patients suffering from chronic liver disease and with the additional burden of the use of nephrotoxic immunosuppressive drugs such as cyclosporin and tacrolimus many have significant renal impairment of function in the long-term. The importance of renal sparing strategies in immunosuppression is becoming increasingly evident as long-term survivors present with drug induced renal failure.

Chronic rejection is an irreversible phenomenon, which is chiefly intrahepatic and ductular rather than a vascular phenomenon in contrast to other organ transplants. This is usually manifested by disruption of bile duct radicals with development of the vanishing bile duct syndrome. The incidence seems less frequent with tacrolimus based immunosuppressive regimens as opposed to cyclosporin where an incidence of up to 10% has been recorded. Late chronic rejection may also be associated with a vasculopathy affecting larger arteries.

**RETRANSPLANTATION**

Ten to 20% of patients may suffer graft failure at some time and need retransplantation. Early indications may be primary non-function, early hepatic arterial thrombosis, severe drug resistant acute rejection and established chronic rejection. Early retransplantation is technically a much less traumatic procedure than the original transplant although the patient may be in a poorer condition. Outcome largely depends on the indication for retransplantation and is quite good for technical causes but less satisfactory for rejection and infection. An increasingly poorer outcome can be expected after third and fourth retransplants and the efficacy and ethics of these interventions are in question.

**LONG-TERM SURVIVAL AND QUALITY OF LIFE**

One year survival of > 95% is being achieved in the best centers with predicted 10-year survivals of around 70-75%. Patients grafted for acute liver failure have done less well with a higher early death rate usually
associated with cerebral complications and multi-organ failure. Excellent quality of life can be achieved and most children are fully rehabilitated.

It is however increasingly evident that prolonged cholestatic jaundice and malnutrition in infancy may have late effects and despite good physical rehabilitation evidence of significant cognitive deficits, which present during early schooling as learning difficulties and attention deficit disorder, are common. As with any immunosuppressed patient, the incidence of neoplasia in a lifetime is greatly increased.

**RESULTS**

Liver transplantation for infants and children has been available in South Africa for more than a decade. Concerns have shifted from an initial target of short-term survival to quality of life in the long-term. Since 1985, more than 300 patients have been assessed with 124 being accepted for transplantation. Ninety-two have undergone liver transplantation, 90 at the Red Cross Children’s Hospital and 2 abroad. Biliary atresia (52%) was the most frequent diagnosis followed by acute liver failure (ALF) (16%). Waiting list mortality has remained high (15%), particularly for the ALF group (50%).

Sixty-three patients survive (72%), 2 months to 22 years post-transplant. Survival since 1996, when HBV core antibody positive donors were excluded and an active anti-viral prophylaxis program was instituted has been > 80%. Early post-transplant mortality was low (7%) but late morbidity and mortality (23%) was mainly due to viral infections: de novo hepatitis B (5 patients and 2 deaths), EBV-related PTLPD (6 patients and 4 deaths), and CMV disease (10 patients and 5 deaths), were most frequently implicated. Tuberculosis prophylaxis, required in 6 cases, resulted in major morbidity in 1. Hypertension requiring medication along with some compromise of renal function has been present in all but 2 patients. However, all those of school going age attend school normally and remain in good health. Only 3 of the survivors have abnormal liver function tests.

Successful liver transplantation is possible in a developing country with limited resources. Scarcity of virus free donors (HIV and HBV) has led to waiting list mortality and infrequent retransplantation. The consequences of prolonged immunosuppression, infections, lymphoma and renal toxicity remain challenges. Compliance problems with medication particularly amongst teenagers, has required constant vigilance and supervision.

**CONCLUSION**

Careful planning, extensive preparation of personnel and a broad base of skills along with good teamwork between health professionals are required for the development of a successful pediatric transplant program. Surgical technique, anesthetic skills, and medical care of the highest order are essential.

A patient with a liver transplant is a patient for life and requires complete commitment from the transplant medical and surgical team, which cannot be abrogated after discharge from hospital. Endemic viral and bacterial infections particularly HBV, CMV, EBV and tuberculosis, impact negatively on any program in the setting of a developing country.

Extended hospital stay may be required and this, along with long-term therapy may be expensive. Hepatitis B acquired with the liver graft is a tragic occurrence and is not a benign disease. Pretransplant immunization and avoiding the use of hepatitis B core antibody positive donors will reduce the incidence to almost nil but is likely to greatly reduce the numbers of cadaver donor livers presenting particularly if hepatitis B is endemic in the local population. Unfortunately, prophylactic therapeutic measures are costly.

The need for pediatric liver transplants has been assessed at approximately 1 to 2 children per million per year. Thus, transplant activity should be concentrated in specific centers preferably doing more than 12 transplants a year. The shortage of donor organs will continue and future efforts must be focused on maximum use of cadaver donors and increasing living related donation. Transplant activity is rapidly increasing throughout the developing world. This endeavour should be strongly supported as poor socio-economic status is not a contraindication to transplantation and we have frequently been impressed by how parents with relatively few material resources have been able to diligently care for their children. No child with end stage liver disease should be denied the opportunity of receiving appropriate treatment. As with any new development, knowledge and experience improves, costs decline and success is ensured.
These challenges must be met to offer any infant or child requiring liver replacement a chance of a life. The ultimate aim is to restore the child to normal health such that he/she can grow up into a productive healthy adult who can make his/her contribution to society and develop all of his/her human potential.

REFERENCES

Jaundice is the clinical description for the yellowish tinge to the skin, mucous membranes and sclera caused by raised levels of bilirubin in the blood. The word itself derives from Old French (Jaundice = yellow). Interestingly the alternative medical term, icteric, derives from the Greek word (Ikteros) for a variety of yellow bird. It was believed that a sufferer from jaundice would be cured by gazing at such a bird!

The normal range of total and conjugated bilirubin are < 1 mg/dL (< 17 µmol/L) and < 0.25 mg/dL (< 5 µmol/L) respectively, although jaundice can only be appreciated when total bilirubin is greater than 4 mg/dL (~50 µmol/L).

**BILIRUBIN METABOLISM**

Bilirubin is an open chain tetrapyrrrole with eight side chains (Mol. wt. = 585) and a metabolic by-product of red cell breakdown (largely in the spleen). Hem is converted (enzyme: hem oxygenase via biliverdin) to bilirubin which is transported (on albumin) to the liver in an unconjugated fat-soluble form. Hepatocyte uptake occurs with (enzyme: UDPGT) conversion to the water soluble form by conjugation with glucuronic acid. This is then excreted into the biliary canaliculus.

Further metabolism occurs in the ileum (to urobinogen which is absorbed and re-excreted in urine) and colon (stercobilinogen - excreted in stools) although the process is poorly developed in infancy.

**PHYSIOLOGICAL JAUNDICE**

Physiological jaundice (always unconjugated) occurs from 2nd to 10th days of life and is due to a number of factors including immaturity of neonatal liver enzymes and shortened postnatal red cell survival. Prematurity, growth retardation, breast feeding and cephalohematoma tend to exacerbate the intensity and duration of physiological jaundice. Usually, serum bilirubin levels do not rise above 8 mg/dl in a full-term and 12 mg/dl in a premature infant. At high levels, unconjugated bilirubin can cross the blood-brain barrier and cause brain injury (kernicterus). The usual therapy for unconjugated jaundice is phototherapy and occasionally exchange transfusion.

**MEDICAL CAUSES OF CONJUGATED JAUNDICE**

There are important medical causes of conjugated jaundice which include Alpha-1-antitrypsin deficiency, giant cell hepatitis, cytomegalovirus hepatitis, Alagille's syndrome (biliary hypoplasia, abnormal vertebrae, pulmonary stenosis, odd facies), cystic fibrosis and galactosemia (due to defect in enzyme galactose-1-phosphate uridyl transferase).

From 2-15% of neonates will remain clinically jaundiced beyond 2 weeks. Although only in 0.2-0.4% neonates, will this be a conjugated jaundice due to hepatobiliary disease of either medical or surgical origin. All infants with persistence of jaundice beyond 2 weeks and in the absence of an apparent medical cause should be investigated for a potential surgical cause. Figure 89.1 illustrates a suitable investigation algorithm used to discriminate between the various causes of surgical jaundice.

The most common surgical causes included biliary atresia, choledochal malformation, inspissated bile syndrome, spontaneous perforation of bile duct and rarely the tumors.
Biliary atresia (BA) is a cholangio-destructive disease affecting both the intra- and extra-hepatic biliary tract ultimately leading to obliteration of the ducts, cirrhosis and liver failure. The incidence is higher in Japan and China (1 in 9,000) than in Europe and the UK (1 in 16,000).

ETIOLOGY AND PATHOGENESIS

The exact etiology of BA remains obscure, and hypotheses abound. Whatever the cause, the process leads to complete obliteration of the lumen of extrahepatic bile ducts and progressive cellular inflammation of the intra-hepatic ducts.1-4

1. In some infants there is evidence to suggest that the process begins early in gestation. Thus antenatal ultrasonography allows detection of that subgroup of BA that show cystic changes within the extrahepatic ducts.5 Furthermore, about 10% cases of all cases have other congenital anomalies.6,7 These anomalies are unusual but characteristic such as polysplenia, asplenia, situs inversus, absence of inferior vena cava and pre-duodenal portal vein, for which the term Biliary Atresia Splenic Malformation (BASM) syndrome has been coined.6 In these infants there is a high incidence of first trimester maternal problems such as diabetes and it is a reasonable supposition that all of the constituent anomalies occur during the critical period of organogenesis within that period. There are similarities between the appearance of developing bile ducts at the porta hepatis at 12-14 weeks gestation and the appearance of the residual biliary ductules at the porta hepatis in BA patients, suggesting that even some cases of isolated BA may be due to alteration in bile duct development and remodeling.8

Alternatively, BA may arise due to damage of a fully-developed biliary tract at some point in postor at least perinatal life. Thus, some studies report an association of a host of various gastrointestinal viral infections with BA including reovirus type 3, cytomegalovirus respiratory syncitial virus, Epstein-
Barr virus, human papillomavirus and rotavirus type A.\textsuperscript{9-18} Other similar studies on the same viruses, however have been negative.\textsuperscript{19-21} The most common hepatotropic viruses causing disease in older children and adults (such as hepatitis A, B and C) have not been related to BA in infants.\textsuperscript{22-25} There are also various animal models which can mimic the pathological features of BA and rely upon exposure of the newborn animal to viruses such as rotavirus.\textsuperscript{24-26}

Genetics may play a role in the pathogenesis of BA, although this is probably a fairly minor role in most. Familial cases of BA have been rarely reported, but there are also reports of BA seen in discordant monozygotic twins.\textsuperscript{27-34}

### PATHOLOGY

The gross appearance of the extrahepatic biliary tract varies from an inflamed, hypertrophic occluded biliary tract to an atrophic remnant. Histologically, the liver has features of portal tract inflammation, with a small cell infiltrate, bile duct plugging and bile duct proliferation. Later on, bridging fibrosis and ultimately biliary cirrhosis occurs.

The lumen of the extrahepatic duct is obliterated at a variable level and this forms the basis for the commonest classification in clinical use as suggested by the Japanese Society of Pediatric Surgeons (JSPS) (Table 89.1). In the Type I BA, the atresia involves the common bile duct only. In type II, the atresia involves the common hepatic duct only. Type III BA, is the commonest (~ 90% cases) type and involves the whole of the extrahepatic biliary tree, including the porta hepatic. In this type, there are no visible ducts present.

An important variation is that of cystic change, seen in about 5% of cases, within some part of the extrahepatic biliary tract. Some cysts contain mucus, while others contain bile. The cyst is usually small, about a cm in diameter (Figs 89.2A and B) while rarely it could attain a large size and is very thin walled and transparent, filled with bile stained fluid (Figs 89.3A and B). If it is bile, there may be diagnostic confusion with that of a true choledochal cyst. In cystic biliary atresia, the wall is invariably thickened, lacks an epithelial lining and communicates poorly with abnormal non-dilated intrahepatic ducts. This should be evident at operative or percutaneous cholangiography.\textsuperscript{35,36}

### PRESENTATION

All patients with BA present with varying degree of jaundice, clay-colored stools and dark yellow urine. The severity of jaundice increases steadily and it is not unusual to find bilirubin levels around 20 mg% at the time of first presentation in developing countries. Failure to thrive, coagulopathy and anemia are not uncommon. Some will present with signs of advanced disease and cirrhosis such as ascites, umbilical hernia, prominent abdominal veins and respiratory discomfort. In comparison to European or North American experience, most cases in developing countries present late. In a review of BA, only 5% cases were seen below 60 days of age, 40% between 2 and 3 months, 30% between 3 and 4 months and 25% presented beyond 4 months of age. Hepatomegaly was seen in all and 60% patients had a palpable spleen.\textsuperscript{37}

Figs 89.2A and B: A 3-month-old boy presented as EHBA with a cyst (1x1cm) at the portahepatis. The liver was cirrhotic and the LFT were deranged. Intrahepatic ducts were absent. HIDA showed no excretion even after 24 hrs. USG failed to pick up a small cyst, about 1x1 cm, at the porta hepatic. After opening the cyst A, there was no flow of bile. Cystojejunostomy with a Roux-en-Y was completed B.
Biliary Atresia

A fair idea can be made in over 80% cases using the bedside clinical scoring system whether it is a case of biliary atresia or neonatal hepatitis. 38

DIAGNOSIS

The clinical diagnosis of BA is usually quite obvious in late-presenting cases. However, in infants of < 60 days, the diagnosis can be difficult. Key investigations include ultrasonography, biochemical liver function tests, nuclear imaging, viral serology, and a percutaneous liver biopsy. In some centers, duodenal intubation and measurement of intralumenal bile is practiced as the routine test for BA. Newer modalities such as ERCP and MRCP have been used at times, although the former is clearly highly operator-dependent and the latter not sufficiently precise in its delineation of infantile biliary anatomy to offer real advantage. 39 Possibly in most surgical centers, operative cholangiography remains the principal investigation in demonstrating biliary patency. This can also be performed laparoscopically with apparently good results. 40

Liver Function Tests (LFTs)

LFTs are abnormal in all patients of BA and neonatal hepatitis. There is a rise in total serum bilirubin (mainly conjugated) and fall in serum proteins (especially albumin) and a reversal of the albumin/globulin ratio in advanced cases. Alkaline phosphatase and transaminase (e.g. SGOT, SGPT) levels all rise. Deranged LFTs correspond to the degree of parenchymal damage rather than the duration of disease. Serum y-Glutamyl transpeptidase (GGTP) levels more than 250 units are suggestive of obstruction due to biliary atresia while the GGTP levels less than 150 units are indicative of neonatal hepatitis. 41

Imaging

Hepatobiliary ultrasound after 12 hours of fasting (with intravenous fluid support) is perhaps the initial investigation of choice. Certainly BA is highly unlikely if a dilated intrahepatic biliary duct is found (being more indicative of an obstructed choledochal cyst, or inspissated bile syndrome). Percutaneous liver biopsy after exclusion of medical causes of cholestatic jaundice (e.g. Alpha 1-antitrypsin deficiency, Alagille's syndrome, and neonatal hepatitis) is a helpful investigation in diagnosis, but relies upon expert pathological interpretation. Negative ultrasonography and positive histology results should be able to establish the correct preoperative diagnosis in about 85% cases of BA. 42 In our series, an incorrect (typically giant-cell hepatitis) or nonspecific biopsy diagnosis was reported in about 15% of those eventually shown to have BA. 42 ERCP may be considered in infants with equivocal biopsy results, although it should be noted that this diagnosis depends crucially on failure to show...
Pediatric Surgery—Diagnosis and Management

a biliary tree, and hence appropriate experience and judgment are essential. Percutaneous transhepatic cholangiography (PTC) is valuable in those diagnostic groups in which dilated intrahepatic bile ducts are a feature. This is particularly so in the inspissated bile syndrome group, when not only can the diagnosis be established but an attempt at therapeutic saline lavage also can be made. About half of this group can be treated effectively without the need for laparotomy and without any recurrence or long-term sequelae. The simplified algorithm shown in Fig. 89.1 should be helpful in investigating these children with conjugated hyperbilirubinemia.

Nuclear Scanning

Excretion of Technetium labeled isotopes into the gut within 24 hours, establishes the patency of the biliary tract. However, a negative scan even after 24 hours may still be consistent with both BA and advanced stage of neonatal hepatitis. Negative HIDA scans may be repeated after one week of phenobarbitone therapy, if clinically indicated. Phenobarbitone is known to stimulate the hepatic enzymes and increase the flow of bile. One study showed that 40% patients with neonatal hepatitis excreted the isotope into the gut within 24 hours in postluminal HIDA scan while that of BA again failed to do so. Alternatively, further improvements have been suggested with the addition of betamethasone to phenobarbitone prior to HIDA scanning. To improve the efficacy and also importantly without loosing any time, it is recommended that the infants with suspected biliary atresia undergoing nuclear imaging, should be primed by both, the phenobarbitone and the betamethasone for a week instead of phenobarbitone alone. Though the exact mechanism is not known, yet the steroids serve not only as choleretics but also as anti-inflammatory and antifibrotic agents. These are also known to stabilize the cell membrane of the red blood cells to prevent their early breakdown thus reducing the bilirubin load to the liver.

Percutaneous Needle Biopsy

Sometimes the interpretation of biopsy can be difficult and need experienced pathologist as there is a lot of overlapping in the histologic finding of BA and neonatal hepatitis. There is also an inherent risk of bleeding in performing needle biopsy. While this forms a regular armamentarium of the diagnostic workup of the patient under care of the pediatricians, most pediatric surgeon do not depend on the outcome of this investigation in absence of the sensitivity and the specificity of the test. Infants with cholestasis show inflammatory infiltrate, hepatocellular necrosis, mild portal proliferation and fibrosis. The infants with biliary atresia show bile duct proliferation, bile plugs, portal fibrosis with well preserved normal architecture. The common features on histology in infants with biliary atresia and neonatal hepatitis include multinucleated giant cells, pseudoglandular transformation and hematopoiesis.

Duodenal Drainage Test

A 4 hourly duodenal aspiration is done to confirm the presence of bile in it. Again, the test may be false-negative in patients of neonatal hepatitis with severe cholestasis. A presence of bile in the aspirate confirms patency of the biliary tree. Before resorting to surgery, neonatal hepatitis can still be suspected if the liver is soft, the jaundice is fluctuating, the color of the urine is not dark, the GGTP values are less than 150 units. HIDA may or may not show excretion depending on the degree of cholestasis.

Peroperative Cholangiogram

In most centers, having excluded medical causes of jaundice and failed to show isotope excretion in a HIDA scan, then progression to peroperative cholangiogram is a reasonable option. The key observation at laparotomy is presence or absence of bile in the gallbladder. Clearly in the presence of bile, apart from the rare type 1 cases, then BA can be excluded. Cholangiogram through the gallbladder should demonstrate the entire biliary tree, but in those cases, where only the distal common bile duct (CBD) opacifies an attempt should be made to delineate the proximal intrahepatic tree by application of a distal vascular clamp in the common bile duct.

Surgical Management

Currently BA is being Managed in Two Phases

First Phase

An attempt to preserve the infant's own liver. This usually involves the Kasai operation which essentially
excises all extrahepatic biliary remnants leaving a transected portal plate, followed by biliary reconstruction using a Roux loop onto that plate as a portoenterostomy.

**Second Phase**

If bile flow is not restored at exploration or life-threatening complications of cirrhosis ensue, then consideration should be given to liver transplantation. Sometimes this is done as a primary procedure, in those who present late with features of advanced cirrhosis.

**Preoperative Preparation**

Preoperative preparation includes broad-spectrum antibiotics, vitamin K, correction of anemia, hypoproteinemia, chest infection and ascites.

**Surgical Technique**

The major breakthrough in the surgery for biliary atresia was seen in 1959 when Morio Kasai reported the operative relief of biliary obstruction in infants traditionally considered to have non-correctable biliary atresia. As described by Kasai and modified subsequently by others, the surgical steps of portoenterostomy starts with opening of the abdomen through a right upper transverse incision, a peroperative cholangiogram (if required) and a wedge liver biopsy. Once the diagnosis of BA is established the liver should be mobilized fully, outside of the abdominal cavity (by division of its suspensory ligaments), to ensure maximal exposure of the porta hepatis and facilitate a detailed dissection (Figs 89.4A to C). The atretic gallbladder, cystic duct and the entire remnant extrahepatic biliary tree are excised up to the level of the porta hepatis. The portal dissection itself must be wide extending from exposure of the origin of the umbilical vein from the left portal vein (in the Rex fossa) to the bifurcation of the right portal vein pedicle. Small veins from the portal vein to the portal remnant should also be divided to expose the caudate lobe posteriorly. The correct level of transaction is flush with the liver capsule, where the plane is usually self-evident. Transgression into actual liver parenchyma, however, adds nothing to the success of surgery. Most transected ductules are found in the marginal areas,
recapitulating the normal biliary arrangement, and it is important to allow these to drain into a long (~40 cm) Roux loop of jejunum (retrocolic). A single layer anastomosis is performed between the transected end at the porta hepatic and the jejunal loop, using absorbable interrupted sutures (Fig. 89.4C). Modifications such as incorporation of an intussusception valve in the ascending limb near the distal end, creation of a stoma or implanting the distal end of the Roux into the duodenum have no real advantages in clinical practice and have been discontinued in most centers. The size of the lumen of the ducts found on histology from the porta hepatic have been grouped as > 150 micron, 50-150 micron and < 50 micron in size. Smaller the size, poorer is the bile flow and the prognosis. Various technical variants have been proposed according to the anatomical pattern of the biliary remnant. In Type 1 BA, hepaticojejunostomy may be an option. Sometimes the gallbladder may be used as the conduit to the transected portal plate (portocholecystostomy) with a consequent reduction in postoperative cholangitis. The appendix has also been described as a conduit (appendico-duodenostomy). A number of drugs have been suggested to try and improve postoperative results. For instance, there are anecdotal and uncontrolled studies suggesting benefit from corticosteroids ursodeoxycholic acid and Chinese herbs. However, none have been universally accepted and subjected to extensive clinical acceptable scientific scrutiny. The initial results of a randomized double-blind, placebo controlled trial using postoperative prednisolone (2 mg/kg/day) showed a reduction in initial bilirubin levels but no significant difference in ultimate clearance of jaundice or reduction in need for transplantation.

**COMPLICATIONS**

Early postoperative complications include: cholangitis, bleeding, leak from anastomosis, prolonged ileus, and intestinal obstruction. Late complications include: cessation of bile flow, recurrent cholangitis, portal hypertension, ascites, hepatopulmonary syndrome/pulmonary hypertension, formation of bile-filled cavities in liver and cirrhosis.

**Cholangitis**

Cholangitis occurs in 30-60% of cases of biliary atresia after HPE. The attacks are more frequent during the first two years following the Kasai procedure. The severity can vary from mild to fulminant sepsis. Clinically, the patient will develop fever or hypothermia, vomiting, jaundice, hepatosplenomegaly, abdominal pain/distension and acholic stools. The diagnosis can be confirmed by blood culture (and conduit cultures if present) and/or liver biopsy. However, although gram-negative organisms or a mixed flora can be seen, mostly cultures are negative. The cause of cholangitis is not clear but there must be an intestinal-biliary communication and therefore the most favored hypothesis is that of an ascending infection from the gut.

Treatment includes resuscitation, intravenous fluid, broad spectrum antibiotics, (and in some centers high doses of steroids) for 7-10 days. In recurrent or late-onset cholangitis, obstruction to the drainage of the Roux loop should be considered. In those where a mechanical cause can not be found, a prolonged course of antibiotics should be considered.

Historically various measures have been tried with to reduce cholangitis although none have stood the test of time. These include creation of external stomas or placing catheters in the proximal limb of the Roux loop, use of an omental wrap applied to the porta hepatis, jejunal loop "valves", creation of an intussuscepted ileocecal conduit and use of an appendiceal conduit based on its vascular pedicle. Biliary stomas may cause problems such as prolapse, retraction, fluid and electrolyte loss, bleeding and malabsorption due to bile losses. As a routine practice, a valve is incorporated in patients with biliary atresia in the ascending limb of the Roux-en-Y loop with the presumption that the intestinal contents would not be allowed to go up and cause cholangitis.

**Portal Hypertension**

The incidence of portal hypertension is about 75% after Kasai operation and has a clear relationship with liver fibrosis. In a recent study, it was found that increased portal pressure (measured at the time of Kasai operation) is a bad prognostic sign. These patients...
Biliary Atresia

will have higher chances of developing portal hypertension, even if bilirubin level normalizes after operation. This study reported that portal pressure index (height of the saline level column above the liver surface level) was safe, simple and better predictor of postoperative outcome than the hepatic fibrosis score. Portal hypertension may cause clinically significant variceal formation at the esophagus, stomach, Roux loop and/or rectum. In patients with good liver function, varices are treated with endoscopic sclerotherapy or banding, but in those with persisting jaundice, poor synthetic liver function, then this will only be temporizing and liver transplantation is the only really successful option. Interventional radiological techniques such as transjugular intrahepatic portosystemic shunts (TIPS) are possible for some cases, as a bridge to transplantation, but requires skill and perseverance if good results are to be obtained. Portal vein hypoplasia may preclude this option. In those unusual cases of life-threatening bleeding, but non-progressive liver disease and good liver function, a conventional portosystemic shunts should be considered, particularly if transplantation is not an option.

Hepatopulmonary syndrome: Hepatopulmonary (HP) syndrome is characterized by hypoxia, cyanosis, dyspnea and clubbing and is due to development of pulmonary arteriovenous shunts. This seems to be due to gut derived vasoactive substances that are not cleared by the cirrhotic liver. The diagnosis is made by pulmonary scintigraphy. HP syndrome can be reversed after liver transplantation.

Biliary Lakes

Bile containing cysts can develop in liver postoperatively even in patients with complete clearance of jaundice. These bile lakes could be drained either externally or by cystoenterostomy if infection supervene or they cause pressure on portal veins. Ultimately, liver transplantation may be required in these cases.

Malignancies

In cirrhotic liver patients of biliary atresia, a number of malignancies have been reported including hepatocellular carcinoma, hepatoblastoma and cholangiocarcinoma.

OUTCOME

The outcome following Kasai operation can be assessed in two ways:

i. Clearance of jaundice
ii. Proportions of native liver survival.

Clearance of jaundice (< 2 mg/dL or < 34 μmol/L) after Kasai has been reported to be around 60%, whereas five year survival with native liver ranges from 35-64%. Long-term (10 years or greater) survival have been reported in the range of 27 - 53%. Only about 15% will have a true long term survival with no jaundice, normal liver biochemistry and no signs of liver disease or portal hypertension. However, even in this apparently ”cured” group, liver histology still remains abnormal.

In the children with a failed Kasai operation, liver transplantation is the only hope. The main problems associated with this major operation are lack of a suitable donor, small size of the recipient abdomen, immunosuppression and a significant postoperative morbidity and even mortality. At present, 3-year survival after liver transplantation in good centers is 85-90%.

PROGNOSTIC FACTORS

Biliary atresia is a rare disease and surgical outcome following biliary atresia depends upon adequate dissection and restoration of bile flow, together with effective treatment of the two major complications (cholangitis and portal hypertension). A number of factors contribute to good outcome and may be listed as:

i. Operator experience and size and experience of referral center.
ii. Extent of the pre-existing liver damage
iii. Frequency of cholangitis
iv. Syndromic (e.g. BASM) patients have poorer prognosis than non-syndromic group. This may be due to severe cardiac disease and hepatopulmonary syndrome.

v. Age at operation—The age at Kasai operation has an effect on outcome, but it is not as clear-cut as was once thought. There is no real cut-off (e.g. six or eight weeks or 60 days). These were simply the arbitrary values from earlier small studies. There is no doubt that the fibrotic element of the hepatopathology is progressive but beyond what
age an attempt at a Kasai portoenterostomy is pointless, is not known. Some infants will come to surgery early with very soft, non-fibrotic livers, at 20 days for instance, but because they have few residual ductules at the porta hepatis, that their Kasai’s will fail. In contrast, some infants will be operated late (beyond 100 days) and 10 year survival in these infants could be 40%.77

It is unfortunate that despite ongoing research in the field, biliary atresia remained a dreadful disease, especially in the underdeveloped nations.78 About 25% infants still present beyond 4 months of age not only with the features of biliary atresia, portal hypertension and ascites but also with severe anemia, chest infections and malnutrition. HPE is a major undertaking and if performed in such advanced cases of biliary atresia (with bilirubin > 10 mg%, age more than 120 days, liver fibrotic), it carries a high morbidity and mortality. In such cases, a modified approach is safer and better in the interest of the patient. This includes the benefit of the surgical exploration, dissection at porta hepatic to assess for the flow of bile and HPE only if there is a bile flow. In absence of bile flow, the porta hepatitis is drained with a sump drain for 5-7 days. In the postoperative period, cholestasis is induced and even if there is no flow of bile noted in the contents of the drain, it is simply pulled out and the prognosis is explained.79, 80

The results of HPE are not satisfactory in the long run and most patients would require liver transplantation, the facilities for which however, remain limited to major centers in the developed world. The availability of live related donors is a serious issue and the waiting list for liver transplant is quite long. Majority infants die during the waiting period alone. Also the surgical expertise, the cost for transplant, the maintenance cost for immunosuppression are also important considerations while considering this option. Thus attempt for finding an alternate procedure remains alive amongst the researchers in the field. Efforts are on to use the modern technology of tissue engineering to produce liver in the laboratory however, the success is still far away due to the complex nature of tissues (biliary system, blood vessels and the hepatocytes) involved in liver regeneration. Artificial liver on the pattern of renal dialysis, is another option but not yet fully successful and easily available. Recently, a significant interest has been generated to use stem cells to treat the damaged liver cells, with the hope that once transplanted the stem cells would repair or replace the diseased hepatocytes to prolong or obviate the need for liver transplantation.81 With the use of stem cells, the hepatic fibrosis has been shown to have regressed over months and years. However, lot of work is needed to prove this further.82

REFERENCES

Biliary Atresia

Choledochal cyst is an uncommon anomaly of the biliary tract. First reported by Douglas in 1852, it was not until early this century that precise clinical recognition and surgical treatment were developed. There is little doubt that choledochal cyst is a congenital lesion with a strong hereditary component, which may explain the higher incidence seen in Asia, and its familial occurrence in siblings and twins. Incidence in the newborn has been increasing in recent years due to advances in diagnostic imaging techniques and in our series about 20% of patients were detected either neonatally or antenatally.

Choledochal cyst is commonly associated with pancreaticobiliary malunion (PBMU) through which the pancreatic fluid can reflux into the biliary system and bile can flow into the pancreatic duct, and in recent years, combined anomalies of the common channel, pancreatic duct and intrahepatic duct are being recognized with increasing frequency, underlying the importance of cholangiography for visualizing the pancreaticobiliary system in its entirety.

EMBRYOLOGY

The extrahepatic biliary duct system and the ventral pancreas arise from the hepatic diverticulum during the fourth to sixth weeks of life. On day 22 of gestation, a small endodermal thickening, the hepatic plate, appears on the ventral side of the duodenum. The cells in the plate proliferate and form a hepatic diverticulum, which rapidly enlarges and divides into three parts: the large cranial part (the liver bud), the cystic diverticulum, and the small caudal part (the ventral pancreatic bud). On day 26 of gestation, another duodenal bud (the dorsal pancreatic bud) appears opposite the hepatic diverticulum. The cells at the junction of the liver, cystic, and ventral pancreatic buds proliferate and form the common bile duct.

Initially, the main duct of the ventral pancreatic bud develops near the entry of the common bile duct develop into the duodenum. As the duodenum rotates to the right (clockwise) and becomes C-shaped, the ventral pancreatic bud is carried dorsally with the bile duct and fuses with the dorsal pancreas. Later it comes to lie posterior to the dorsal pancreatic bud and fuses with it. The ventral pancreatic bud forms the uncinate process and part of the head of the pancreas.

The ventral pancreas fuses with a pair of ventral buds in the fifth week of fetal life and is connected by two ducts to the primitive hepatic duct. The ventral duct regresses with development. The duct of the right ventral pancreas divides into superior and inferior branches. As the pancreatic buds fuse, the superior ventral branch joins the dorsal pancreatic duct to form the main pancreatic duct, which merges with the common bile duct, inserting into the duodenum via the papilla of Vater.

ETIOLOGY

The etiology of choledochal cyst has not been fully clarified. Choledochal cyst is believed to be caused by two factors, i.e. weakness of the wall and an obstruction distal to it. Spitz stressed on the role of an obstructive factor in the early developmental stage, based on his experimental study on sheep, in which cystic dilatation of the common bile duct was produced by ligation of the distal end of the choledochus in a neonatal lamb, but not at later stages of development.
Our research in different animals confirmed this hypothesis.\textsuperscript{22-27} Similarly, our radiological and histological studies on patients with Choledochal cyst clearly demonstrate that distal segmental stenosis is closely associated with the cystic dilatation of the common bile duct and the site of stenosis is related to the abnormal choledochopancreatic ductal junction.\textsuperscript{23-27} In recent years, improved accuracy of cholangiography has drawn attention to a close association between choledochal cyst and anomalous arrangement of the pancreaticobiliary ductal system. In 1969, Babbit first proposed this long common channel theory.\textsuperscript{28} Since then, pancreaticobiliary malunion (PBMU) has been reported in choledochal cyst from endoscopic retrograde cholangiopancreatography (ERCP) and intraoperative cholangiography. High amylase levels in the aspirated cyst fluid from cases of choledochal cyst would appear to support this association. Between 1969 and 1997, we treated 210 patients with choledochal cyst. All had PBMU proven by cholangiography, and most had high amylase levels in the cyst fluid. Both a dilated common channel and anomalous pancreatic duct are also frequently observed, and may be related to the formation of protein plugs or pancreatic stones, which may cause pancreatitis.

In spite of these findings, controversy surrounds the cause of the stenosis that lies distal to the dilated common bile duct. Babbit stressed that the pancreatic fluid is the most basic causative factor for edema and subsequent fibrosis in the distal common bile duct as well as weakness of the choledochal wall.\textsuperscript{28} However, the chemical reaction of the refluxed pancreatic fluid in the bile duct appears to be extremely mild, according to our animal experiments in which choledochoPancreaticostomy was performed in puppies to allow pancreatic fluid to regurgitate into the bile duct.\textsuperscript{29} In this animal model, fusiform dilatation rather than cystic dilatation of the common bile duct was induced. Also, a number of patients with PBMU and high amylase level in the gallbladder do not have dilatation of the choledochus, although some had gallbladder carcinoma.\textsuperscript{30} The chemical effect of pancreatic fluid on the bile duct has not been clarified in the antenatal period. However, choledochal cyst can now be diagnosed as early as the 15th-20th weeks of gestation, a period when pancreatic acini are only just beginning to appear, and zymogen granules are immature, and there is no evidence of secretion seen on electron microscopy.\textsuperscript{8,11-13,31} Even in the newborn, the pancreas has not matured enough to produce functional enzymes, so the role of pancreatic fluid in choledochal cyst formation may be overemphasized.\textsuperscript{32}

Jona suggested that choledochal cyst is related to faulty budding of the primitive ventral pancreas.\textsuperscript{33} Tanaka proposed that canalization of the ventral pancreatic duct and regression of the terminal choledochus is responsible for PBMU formation.\textsuperscript{34,35} Based on human fetus observation, Wong demonstrated that choledochopancreatic junction lies outside the duodenal wall before eighth week of gestation then moves inward and towards the duodenal lumen as age advanced, suggesting that an anomalous junction can be caused by arrest of this migration.\textsuperscript{36}

Therefore, based on these radiological and experimental studies, we believe that an anomalous choledochopancreatic ductal junction combined with congenital stenosis are the basic causative factor of choledochal cyst rather than weakness caused by the reflux of pancreatic fluid, at least in perinatal and young infants. The anomalous choledochopancreatic junction and stenosis may cause abnormal development of the ventral pancreatic duct and biliary ductal system by unknown genetic associations.

**CLASSIFICATION**

Choledochal cyst can be roughly classified into two types according to the shape of the common bile duct: cystic dilatation and fusiform dilatation.\textsuperscript{37} It could be intra or extrahepatic or both. Both Todani and Komi have described classifications for choledochal cyst based on cholangiographic studies of the pancreaticobiliary ductal system (Figs 90.1A to E).\textsuperscript{38,39} However, the authors prefer to classify Choledochal cyst into groups according to the presence or absence of PBMU (Figs 90.2A to F).

1. **With PBMU:** (A) cystic dilatation of the extrahepatic bile duct*. (B) Fusiform dilatation of the extrahepatic bile duct*. (C) Forme fruste choledochal cyst+.
2. **Without PBMU:** (D) Cystic diverticulum of the common bile duct. (E) Choledochocele (a diverticulum of the distal common bile duct). (F) Intrahepatic bile duct dilatation alone (Caroli’s disease).
The clinical manifestations of choledochal cyst differ according to the age of onset. Neonates and young infants usually present with an abdominal mass, jaundice, and acholic stools. Some present with a huge upper abdominal mass with or without jaundice. Since the advent of routine antenatal ultrasound (US) for the detection of fetal anomalies, the number of neonates being detected with incidental choledochal cyst has increased. According to our investigations, the ratio of cystic to fusiform type antenatally or neonatally is 20:1, in contrast to an overall ratio of 5:3. In older children, the classical triad of pain, mass and jaundice may be present. Fever and vomiting may also occur. The pattern of pain has been described as being similar to that of recurrent pancreatitis in which a high serum amylase level is often present. However, in our series, there was little clinical evidence of pancreatitis in the newborn, because amylase levels were not found to be elevated.

**Asymptomatic Neonatal Choledochal Cyst**

There are very few reports on the management of asymptomatic choledochal cyst detected in the antenatal or neonatal period. Some pediatric surgeons recommend primary cyst excision soon after diagnosis, but our experience had been that cyst excision need not be performed hastily in these young infants; rather, they should be thoroughly assessed and surgery should be planned.

**PBMU with Nondilatation or Minimal Dilatation of the Common Bile Duct**

In children who present with recurrent pancreatitis, PBMU must be suspected even if the common bile duct appears to be normal. Treatment of choledochal cyst today is primary excision of the cyst followed by hepaticoenterostomy. However, PBMU without dilatation of the biliary tract is often encountered and its treatment is controversial. In adults, simple cholecystectomy without biliary reconstruction is usually performed, because PBMU presents with gallbladder related symptoms.

Over 30 years, we have treated eight patients with nondilatation or minimal dilatation of the common bile duct at our institution, approximately 4.4% of the whole choledochal cyst population (Fig. 90.3).
These patients presented with signs and symptoms of pancreatitis, i.e. abdominal pain associated with elevation of serum amylase levels. Five of those had jaundice or a history of pale colored stools.

At presentation, ERCP showed that five (62.5%) of these eight patients had dilatation of the common channel, a finding that is usually seen in about 30% of the choledochal cyst cases. Three cases (37%) also had protein plugs or debris at the level of the common channel, a finding that is usually only observed in 16% of choledochal cyst cases. Histopathologically, there was mild to moderate inflammation and mucosal hyperplasia manifested in the gallbladder and epithelial denudation and fibrosis also observed in the common bile duct.

The extrahepatic bile duct was excised with the gallbladder followed by a Roux-en-Y hepatico-jejunostomy in six cases and a hepaticoduodenostomy in two cases for biliary reconstruction. No postoperative complications were encountered. All patients had resolution of their symptoms after operative repair on follow-up (average duration 4.3 years).

Since clinical symptoms in patients with PBMU arise from stasis or protein plugs at the level of the common channel, caused by reflux of the pancreatic secretions and chronic inflammation, we believe that radical treatment by pancreaticobiliary separation should be selected to prevent serious long-term complications. Based on our close and long-term observation, it is difficult to manage these patients conservatively.

INVESTIGATIONS

Currently, abdominal US is the best method for detecting choledochal cyst even though it does not permit visualization of the entire duct system and it is not clear enough to demonstrate an undilated common channel and pancreatic duct (Figs 92.4 and 90.5). However, routine antenatal US for the detection of fetal anomalies allow the diagnosis of choledochal cyst to be made as early as 15th week of gestation.11 For a complete diagnosis of choledochal cyst, it is also
important to investigate for coexisting PBMU, abnormalities of the pancreatic duct, intrahepatic ducts and extrahepatic duct. ERCP can accurately visualize the configuration of the pancreaticobiliary ductal system in detail, and is unlikely to be replaced by other investigations, especially in cases where fine detail is required preoperatively. ERCP is routinely performed in the diagnosis of biliary malformations in infants and the newborn in many centers in Japan, with a reasonable success rate. However, it is invasive and therefore unsuitable for repeated use, and is contraindicated during acute pancreatitis.

We have shown that magnetic resonance cholangiopancreatography (MRCP) can provide excellent visualization of the pancreaticobiliary system in patients with choledochal cyst allowing narrowing, dilatation and filling defects to be detected with medium to high degrees of accuracy (Figs 90.6 and 90.7). Because MRCP is noninvasive, it can partially replace ERCP as a diagnostic tool for the evaluation of anatomical anomalies of the pancreaticobiliary tract. Another advantage of MRCP over ERCP is that the pancreatic duct can be visualized upstream to an obstruction or area of stenosis. So far, there are limitations of patient's size, weight and age for using MRCP. Once the quality of MRCP improves, ERCP may become optional.

If preoperative imaging can clearly visualize the entire pancreaticobiliary ductal system, including the intra- and extrahepatic bile ducts, and pancreatic duct in detail, intraoperative cholangiography is unnecessary; however, if sufficient information is not obtained, it must be performed (Figs 90.8A and B). Also, if the cyst is too large, intraoperative cholangiography via the gallbladder or directly via the common bile duct is useless. In such cases, intraoperative cholangiography should be performed separately for the intrahepatic bile duct and distal common bile duct by a selective technique during excision of the cyst. Rarely, intraoperative cholangiogram may help to diagnose unsuspected anomalies if MRCP was not done earlier (Figs 90.9A to D).

**DIFFERENTIAL DIAGNOSIS**

Choledochal cyst can be diagnosed without difficulty using abdominal US and ERCP. Caroli’s disease, congenital stricture of the common bile duct, correctable biliary atresia, congenital hepatic fibrosis and pancreatic disorders with bile duct obstruction, need to be considered in the differential diagnosis. In such cases, there is usually a normal pattern of pancreaticobiliary union. The typical feature of Caroli’s disease is cystic dilatation of the intrahepatic ducts, which resemble a string of beads. There is usually a normal extrahepatic bile duct without PBMU. In fully developed biliary atresia, the bile duct may be obstructed distally with dilated extrahepatic bile ducts. On such occasions, Choledochal cyst can be differentiated from biliary atresia because there is a patent communication with the duodenum and a well-developed intrahepatic bile duct tree (Figs 90.10A and B).

Surgery

Choice of Operative Procedure

Cyst excision with Roux-en-Y hepatoenterostomy is the definitive treatment of choice in all patients with Choledochal cyst, regardless of age or symptomatology (Fig. 90.11). In patients who have already had internal drainage without cyst excision, revision with cyst excision is strongly recommended if there is any symptom of postoperative biliopancreatic dysfunction. By doing so, a good prognosis can be expected. However, there is high morbidity and high risk of carcinoma after internal drainage without cyst excision, a commonly used treatment in the past.

Complete Excision

In newborn and young infants, choledochal cyst is usually cystic type. Complete cyst excision (full thickness of the cyst) is much easier in young infants, because the wall of the dilated common bile duct is generally thin and there are fewer adhesions to the surrounding vital structure, such as portal vein. Aspiration of the cyst prior to dissection makes surgery easier, if the cyst is large and tense. Care is also taken if the cyst is infected and the gallbladder is turgid (Fig. 90.12). The cyst should be opened at the midportion close to the duodenum, because there is often an anomalous opening of the hepatic duct, i.e. a separate opening or opening to the distal part of the cyst. The cyst is then transected midportion after careful circumferential dissection from the hepatic artery and portal vein. Calculus, if any, in the cyst is carefully removed (Fig. 90.13). Subsequently, dissection of the distal portion is carried out. It is important that the cyst be completely excised at the level of caliber change, in order to avoid malignant changes in the remaining cyst epithelium. If there is no distinct caliber change (i.e. fusiform type), excision...
Pediatric Surgery—Diagnosis and Management

Pediatric Surgery—Diagnosis and Management

by open drainage, precutaneous transhepatic cholangiodrainage or direct precutaneous cyst drainage. Subsequently, delayed primary excision may be carried out one or two months later.\textsuperscript{14,42,43}

Biliary Reconstruction

Most surgeons use a Roux-en-Y hepaticojejunostomy, however some surgeons recommend a wide anastomosis at the level of the hepatic hilum to allow

**Fig. 90.14:** Diagram of intraoperative endoscopy showing the bile duct distal to the cyst with debris and protein plug. After identification of the orifice of the pancreatic duct, the cyst is excised at level 2. (1) likelihood of leaving the residual cyst, (2) adequate excision level of the cyst, (3) likelihood of injuring the pancreatic duct

**Fig. 90.12:** A girl with infected choledochal cyst presenting with features of cholangitis. The cyst and the gallbladder were tense cystic with full of pus. The liver was enlarged and edematous. A two stage procedure may be preferred in these cases, to allow the inflammation to subside before resorting to cyst excision and definitive operative procedure with internal drainage (courtesy: Prof DK Gupta, New Delhi)

**Fig. 90.13:** A small calculus being removed from the lower end of the choledochal cyst (Courtesy: Prof DK Gupta, New Delhi)

Mucosectomy

In a patient in whom complete excision of the distal portion of the cyst is difficult, mucosectomy of the distal portion of the cyst is recommended in order to avoid not only damage to the pancreatic duct, hepatic artery and portal vein, but also to avoid cancer arising from the remaining epithelium of the distal portion of the cyst.

Staged Procedure

If primary excision is considered to be difficult, for example, in the case of perforated bile peritonitis, severe cholangitis or severe general condition, or in neonates, external biliary drainage is recommended should be carried out just above the choledochopancreatic junction (Fig. 90.14).\textsuperscript{52} The stump should be double-suture ligated and transected. If a protein plug is found in the common channel, it must be washed out toward the duodenum to avoid postoperative stone formation and pancreatitis.\textsuperscript{42} Finally, the common hepatic duct is transected at the level of distinct caliber change. Since proximal cyst mucosa is prone to malignant changes, it must not be left for large anastomosis.\textsuperscript{43}
free drainage of bile to prevent postoperative anastomotic stricture and stone formation. Based on a wealth of experience from a large number of series, we recommend conventional hepaticoenterostomy as the treatment of choice. Hepaticoenterostomy at the hepatic hilum is indicated in specific cases only, such as in patient’s with dilated intrahepatic bile duct with stenosis in the common hepatic duct or adolescent patient with severe inflammation of the common hepatic duct. Although we initially used end-to-side anastomosis, we now prefer end-to-end, because drainage is smoother and more direct, with less possibility of stasis (Figs 90.15A to C). With end-to-side anastomoses, we have experienced overgrowth of the blind end, which caused bowel obstruction in one case, and bile stasis in the blind pouch, which caused bowel obstruction in one case. Bile stasis in the blind pouch can also cause stone formation in the pouch or dilatation of intrahepatic bile ducts.

However, our results do not compel us to resort to other procedures such as hepaticoenterostomy at the hilum and valved jejunal interposition hepaticoduodenostomy to prevent reflux of digested food into the intrahepatic bile duct, which are appealing theoretically, but offer no significant improvement in morbidity. Hepaticoenterostomy at the hepatic hilum also appears to be more difficult than conventional hepaticoenterostomy, particularly in small children without the dilatation of intrahepatic bile duct.

A hepaticoduodenostomy has a limited indication and is found useful if the lumen of the duct is less than one cm in diameter after the cyst has been excised. Duodenum should be mobilized so as to reach the portahepatis comfortably. A single layer anastomosis is made with the duct and the superoposterior aspect of the first part of the duodenum. The area should always be drained as 10% leak is reported. The valved jejunal interposition hepaticoduodenostomy though practiced by a few surgeons, is a rather complicated procedure and is not preferred for routine use.

### Role of Intraoperative Endoscopy
Since 1986, we have routinely performed intraoperative endoscopy of the common channel, pancreatic duct and intrahepatic ducts to examine the duct system directly for stone debris and ductal stenosis and remove any stone debris by irrigation with normal saline. Intraoperative endoscopy with a pediatric cystoscope or fine fiberscope with a flush channel is also recommended as a valuable adjunct to determine the transection level of the common hepatic duct, irrigating the common channel and to determine the level of excision of the distal end of the cyst to avoid injuring to the pancreatic duct, leaving only a minimal intrapancreatic terminal choledochus.

### Laparoscopic Cyst Excision
Recent advances in laparoscopy have enabled pediatric surgeons to perform minimally invasive surgery for Choledochal cyst. Although technically demanding and long-term follow-up results remain unknown, experienced laparoscopic surgeons can obtain results as good as those for open surgery. The disadvantages are mainly the longer operating time and the higher costs, which, however, may be offset by a shorter hospital stay.

### ASSOCIATED CONDITIONS

**Intrahepatic Bile Duct Dilatation**
Recently, more attention has been paid to the treatment of intrahepatic ductal disease such as intrahepatic bile...
duct dilatation with downstream stenosis, which is closely associated with late postoperative complications. Intrahepatic bile duct dilatation can be managed by segmentectomy of the liver, intrahepatic cystoenterostomy or balloon dilatation of the stenosis at the time of cyst excision. In three cases in our series, we performed an intrahepatic ductoplasty and cystojunostomy or hepaticojejunostomy at the hepatic hilum for stricture of the intrahepatic bile duct at the hepatic hilum to create a wide stoma by incising along the lateral walls of the hepatic ducts following excision of the narrowed segment of the common hepatic duct. By using intraoperative endoscopy, the ideal level of resection of the common hepatic duct can be safely determined without injuring the orifices of the hepatic duct or leaving any duct remnant.

Disorders of Pancreatic Duct and Common Channel

With the advent of endoscopy, more anomalies of the pancreatic duct and common channel have been identified. These include protein plugs or stones in the common channel, stenosis of papilla of Vater, stricture of the pancreatic ducts, or even septate common channel. Stone debris in the common channel and intrahepatic duct are responsible for abdominal pain, pancreatitis and jaundice. If not removed at the time of radical surgery, they can be the cause of recurrent pancreatitis or calculi formation in pancreatic and biliary system postoperatively. We use a pediatric cystoscope for intraoperative pancreatoscopy of the common channel and intrahepatic duct. A neonatal cystoscope with a flush channel can also be used and is finer and more flexible (1.9-2.0 mm). We have performed intraoperative pancreatoscopy in 67 patients with Choledochal cyst. Stone debris in pancreatic duct distal to the common channel was detected in eight cases (11.9%). All eight patients had a dilated long common channel with PBMU and presented with acute pancreatitis. They are all well after a mean follow-up period of 7.3 years.

Complications and Outcome

Cyst excision combined with hepaticoenterostomy (CEHE) is the treatment of choice for choledochal cyst. A satisfactory surgical outcome with early low morbidity is expected after this standard surgical procedure.

We have reviewed 200 children and 40 adults who underwent CEHE and found 9.0% (18/200) of children, and 42.5% (17/40) of adults had post-CEHE complications. The complication rate in children was significantly lower than in adults. No stone formation was seen in the children who had CEHE before the age of five years.

The post-CEHE complications recorded were cholangitis, intrahepatic bile duct stone formation, stone formation in the intrapancreatic terminal choledochus or pancreatic duct, and bowel obstruction. No complications were found in the 70 children who had intraoperative endoscopy in our series. Stone formation was seen in seven of the 55 children (12.7%) aged over five years at the time of CEHE. There was no stone formation in the 145 children who had CEHE before the age of five years. Stones developed in seven (17.5%) adults. One patient presented with relapsing pancreatitis owing to a stone within the residual segment of an intrapancreatic cyst, six years after excision of a fusiform-type dilatation of the common bile duct with hepaticojejunostomy. One patient was found to have stones in the blind pouch of an end-to-side anastomosis.

Reoperation was required in 15 children-revision of hepaticoenterostomy in four, percutaneous transhepatic cholangioscopic lithotomy in one, excision of intrapancreatic terminal choledochus in two, endoscopic sphincterotomy of the papilla of Vater in one, pancreaticojejunostomy in one, and laparotomy for bowel obstruction in six. Ten adults required reoperations-revision of hepaticoenterostomy in two, percutaneous transhepatic cholangioscopic lithotomy in two, exploratory laparotomy in two, adhesiolysis in one, endoscopic sphincterotomy in two, and left lobectomy of liver in one. Anastomotic stricture appears to be related to the severity of mucosal denudation in the common hepatic duct and/or to prolonged inflammation secondary to bile stasis in the dilated intrahepatic bile duct. On such occasions, a hepaticojejunostomy should be performed at the hepatic hilum to create a wide stoma by incising along the lateral walls of the hepatic ducts following excision of the narrowed segment of the common hepatic duct, because the inflammation of the walls of the extrahepatic cyst is more chronic and fibrotic and the...
Choledochal Cyst

Wall of the intrahepatic bile ducts also may be severely and irreversibly damaged, resulting in poor resolution of the intrahepatic bile duct dilatation. Patients who present late during infancy or childhood with liver cirrhosis, portal hypertension, associated pancreatitis and superadded infection have poor prognosis (Fig. 90.16).

Careful long-term follow-up is required, particularly in patients who have had intrahepatic bile duct dilatation and also dilatation of the remaining distal bile duct, pancreatic duct and common channel, because of chronic inflammation, calculus formation as well as the possibility of carcinoma arising at a later stage.

REFERENCES

Pancreatic pseudocysts are the most common cystic lesions of the pancreas; accounting for 75-80% of such masses. Pancreatic pseudocysts in children are usually a sequelae of pancreatic blunt trauma though it may rarely be associated with chronic pancreatitis and parenchymal disease. Imaging studies, such as ultrasound, computed tomography scan and endoscopic retrograde cholangiopancreatography are helpful in establishing diagnosis. Most of the diagnoses are usually made by an ultrasonogram or a CT scan abdomen.

DEFINITION

A pancreatic pseudocyst is a collection of fluid around the pancreas as a result of acute or chronic pancreatitis bound to the pancreas by inflammatory tissue. The true incidence of pancreatitis in children is unknown. Pseudocysts complicate acute pancreatitis in approximately 10-30% cases. The incidence of pancreatic pseudocysts is greater than 50% when associated with traumatic injury to the abdomen.

ETIOLOGY

Pancreatic ductal disruption in children leading to pseudocyst formation may occur secondary to:
1. Trauma.
2. Ductal obstruction.
3. Acute pancreatitis.
4. Chronic pancreatitis from strictures or ductal calculi.
5. Pancreaticobiliary malformations, most commonly pancreatic divisum, bifid duct.
6. Chronic pancreatitis resulting from systemic diseases like Systemic Lupus Erythematosus.
7. Chronic relapsing pancreatitis resulting from hereditary pancreatitis.
8. Drug induced acute pancreatitis—Valproic acid for epilepsy, L-asparaginase in pediatric malignancies.
10. Pancreatic neoplasms
11. Idiopathic.

The most common etiology of the pancreatic pseudocyst identified in children is post-traumatic, being upto 80-100% of the cases in different series. Idiopathic causes comprised up to 25% of the cases in a series of pediatric pseudocysts.

PATHOPHYSIOLOGY

The formation of a pseudocyst usually requires four or more weeks from the onset of pancreatitis-acute or chronic. Pseudocysts have a higher incidence in chronic pancreatitis as compared to acute pancreatitis. Acute pancreatitis can cause necrosis. Chronic pancreatitis can cause elevated pancreatic duct pressures. Crushing or blunt abdominal trauma can injure the pancreas by compression against the vertebra.

A pancreatic pseudocyst is a fluid collection contained within a well-defined thick capsule of fibrous or granulation tissue or a combination of both.

Typically, the wall of a pancreatic pseudocyst lacks an epithelial lining, and the cyst contains pancreatic juice or amylase-rich fluid. The location of the pseudocyst is in the lesser peritoneal sac in proximity to the pancreas. It may involve any part of the pancreas, head, body and tail. Large pseudocysts can extend into the paracolic gutters, pelvis, mediastinum, neck or scrotum.
More than 90% of the cysts are single though they can be multiple.\textsuperscript{12} The cyst may be loculated. The fluid in the pseudocyst has similar electrolyte concentrations to plasma and a high concentration of amylase, lipase and enterokinases such as trypsin.

Pancreatitis originates with blockage or disruption of the collecting ducts and damage to the acinar cell, that leads to activation and release of digestive enzymes that autodigest the pancreatic parenchyma. The localized collections of pancreatic secretions become walled off by granulation tissue and form a pseudocyst either within the pancreatic tissue or immediately adjacent to it.

**CLINICAL PRESENTATION**

Though the most common etiology is post-traumatic in children, yet a negative history of trauma is not uncommon. This is so as the trauma is often subtle and long forgotten and the history from children may not be reliable. The cysts have been detected from 3-57 days after injury.\textsuperscript{13} It is more common in boys.\textsuperscript{13}

The most common presenting symptom is epigastric pain.\textsuperscript{14} Other symptoms include mass, nausea, vomiting, feeling of bloating or a deep ache in the abdomen (Figs 91.1A to C). Additional symptoms include jaundice, chest pain, anorexia, weight loss, ascites and rarely gastrointestinal hemorrhage. If infection has set in, the child may present with fever, worsening abdominal pain and systemic signs of sepsis. The child may also present with failure to thrive.\textsuperscript{4}

On examination, a tender epigastric mass may be palpable. It is usually tense cystic.

**COMPLICATIONS**

These include:
1. Infection of the pseudocyst with a pancreatic abscess. About 10% pseudocysts become infected.\textsuperscript{15}
2. Bleeding into the pseudocyst.
3. Intestinal obstruction.
4. Rupture.\textsuperscript{16}
5. Pleural effusion.\textsuperscript{17}
6. Thrombosis—Splenic vein is the most common site.
7. Pseudoaneurysm formation—Splenic artery is the most common site; other sites include gastro-duodenal artery and pancreato duodenal artery.\textsuperscript{16}
8. Spread into the mediastinum. Mediastinal pancreatic pseudocyst is a rare occurrence in children and may be difficult to diagnose.\textsuperscript{18}

**INVESTIGATIONS**

**Blood Investigations**

Blood investigations may reveal leukocytosis, and persistent elevation of serum amylase. The initial serum amylase level has been found to correlate with neither the time of resolution nor the appearance of cyst after the trauma.\textsuperscript{13} Genetic testing may detect established risk factors for chronic pancreatitis like homozygous SPINK1-N34S mutation.\textsuperscript{3}

**Plain Skiagram**

Plain skiagram may demonstrate nonspecific findings ranging from a distended loop of small intestine (sentinel loop), calcifications, dilation of the transverse colon (cutoff sign), peripancreatic extraluminal gas bubbles, ileus, left-sided basal pleural effusion and

Figs 91.1A to C: A. Post-traumatic pseudocyst in a boy presenting as acute intestinal obstruction due to mass effect. The boy had bilious vomitings. He was managed conservatively with total parenteral nutrition and octreotide started on day 5. B. Lateral view of the same in which the mass can be seen extending up to below the umbilicus. C. The mass reduced in size gradually after 3 weeks and the boy could be discharged.
blurring of the left psoas margin to pancreatic calcifications from chronic or recurrent pancreatitis. A soft tissue shadow of the pseudocyst may be identified. Concretions in the main pancreatic duct may be picked up.3

**Ultrasonography**

This is the primary screening tool for evaluation of the pediatric pancreas. Ultrasonography findings may identify a pseudocyst as a well-defined, hypoechoic mass that may be multilocular. Pancreatitis may be identified with a focally or diffusely enlarged, hyperechoic, sonolucent, or edematous pancreas; dilated pancreatic ducts; a fluid collection or peripancreatic fluid or an abscess. Ascites is easily picked up on ultrasonography. Endoscopic Ultrasonography (EUS) can also be added to the armamentarium. Serial sonogram examinations play an important role in monitoring the progress of pancreatic pseudocysts.13

**Computed Tomography Scan**

CT scan is a better modality to detect chronic pancreatitis and its complications, pancreatic trauma and neoplastic conditions. A pseudocyst with a well-defined wall or capsule and central area of low attenuation is well appreciated (Fig. 91.2). CT scanning is also a better modality for evaluating the presence and the extent of pancreatic necrosis and inflammation of peripancreatic fat.

**Endoscopic Retrograde Cholangiopancreatography (ERCP)**

ERCP is essential for evaluation of pancreatic and biliary anomalies and has been found useful in establishing pancreas divisum as the etiology.18 It can identify various ductal abnormalities or obstructions. It is also an important tool as a therapeutic intervention. ERCP is also essential to assess pseudocyst communication with the pancreatic duct to determine definitive operative therapy.

**Magnetic Resonance Imaging (MRI) and Magnetic Resonance Cholangiopancreatography (MRCP)**

Magnetic resonance imaging (MRI) is another modality to diagnose pancreatitis and is used for the same indications as CT scan. Magnetic resonance cholangiopancreatography (MRCP) is a noninvasive alternative to ERCP but lacks therapeutic capabilities.

**MANAGEMENT**

The aim of treatment for pseudocyst is the avoidance of complications. It has been reported that pseudocysts from nontraumatic etiologies are more likely to benefit from surgical interventions, whereas pseudocysts from traumatic etiology are more amenable to conservative management.4

**Observation**

All cysts do not require treatment. In many cases the pseudocysts resolve without interference and require only supportive care.19 In a child with a cyst less than 6 cm that is not causing any symptoms, careful observation of the cyst with periodic CT scans is indicated. In general, larger cysts are more likely to become symptomatic or cause complications. However, some patients even with larger collections do well; therefore, size of the pseudocyst alone is not an indication for drainage.

Conservative therapy is required for approximately 4-6 weeks to allow the cyst wall to mature drug induced pancreatitis complicated by a pseudocyst may be managed conservatively by just stopping the drug. Valproic acid induced pancreatitis complicated by a pseudocyst has been reported to resolve spontaneously in four weeks.7
**Conservative Medical Treatment**

Medical therapy reduces the pancreatic stimulation and favors the resolution or the maturation of the pseudocyst.9 Many patients with pancreatic pseudocysts can be managed conservatively if the presenting symptoms can be controlled.20

If the child is symptomatic with pain abdomen, an initial supportive management may be given till there is relief in symptoms. This consists of adequate rehydration, keeping the child nil orally and on nasogastric decompression. Total parenteral nutrition may be added if there is no relief within five days (Fig. 91.1). Octreotide can be useful to decrease the amount of pancreatic secretions,21 Antacids or H₂-histamine blockers are useful to prevent gastritis and reduce duodenal acid exposure. Antibiotics may be added if the cyst is infected. Acute pancreatitis should resolve in 2-7 days with adequate resuscitation. In chronic relapsing pancreatitis, pancreatic enzyme supplementation, insulin and elemental or low-fat diets are useful adjuncts to maximize nutritional status. About 1/3-1/2 of the pseudocysts resolve spontaneously.

**INTERVENTION**

The management of pseudocysts in children should be individualized as suggested for management of pancreatic injuries in children.22

Certain indications for operative interventions have been identified. If a pseudocyst is persistent over 6 weeks or causing symptoms, then surgical treatment of the cyst is required. Indications for drainage include enlargement of the cyst to more than 6 cm, setting in of complications, symptoms and concerns about possible malignancy.23

Surgical intervention is also indicated for the management of congenital anatomic defects like pancreatic divisum.

The methods of intervention include percutaneous drainage, endoscopic drainage and surgical drainage.

**Percutaneous Drainage**

Percutaneous catheter drainage is the procedure of choice for treating infected pseudocysts. Octreotide can be useful as adjunct to catheter drainage.24 Percutaneous continuous drainage may be done until the output is < 50 ml/day or the serum amylase is normal. The failure rate is about 15% and recurrence rate is 7%. The complications include conversion into an infected pseudocyst (10%), catheter-site cellulitis, gastrointestinal hemorrhage, pancreatico-cutaneous fistula and damage to the adjacent organs.

L-asparaginase (used for acute lymphocytic leukemia) induced pancreatitis, complicated with pseudocyst formation has been treated by percutaneous external drainage, total parenteral nutrition (TPN), administration of octreotide and antibiotic therapy for one month.8 Percutaneous external drainage proved to be an effective, noninvasive method in this special case with a systemic disorder and the high risk of mortality should a surgical intervention have been performed.9

**Endoscopic Drainage**

Recently, there has been an increasing trend towards the use of endoscopic treatment for the management of pancreatic pseudocysts in children with success rates as high as 85%.25,26 Some authors suggest that endoscopic treatment should be the first choice and surgical treatment can be reserved for cases that fail to the endoscopic treatment.

Endoscopic drainage may be either transpapillary (via ERCP) or transmural (transenteric).27,28 The procedure adopted requires careful patient selection to ensure success and safety.

The indications for endoscopic drainage include; mature cyst wall < 1 cm thick, cyst adherent to the duodenum or posterior gastric wall and a history of previous abdominal surgery or significant co-morbidities. The contraindications for endoscopic drainage include bleeding dyscrasias, gastric varices, acute inflammatory changes that may prevent cyst from adhering to the enteric wall, evidence of intrapancreatic ductal obstruction, presence of thick debris and multiloculated cyst.

Transpapillary drainage is feasible as 40-70% of pseudocysts communicate with pancreatic duct. The usual procedures adopted are ERCP with sphincterotomy, balloon dilatation of pancreatic duct strictures, and stent placement beyond strictures. Endoscopic transpapillary nasopancreatic drainage placement is a safe and effective modality for the treatment of multiple and large pseudocysts, especially when there is partial ductal disruption, and the disruption can be bridged.29
Large pseudocysts of the pancreas have been successfully treated in the short-term by minimally-invasive stent placement to create an internal cyst-gastric communication. Endoscopic placement of stents has been found successful in the treatment of pancreatic pseudocysts in children, in even a baby as young as 17-month-old. Transmural drainage may be cystogastrostomy or cystoduodenostomy. Endoscopic transmural drainage is a minimally invasive, effective and safe approach in the management of pancreatic pseudocysts and abscesses. Cystogastrostomy and cystoduodenostomy have been created with an interventional linear echoendoscope under endosonographic and fluoroscopic control by the endoscopic insertion of straight or double pigtail stents. Complications have been seen more frequently in patients with a recent episode of acute pancreatitis. The majority of major complications in endoscopic drainage may be prevented by using pigtail stents instead of straight stents and by taking a more aggressive approach to the prevention and treatment of secondary cyst infection. The technical success rate of the drainage procedure has been reported as 97%. Complications include hemorrhage caused by erosion of a straight endoprosthesis through the cyst wall, secondary infection and perforation.

Surgical Treatment

Pancreatic pseudocysts with associated major ductal disruption or a transected pancreas require operative therapy with cyst enterostomy.

Surgical internal drainage is the procedure of choice and has a success rate of 85-90%. Surgical drainage is the standard criteria against which all therapies are measured.

Patients who failed non-operative measures should have a period of stabilization prior to operation. This is important to reverse sepsis and to improve nutritional status prior to intervention.

The type of surgical procedure depends on the location of the cyst. For cysts that occur in the body and tail of the pancreas either a cysto-jejunostomy or cystogastrostomy is performed depending on the location of the cyst in the abdomen. For pseudocysts that occur in the head of the pancreas a cystoduodenostomy is usually performed. A cystoduodenostomy may be complicated by duodenal fistula and bleeding at anastomotic site.

Successful enucleation of the pseudocyst has also been reported. However, since the anterior wall of the pancreas forms a wall of the cyst, it is not at all advisable to attempt this procedure in most cases. Larger cysts and those located in the head and neck, tend to be drained, while smaller and distal cysts have more often been resected.

Some surgeons have performed an intraoperative pancreatic ductography in adults with chronic pancreatitis to determine the site of ductal disruption and adopt the most appropriate operative procedure. Ductal anatomy on ERCP has been used as a guide to the choice of modality. Cases with a normal duct with a noncommunicating or a communicating pseudocyst have been managed non-operatively. Cases with an isolated ductal segment and chronic pancreatitis have been managed operatively.

Definitive management with subtotal or total pancreatectomy is associated with considerable morbidity and mortality due to loss of both endocrine and exocrine functions of the pancreas. Generally, pancreatectomy is not indicated in children; however, it may be considered in cases of intractable pain and diffuse parenchymal damage without ductal dilation. Distal pancreatectomy may also be considered when the pseudocyst is in the tail of the gland.

Surgical options for chronic pancreatitis include distal pancreatectomy with Roux-en-Y pancreatico-jejunostomy (i.e. Duval procedure), lateral pancreatico-jejunostomy (Puestow procedure), or ERCP sphincteroplasty. In presence of a dilated pancreatic duct with multiple calculi, a transverse pancreaticojejunostomy is justified after removal of the calculi.

Pancreatic pseudocyst has been reported to account for 6% of the 253 cases undergoing distal pancreatectomy. Cyst wall biopsy obtained confirmed the diagnosis of pseudocyst in 8 of 10 cases while a true cyst with epithelial lining was found in only 2 cases in a series. A mediastinal pseudocyst has been approached thoracoscopically.

Laparoscopic cystojejunostomy and cystogastrostomy have been successfully performed in children.
with pancreatic pseudocysts.\textsuperscript{40,41} A technique combining upper endoscopy with percutaneous transgastric minilaparoscopic instrumentation for the formation of pancreatic cystgastrostomy has been performed safely and effectively for the internal drainage of pancreatic pseudocysts.\textsuperscript{42} Ports have been placed through the anterior abdominal and gastric walls, and into the lumen of the stomach for access to the posterior gastric wall. Using electrocauterity diathermy, an incision was made through the posterior gastric wall and into the adjacent pseudocyst to obtain complete and unobstructed drainage.

**MORBIDITY AND MORTALITY**

Management of pancreatic pseudocysts has been associated with considerable morbidity (15-25%).\textsuperscript{21} These morbidities include pancreatic leak, wound infection, failure to thrive and insulin-dependent diabetes.\textsuperscript{4} The mortality is however 0-1%.

**AIIMS EXPERIENCE**

At AIIMS, most pseudocysts were seen following trauma. Post-pancreatitis pseudocysts were uncommon in our setup. Most of these were large and unilocular. Only a few were multiloculated. While ultrasonography offers the diagnosis, CT scan was mandatory to evaluate the pancreas properly. Children without any symptoms or the cysts less than 5 cm in size were observed with serial monthly ultrasonography. Larger cysts, if found feasible were drained with a pigtail catheter under ultrasonographic control. The amount of the daily output of the pancreatic fluid and the amylase content was monitored. Cystogastrostomy was performed for the infected cysts or the cysts that fail to resolve even with after 3 months. The cyst fluid drained into the stomach and the cyst disappeared completely in a few months. Authors’ have no experience with the endoscopic management of the pseudocyst of the pancreas.

**REFERENCES**

Pancreatitis is encountered far less commonly in children when compared to its frequent presentation in adult clinical practice. A major reason is that some of the principal causative or predisposing factors–alcohol, gallstone disease, drug abuse, multisystem disorders–are fortunately less prevalent in childhood; idiopathic, traumatic, hereditary and congenital causes are more common. Pancreatitis in childhood usually runs an acute self-limiting course and is often less severe than in adults, but it can be associated with a considerable long-term morbidity and a significant mortality. A high index of suspicion and a special interest is necessary to make the diagnosis in a child with unexplained or recurrent abdominal pain.1

INCIDENCE

The incidence of pancreatitis in childhood is difficult to establish with accuracy. Reports vary partly due to different policies regarding the inclusion of adolescent and young adult patients in series. An estimate of 1:50,000 for the incidence of pancreatitis has been made but variations occur between different populations, particularly in relation to the prevalence of sickle cell disease and gallstones.2,3 Major pediatric centers often see only a handful of cases each year. The sex ratio is equal. A carefully analysed study of all ages in the Netherlands suggests a gradually increasing incidence but a reducing mortality over the decade 1985-1995.4

ETIOPATHOGENESIS

Clinically, pancreatitis can be classified as acute, chronic or relapsing. Acute pancreatitis presents a spectrum from a relatively mild inflammatory disorder to severe hemorrhagic destruction of the gland itself.5-7 The precise mechanisms of initiation of pancreatitis are poorly understood though factors such as obstruction, toxins and ischemia are implicated. Injury to acinar cells disturbs the formation and transport of zymogen granules and leads to the activation of precursor digestive enzymes (e.g. trypsinogen to trypsin).8 In turn, this activates other enzymes such as kallikrein, elastase and phospholipase 2. This precipitates a cascade of events progressing to autodigestion and necrosis of pancreatic tissue. Macroscopically, mild disease consists of interstitial edema whilst severe disease produces extensive peripancreatic fat necrosis and outpouring of hemorrhagic fluid into the peritoneal cavity. A massive coagulation necrosis of both pancreatic and peripancreatic tissue may result–necrotising pancreatitis.

Recent work has centered on the possibility of pancreatitis being related to ischemia–reperfusion injury and the role of inflammatory mediators such as arachidonic acid, interleukin 6, tumor necrosis factor alpha and platelet activating factor is being explored.8,9 Cytokine activation and the generation of toxic oxygen free radicals during reperfusion is considered a potent source of damage to cell membranes and tissues.8 Secondary gram-negative bacterial infection of the necrotic pancreas is relatively common (40-60%) and an abscess may form.10

The systemic effects of acute pancreatitis include vasodilatation, capillary permeability, coagulopathy, respiratory distress, renal insufficiency, CNS effects, hypocalcemia and shock. In turn, multi-system organ failure may supervene.
Chronic pancreatitis may follow a recurrent or relapsing course and is often based on an identifiable underlying cause (systemic infection, hereditary pancreatitis, cystic fibrosis, hyperlipoproteinemia, inborn errors of metabolism, inflammatory bowel disease) or is secondary to a definable anatomical abnormality (pancreas divisum, annular pancreas). Similar mechanisms to those in play in the pathogenesis of acute pancreatitis (viz. cytokine release and free radical generation) are responsible for cellular damage in chronic pancreatitis. The process may be focal, segmental or diffuse and can progress to lobular fibrosis of acini, duct dilatation and lesions of the duct epithelium. Precipitation of protein in pancreatic ducts is related to lithostathine (pancreatic-stone protein) secretion and leads to plugging. Subsequently, calcification and stone formation occur. Eventually some degree of irreversible exocrine and endocrine pancreatic dysfunction develops.

The causes of pancreatitis can be classified under broad categories as: idiopathic, hereditary, traumatic, drug-related, secondary to bilio-pancreatic tract anomaly, infection, multisystem disorder or metabolic disorder. Whether an acute or chronic illness develops depends to some extent on the eradication or persistence of the underlying cause.

**Idiopathic:** Between 10 and 30% of cases of pancreatitis are of unknown cause. Some of these patients will subsequently develop recurrent pancreatitis and have an underlying anatomic abnormality identified by endoscopic retrograde cholangiopancreatography or by magnetic resonance cholangiopancreatography. Variations on the “standard” anatomy of the common bile duct and the ducts of Wirsung and Santorini (accessory pancreatic ducts) are not unusual. A long common channel, ectopic sphincter of Oddi, annular pancreas, pancreas divisum and duplications of pancreas and stomach may be found. These may be associated with duct stenosis, stricture, dilatation and both intrinsic and extrinsic obstruction. Whether these are the cause or the result of pancreatitis is not always clear.

Infective causes of pancreatitis include a wide variety of viruses; mumps, Coxsackie, Epstein-Barr, influenza A, hepatitis A and B, measles, Guillain-Barre, enterovirus and rubella. Pancreatitis has a complex relationship with HIV infection involving immunocompromise, opportunistic infection and the drug treatment itself and may follow a severe and prolonged course. Syphilis and toxoplasmosis have also been implicated. Secondary bacterial infection is recognised as a potentially lethal complication of acute necrotising enterocolitis. Venoms from bites by snakes, scorpions and spiders and parasitic infections (e.g. ascariasis) are risks in many parts of the world.

Metabolic problems arise in hyperlipidemia, hyperparathyroidism, alpha-1-antitrypsin deficiency, cystic fibrosis, glucose-6-phosphate dehydrogenase deficiency, diabetes, aminoaciduria (lysine, cystine, arginine), malnutrition and spherocytosis. Such problems usually give rise to a chronic relapsing pattern of pancreatitis that may lead eventually to fibrosis and calcification and, in the long-term, to pancreatic insufficiency. Gallstone disease, giving rise to pancreatic duct obstruction, may complicate the metabolic abnormality. Malnutrition, associated with alcohol or narcotic drug abuse, leads to severe pancreatic damage. Malnutrition has been associated with but not proven as the cause of tropical pancreatitis – a form of chronic pancreatitis in young non-alcoholic adults found in South India, Africa and other tropical areas.

Multisystem disorders such as hemolytic uremic syndrome, systemic lupus erythematosus, polyarteritis nodosa and Reye’s syndrome may be complicated by severe acute pancreatitis. Although in general there is no clear correlation between the cause of pancreatitis and the pathological findings, mortality is higher in the context of multisystem disorders.

PRESENTATION

Pain is the pre-eminent presenting feature in up to 95% of cases, though the characteristics vary. It is most often a continuous epigastric pain (30%), but it may be focused in the right upper quadrant or umbilical areas, or may be diffuse; radiation to the back is a feature. The intense boring nature of the pain may be severe enough to induce anxiety and psychological disturbance. Severity of pain also causes the child to lie still with knees flexed. The pain may be exacerbated by eating. The pain needs to be differentiated from other causes of abdominal pain (Table 92.2).

Nausea and anorexia are common and vomiting occurs in approximately 60%; when bilious, it may be related to paralytic ileus. Fever is low grade (37.5-38.5 °C) initially. Jaundice occurs particularly in chronic relapsing cases in which a fibrosing pancreatitis progresses to common bile duct obstruction. In recurrent chronic pancreatitis, weight loss and diarrhea develop. Additional pointers to the diagnosis of pancreatitis are a previous history of similar pain, a family history of pancreatitis, associated biliary disease or parotid or testicular enlargement suggesting mumps.

The initial clinical finding is localised epigastric tenderness with rebound tenderness progressing to guarding and rigidity in more severe cases. Abdominal distension may be related to ileus or ascites in 10-20%. Pleural effusions, usually left sided, occur in up to 40%. These add to the respiratory problems caused by the tendency to hypoventilation.

In the most severe hemorrhagic pancreatitis, in which massive outpouring of fluid occurs, hemorrhage and hypotension may supervene. Metabolic disturbances follow rapidly due to fluid and electrolyte imbalance, hypocalcemia and hyperglycemia. Tetany occasionally occurs. Retroperitoneal hemorrhage may become manifest as bruising in the flanks (Grey-Turner’s sign) or around the umbilicus (Cullen’s sign). Severity of pancreatitis can be assessed using a variety of clinical scoring systems and criteria.

Table 92.2: Conditions presenting with abdominal pain and raised amylase

- Acute appendicitis
- Perforated duodenal ulcer
- Bowel infarction
- Salivary gland inflammation
- Biliary tract disorders
- Hepatitis
- Renal failure
- Tumors
- Intestinal obstruction
- Peritonitis
- Diabetic ketoacidosis
- Basal pneumonia
INVESTIGATION AND DIAGNOSIS

The diagnosis of pancreatitis is usually based on a suggestive or typical clinical picture supported by biochemical and radiological investigations. The presence of an inflammatory disorder is suspected by the raised white cell count, raised C-reactive protein, raised erythrocyte sedimentation rate and fall in hematocrit. Hypocalcemia, hyperglycemia and raised bilirubin and liver enzymes are all suggestive of pancreatitis and biliary tract obstruction/inflammation.

Biochemical Investigations

Raised amylase though often a mainstay of diagnosis of pancreatitis, is not pathognomonic: However, the test is rapid. It is elevated in a variety of other disorders presenting with abdominal pain that may potentially cause diagnostic confusion (Table 92.3). Only approximately 40% of serum-amylase (P-isoamylase) is derived from the pancreas and 60% (S-isoamylase) is salivary. Normal serum levels in childhood are in the range 48+/– 29 mg/dl (Somogyi units) with elevation to three times normal in most cases of pancreatitis and occasionally up to 1000 mg/dl. However, serum amylase may be normal in up to 10% of cases. Sensitivity is therefore about 95% but specificity is only 86%. The level of serum amylase is not a predictor of severity of disease.

Amylase is a small molecule and is rapidly cleared in pancreatitis due to decreased renal tubular absorption. Urinary amylase is therefore a more specific indicator of pancreatitis. Renal clearance of amylase is related to renal clearance of creatinine to give a ratio with an upper limit of normal of 4%, and a ratio greater than 5% is strongly suggestive of pancreatitis.

Other pancreatic enzymes, such as lipase, elastase and immunoreactive cationic trypsin, also show elevated serum levels. Lipase is more specific (up to 99%) for pancreatitis and, although measurement takes longer, it also clears more slowly from the bloodstream. The diagnosis of chronic pancreatitis may be made in the quiescent phase using a morphine-prostaglandine stimulation test to evoke symptoms of pancreatitis and measure elevation of serum enzymes.

More detailed tests of pancreatic function involve collection and analysis of duodenal juice after stimulation, measurement of chymotrypsin in stool and measurement of products of pancreatic digestion which are absorbed and excreted in urine. Such tests are, of necessity, complex and time consuming and of limited application in pediatrics.

C-reactive protein rises rapidly and in proportion to the severity of disease.

Radiological Investigations

The relative roles and value of different radiological modalities in the diagnosis of pancreatitis have been assessed in detail. Available techniques include plain radiography, upper small bowel contrast, ultrasound (US), contrast-enhanced computed tomography (CT), magnetic resonance imaging (MRI), endoscopic retrograde cholangiopancreatography (ERCP), transhepatic cholangiography and angiography. Which is most appropriate depends on local circumstances and expertise but, overall, contrast-enhanced CT scanning, ERCP and magnetic resonance cholangiopancreatography (MRCP) probably have most to offer.

Plain radiographs may show ileus, sentinel loop (Fig. 92.1), mass, colon cut-off, calcification and abscess (air-fluid level). Up to 55% of plain radiographs may be abnormal, and therefore suggest a significant intraperitoneal problem, though many signs are nonspecific. Chest radiograph may show a left-sided pleural effusion or elevation of the left hemidiaphragm due to fluid collection.

Upper small bowel contrast may show displacement, expansion (Fig. 92.2), distortion or obstruction of the duodenal loop.

Ultrasound has the great advantage of being rapid, non-invasive, readily repeated and available at the bedside. However, interpretation can be difficult due to the concealed retroperitoneal position of the gland and distension of overlying bowel and a high level of expertise is needed. The size and shape of the pancreas can be defined (Fig. 92.3) and features such as edema, calcification, duct dilatation and pseudocyst formation (Fig. 92.4) can be recognised.\(^3\,^6\,^{15}\) Doppler ultrasound gives additional information by delineating vascular flow (Fig. 92.5). Endoscopic ultrasound gives greater definition and may detect pathology (e.g. stones) not seen with transabdominal ultrasound.\(^4\,\!^1\) Peroperative ultrasound may assist in definition and location of cysts in both closed and open drainage procedures. Fine needle aspiration of the pancreas under ultrasound control is helpful in determining the presence of infection and indicating the need for surgical drainage.\(^4\,\!^2\)

CT scanning (contrast-enhanced) (Fig. 92.6) is the method of choice in diagnosis of acute or chronic pancreatic changes, viz. pancreatic necrosis, infected necrosis, acute fluid collection, pseudocyst formation (Fig. 92.7), abscess and hemorrhage.\(^1\,\!^0\,\!^9\,\!^4\,\!^3\) The clear anatomical detail shown on CT scan is especially helpful in identification of the safest and most effective route for percutaneous drainage of fluid collections.\(^3\,\!^9\,\!^4\,\!^4\)

ERCP offers fine detail of duct and gland anatomy that is important if operative resection or drainage procedures are planned.\(^3\,\!^3\,\!^3\) Larger series in childhood report over 90% technical success.\(^2\,\!^5\,\!^2\,\!^7\,\!^2\,\!^8\,\!^4\,\!^5\,\!^4\,\!^8\) Morbidity related to flare-up of pancreatitis is commoner than in adults though it usually resolves rapidly: Bleeding occasionally occurs. The indications for ERCP are acute non-resolving recurrent or chronic pancreatitis and abnormal findings are noted in about 50% of all examinations.\(^2\,\!^1\,\!^2\,\!^2\,\!^1\,\!^2\,\!^5\,\!^4\,\!^0\) The abnormalities include:
Anomalous union of the pancreas and biliary ducts, pancreas divisum, stone in the duct, stricture, sclerosis and deformity of the duct, duct dilatation and choledochal cyst. At ERCP, the resting pressure at the sphincter of Oddi can be measured and procedures such as dilatation of narrowed ducts, removal of stone, insertion of stents and sphincterotomy can be performed safely. However, the expertise to perform ERCP in children is not readily available in all centers and may lead to consideration of earlier surgical intervention.

Magnetic resonance cholangiopancreatography (MRCP) (Fig. 92.8) has the advantages of being fast, non-invasive and reproducible. It allows visualization of biliary and pancreatic ductal anatomy and will detect stones, strictures, intraductal tumors and duct compression. Secretin may improve visualization and false negative results are rare.

MEDICAL MANAGEMENT
The medical management of acute or chronic pancreatitis has three main elements:
- Resuscitation and supportive treatment
- Elimination of the underlying cause of the pancreatitis
Specific therapy directed against the pancreatitis process.

The principal objectives of treatment in clinical terms are to relieve pain, minimise shock, limit electrolyte disturbance and reduce pancreatic exocrine excretion. The speed of onset of symptoms and signs of pancreatitis and the potential for rapid clinical deterioration call for sure judgement and decisive action. The use of guidelines and treatment protocols may facilitate this.

**RESUSCITATION AND SUPPORTIVE TREATMENT**

The immediate assessment of the requirement for resuscitation is based on measurements of full blood count and hematocrit, arterial partial pressure of oxygen, urea and electrolytes (including calcium and glucose) and monitoring of pulse, blood pressure, respiratory rate and temperature. Intravascular monitoring of arterial pressure, central venous pressure and pulmonary artery wedge pressure may be needed to keep track of fluid replacement when massive losses are occurring into the third space (retroperitoneal tissues and peritoneal cavity). Adequate and timely intravenous rehydration is essential to avoid prerenal failure. Crystalloid or colloid solutions can be used; blood transfusion may be needed particularly in the case of hemorrhagic necrosis of the pancreas. Calcium gluconate should be given in the presence of hypocalcemia or tetany and soluble insulin is administered on a sliding scale to control hyperglycemia. Pain relief requires narcotic analgesia. Pethidine, which can be potentiated by the addition of promethazine, is less likely than morphine to cause spasm of the sphincter of Oddi.

**Elimination of the Underlying Cause**

When pancreatitis is drug-related any further administration should obviously be stopped whenever possible. Alcohol is occasionally a factor in pancreatitis in childhood and should be strictly avoided. Relief of pancreatic duct obstruction, (e.g. by removal of impacted gallstone), is important in reversing the inflammatory process.

**Specific Therapy Directed Against the Pancreatitis Process**

The aim of therapy against the process of pancreatitis is to reduce stimulation of the gland to a minimum and to neutralise or inactivate the various exocrine gland secretions and inflammatory agents.

Insertion of a nasogastric tube and aspiration of gastric contents serves both to prevent risks of vomiting and inhalation in the presence of ileus and also to remove the stimulus of food and gastric secretions. Insertion of a long feeding tube beyond the ligament of Treitz allows continued enteral nutrition. Complete fasting and total parenteral nutrition are sometimes necessary in an acute episode but low fat dietary intake may be helpful in reducing pain and risk of relapse in chronic pancreatitis. Medium chain triglycerides (MCT) are absorbed in the absence of pancreatic enzymes or bile salts.

Pancreatic “rest” and the consequent possibility of reduction of pain and complications of pancreatitis, may also theoretically be promoted by anticholinergics, H2-receptor antagonists, exogenous enzyme administration, enzyme inhibitors, cholecystokinin-receptor antagonists, glucagon, somatostatin analogues and the protease inhibitor gabexate. However, evidence of consistent clinical effectiveness is at present sparse.

Similarly, the role of prophylactic antibiotics remains inconclusive except in severe necrotising pancreatitis when they are of proven benefit in
reducing bacterial translocation to necrotic tissue.\textsuperscript{55} In the presence of bacterial superinfection or acute septic necrosis, antibiotics such as imipenem or cefuroxime with good penetration into pancreatic tissue produce therapeutic benefit.\textsuperscript{10} Recognition of the role of free radicals in the inflammatory process has led to trials of the use of antioxidants such as N-acetylcysteine, vitamin C and sodium selenite but proof of effectiveness is awaited.\textsuperscript{8} Antagonists of platelet activating factor (lexipafant) may also have a role.

**SURGICAL MANAGEMENT**

Surgery in pancreatitis is usually reserved for the problems caused by the complicated, relapsing and chronic cases. Inevitably however, pancreatitis will be first diagnosed in some cases at laparotomy when acute abdominal signs have led to emergency surgery. In this circumstance debridement and drainage of necrotic pancreatic tissue is the best option.\textsuperscript{38} If possible, the biliary tree should also be examined to exclude gallstones. Subsequent surgery to deal with abscess formation or encysted fluid collections and definitive surgery for pancreatic or biliary duct abnormalities may be needed. Biliary tract disorders associated with pancreatitis may require cholecystectomy or bile duct drainage using a Roux-en-Y loop of jejunum (bilio-enteric bypass).

The indications for surgery in relapsing and chronic pancreatitis include: failure to respond to medical treatment, frequent relapse, disabling pain, the need to limit further pancreatic damage, pseudocyst formation, duct dilatation, strictures and stones.\textsuperscript{12} When severe acute pancreatitis progresses to necrosis and infection, necrosectomy is necessary but carries a high mortality.\textsuperscript{56} If infection can be excluded, a conservative non-surgical approach is advocated.\textsuperscript{42} Fine-needle aspiration guided by US or CT is a valuable and accurate technique in resolving the question of an infected necrosis.\textsuperscript{57} Up to 60\% of patients may benefit from surgical intervention at some stage in the course of pancreatic disease—particularly when trauma, biliary tract disease or congenital abnormalities are the cause.\textsuperscript{3} Relief of pain and reduced hospitalization are the principal benefits whilst improvement in exocrine and endocrine function is minimal. Pseudocysts can be drained percutaneously by catheter insertion under CT or US guidance but there is a risk of pancreatic fistula formation.\textsuperscript{58} If the cyst is managed conservatively until a surrounding capsule has formed, internal drainage by cyst-jejunostomy or cyst-gastrostomy should be curative.

Information from ERCP and MRCP, from transduodenal retrograde cholangiopancreatography or from operative cholangiography allows the choice of the most appropriate procedure in view of the duct anatomy and the presence of stone, stenosis, obstruction or dilatation.\textsuperscript{10,21} ERCP therapeutic procedures give direct benefit in terms of pain relief and well-being but long-term follow-up studies are needed to assess the full impact.\textsuperscript{46-51}

Operative options consist of sphincteroplasty (endoscopic or open), stent placement to improve drainage and direct pancreatic drainage via an enteric fistula. Distal pancreatectomy and Roux-en-Y pancreaticojejunostomy (Duval procedure) has been shown to be more effective than longitudinal pancreaticojejunostomy (Puestow procedure) in most childhood pancreatitis and is more effective than sphincteroplasty in severe disease.\textsuperscript{54,59} In hereditary pancreatitis, however, both longitudinal pancreatico-jejunostomy and stenting have proved effective.\textsuperscript{60,61} Pancreatic resection, either partial or sub-total, may be necessary in the most severe cases to achieve relief of symptoms. Total pancreatectomy and pancreatocoduodenectomy (Whipple procedure) are not normally considered in childhood. Major pancreatic surgery now carries minimal mortality and complication rates of about 20\%.\textsuperscript{38,62} The most significant complications are pancreatic fistula, intra-abdominal and wound infection and pneumonia.

**COMPLICATIONS**

Complications following pancreatitis arise both from the inflammatory process itself and also from damage to the function of the pancreas. Problems can occur acutely or in the long-term.

**Complications due to the Inflammatory Process**

Systemic effects of acute pancreatitis may be shock, sepsis, respiratory distress syndrome, acute renal failure due to tubular necrosis and coagulopathy.\textsuperscript{6} Hypocalcemia and hyperglycemia, complicate electrolyte and fluid imbalance. The multisystem organ failure that may supervene can be fatal.
Outpouring of pancreatic secretions and fluid from the inflamed gland causes ascites and loculation of the fluid leads to pseudocyst or abscess formation. Portal vein thrombosis may result from the intense inflammatory reaction and cavernous transformation of the vein and portal hypertension may be long-term sequelae. Pancreatic fistulae can be internal or external and may form spontaneously or follow external drainage procedures. Upper gastrointestinal bleeding occurs from diffuse ulceration, duodenal stress ulceration, portal vein obstruction or erosion of the neovascular tissue of the inflammatory mass. Subphrenic inflammation may cause pleural effusion, usually on the left side.

Complications due to Pancreatic Damage

Both exocrine and endocrine functions of the pancreas are affected by pancreatitis. Insufficiency of exocrine secretion leads to malabsorption and steatorrhea in 5–19% of chronic pancreatitis and after extensive resection in which more than 90% of the gland is removed. Pancreatic endocrine failure leads to diabetes mellitus in 3–12% of cases. Although there is a potential risk of carcinoma developing in chronic pancreatitis, which is assessed in about 4% after 20 years disease, there are no reported cases of carcinoma in larger pediatric series of chronic pancreatitis. However, in hereditary pancreatitis, carcinoma has been reported in older family members. Patients with tropical pancreatitis are at increased risk of carcinoma and this occurs at a younger age.

PROGNOSIS

The prediction of outcome from acute pancreatitis has been assessed in detail using various criteria related to the acute episode. The criteria are shown in Table 92.3. Measurement of various markers of oxidative stress have also been correlated with the criteria in an attempt to improve predictive value of severity but do not offer any added value.

The application of such methods to children have some value, as does assessment using the Acute Physiology and Chronic Health Evaluation (APACHE) II system. However, accurate prediction of outcome in childhood acute pancreatitis is certainly not possible. Mortality in the acute episode has been reported to be as high as 15–25% with up to 86% in severe hemorrhagic pancreatitis. Necrosis and infection are bad prognostic indicators. Recurrence of acute pancreatitis is more likely when the initial episode is of unknown etiology or when the problem is structural or metabolic. The underlying cause persists in these situations.

Chronic pancreatitis may be a less severe disease when onset is in early life rather than later and mortality is low. In some cases, disease progression is self-limiting with eventual burn-out.

REFERENCES

Portal hypertension may be defined as a portal pressure gradient of 12 mm Hg or greater. Portal hypertension is less common in children as compared to adults. The significant clinical manifestations are esophageal variceal hemorrhage, ascites and hypersplenism. Portal hypertension in children is commonly due to extrahepatic obstruction from portal vein thrombosis.

**PATHOPHYSIOLOGY**

Portal hypertension is characterized by a pathologic increase in portal venous pressure that leads to the formation of an extensive network of portosystemic collaterals that divert a large fraction of portal blood to the systemic circulation, bypassing the liver. An increased vascular resistance to portal blood flow is the initial factor responsible for the increase in portal pressure. This resistance is exerted along the hepatic and portal-collateral circulation. At a later stage, an increased portal venous blood inflow, promoted by splanchnic vasodilation, contributes to maintenance and aggravation of portal hypertension. Humoral vasodilatory agents play an important role in the splanchnic vasodilation. Several vasodilators are likely to be involved, including glucagon, prostacyclin, endotoxins, and nitric oxide. The splanchnic vasodilation is associated with a hyperkinetic systemic circulation, with reduced arterial pressure and peripheral resistance and increased cardiac output. The splanchnic circulation is probably the vascular territory in which the vasodilation is more pronounced. Therefore, splanchnic and systemic vasodilation probably share some pathophysiologic events. An expanded plasma volume is observed in all forms of portal hypertension. Expansion of plasma volume is due to renal sodium retention, which has been shown to precede the increase in cardiac output and can be prevented or reversed by sodium restriction and spironolactone. The expanded blood volume represents another mechanism that contributes to further increases in portal pressure.

Management of a child with portal hypertension is largely determined by the cause of obstruction to portal venous flow. The cause may be prehepatic, hepatic presinusoidal or hepatic postsinusoidal. Less common is suprahepatic obstruction, i.e. Budd-Chiari syndrome. Management is related to the underlying cause of the portal hypertension. In children with intrahepatic disease, management is usually temporary, stabilizing measures until liver transplantation can be performed. Over the years, sclerotherapy has increasingly replaced shunt procedures. Extrahepatic obstruction in children has been treated successfully by both endoscopic techniques and shunts. Although used sparingly, sometimes, approaches directed at interruption of the varices, such as esophageal transection or Suguira's procedure are the only choice.

**INVESTIGATIONS**

Patients undergoing portosystemic shunt procedures should be stable and not actively bleeding. The source of hemorrhage can be documented endoscopically. In addition to a complete blood count, liver function tests and coagulation studies, the patient should undergo radiological studies. Barium swallow and endoscopy, both can be used to grade the varcies. CT portovenography and MRI are being increasingly used nowadays.
Laboratory Studies

Lab studies are carried out when portal hypertension is due to cirrhosis. The general aim being investigating the etiologies of cirrhosis. These studies consist of: Liver function tests, prothrombin time, albumin, viral hepatitis serologies, platelet count, antinuclear antibody, antimitochondrial antibody, antismooth muscle antibody, Iron indices, Alpha1-antitrypsin deficiency, Ceruloplasmin, 24-hour urinary copper - in children who have unexplained hepatic, neurologic, or psychiatric disease.

Imaging Studies

**Duplex-Doppler Ultrasonography**

Ultrasound (US) is a safe, economical and effective method for screening for portal hypertension. It also can demonstrate portal flow and helps in diagnosing cavernous transformation of the portal vein, portal vein thrombosis, or splenic vein thrombosis.

Features suggestive of hepatic cirrhosis with portal hypertension include, nodular liver surface. However, this finding is not specific for cirrhosis and can be observed with congenital hepatic fibrosis and nodular regenerative hyperplasia. Splenomegaly is a suggestive finding. Patients may demonstrate the presence of collateral circulation.

Limitations of US include—Reproducibility of data as well as variables, such as circadian rhythm, meals, medications, and the sympathetic nervous system which affect portal hemodynamics.

**CT Scan**

CT scan is a useful qualitative study in cases where sonographic evaluations are inconclusive. It is not affected by patients' body habitus or the presence of bowel gas.

With improvement of spiral CT scan and 3-dimensional angiographic reconstructive techniques, portal vasculature may be visualized more accurately. Findings suggestive of portal hypertension include: Collaterals arising from the portal system and dilatation of the IVC are also suggestive of portal hypertension.

Limitations of CT scan are inability to demonstrate the venous and arterial flow profile. Also, intravenous contrast agents cannot be used in patients with renal failure or contrast allergy.

**Magnetic Resonance Imaging (MRI)**

MRI provides qualitative information similar to CT scan when Doppler findings are inconclusive. It detects the presence of portosystemic collaterals and obstruction of portal vasculature. MRI also provides quantitative data on portal venous and azygos blood flow.

**MANAGEMENT OF ACUTE VARICEAL BLEEDING**

A rapid and detailed assessment is done for the extent of blood loss already taken place and the rate of current loss. Patient's vitals are recorded, venous access is gained and blood samples are taken for hematocrit, platelet count and prothrombin time, liver function tests and electrolytes. A sample is send for cross matching. Urinary bladder is catheterized.

Blood volume is restored by blood, crystalloid and colloid transfusion.

A nasogastric tube is inserted to assess the severity of bleeding and gastric lavage.

**Pharmacologic Treatment**

The aim of the pharmacotherapeutic approach is to decrease the portal venous pressure gradient below 12 or even 10 mm Hg. Reduction of this gradient will significantly reduce the risk of re-bleeding. Pharmacological approach following acute bleeding include vasopressin, somatostatin or octreotide. Vasopressin is no more used in view of its marked peripheral vasoconstrictive effect, and is now replaced by somatostatin or octreotide. Acute variceal bleeding originating from gastric varices can be effectively controlled by endoscopic injection of tissue adhesive agent (n-butyl 2 cyanoacrylate).

Endoscopic therapy has largely replaced balloon tamponade.

**Endoscopic Sclerotherapy**

Endoscopic sclerotherapy is successful in controlling acute esophageal variceal bleeding in majority of patients. Control should be obtained with 1-2 sessions. Patients continuing to bleed after 2 sessions should be considered for alternative methods to control their
bleeding. Sodium tetradecyl sulphate and ethanola mine are commonly used as a sclerosants.

Serious complications related to sclerotherapy have been reported in 15-20% of patients, with an associated mortality rate of 2%. Complications of sclerotherapy may include mucosal ulceration, bleeding, esophageal perforation, mediastinitis, and pulmonary complications. Long-term complications, such as esophageal stricture formation, also may occur.

**Endoscopic Variceal Ligation (Banding)**

Endoscopic variceal ligation is based on the widely used technique of rubber-band ligation of hemorrhoids. The esophageal mucosa and the submucosa containing varices are ensnared, causing subsequent strangulation, sloughing, and eventual fibrosis, resulting in obliteration of the varices. Rebleeding occurs less frequently with endoscopic variceal ligation than with endoscopic sclerotherapy (26% vs 45%). Recent trials have demonstrated that ligation and sclerotherapy achieved similar rates of initial hemostasis in patients whose varices were actively bleeding at the time of treatment. Local complications are less common with ligation compared to sclerotherapy.

Transjugular intrahepatic portosystemic shunting (TIPS) is a viable option and is less invasive for those whose bleeding is not controlled. However, if TIPS is not available, then staple transection of the esophagus is an option when endoscopic treatment and pharmacological therapy have failed. TIPS is a useful procedure for continued bleeding despite medical and endoscopic treatment. It is effective only in portal hypertension of hepatic origin.

For prevention of rebleeding when pharmacological therapy and/or endoscopic therapy have failed, surgery is considered.

**SHUNT AND NON-SHUNT OPTIONS**

Decisions regarding the advisability of porto-systemic shunts as opposed to nonshunt options are often difficult. Important factors include the clinical status of the patient, the cause of portal hypertension and the expertise of the treating unit. It is often difficult to predict at the outset regarding outcome of the therapeutic procedures: re-bleeding, hepatic decompensation or encephalopathy.

**Shunt Therapy for Extrahepatic Portal Obstruction**

The goal of any portosystemic shunt is effective decompression of the gastroesophageal veins. There are two distinct types of portosystemic shunts: those that are associated with total diversion of portal blood away from the liver (total shunts) and those that maintain portal blood supply to the liver (selective shunts). Examples of total shunts include portacaval, mesocaval and central splenorenal shunts.

Portosystemic shunts provide a means of decompressing the high-pressure portal system and thus esophageal varices. Although these procedures provide effective decompression and reduce the incidence of variceal bleeding there is a risk of long-term complications. These are: hepatic encephalopathy, accelerated hepatic deterioration and may make future hepatic transplant difficult.

Presently excellent results with portal decompression by shunt procedures in infants and children have been achieved in many centres and age and size are no more the limiting factors.

**Non-shunt Therapy**

Non-shunt therapies have limited application in children. Transthoracic ligation of varices or direct ligation by an abdominal approach are temporizing procedures.

**Devacularization Procedures**

Sugiura and Futagawa advocated extensive esophagogastric devascularization combined with esophageal transection and re-anastomosis.

**Sugiura's Procedure**

This procedure consists of lower esophageal transection and anastomosis, devascularization of the lower esophagus and stomach and splenectomy. It was devised to avoid many of the complications of portosystemic shunts. However, experience in children is limited. This procedure remains an option for controlling esophageal varices due to intrahepatic or extrahepatic portal hypertension when endoscopic methods fail and portosystemic shunts are not possible (Fig. 93.1).
DISTAL SPLENORENAL SHUNT (DSRS)$^5$

Selective Shunting

The concept of selective shunting was first introduced by Warren and his associates in 1967. These authors emphasized the increased morbidity and mortality associated with liver failure and hepatic encephalopathy following total shunting procedures. They attributed these problems to loss of liver portal perfusion. Their goal for the ideal operation for the treatment of patients with variceal bleeding was to achieve effective variceal decompression while preserving portal blood flow to the liver. Since the splenorenal anastomosis is not in direct communication with the superior mesenteric or portal veins, the pressure in these vessels remains elevated. Such pressure elevation is crucial in maintaining portal blood flow to the liver. For its success a complete splenopancreatic disconnection is essential which includes interruption of the coronary gastroepiploic and inferior mesenteric veins. The operation they devised to achieve these objective was the DSRS.

DSRS is created by anastomosing the medial end of the divided splenic vein to the side of left renal vein. The portal end of the splenic vein is oversewn. A functioning DSRS achieves variceal decompression by establishing a route for gastric venous drainage that offers less vascular resistance than the anastomotic channels between the gastric and esophageal veins. This route finally leads to the left renal vein (Figs 93.2A and B). Reversal of hypersplenism has been demonstrated by DSRS.

Central Splenorenal Shunt$^6$

In a central splenorenal shunt, the principal direction of portal flow is to the systemic circulation. Reversal of blood flow from the portal to systemic circulation

Fig. 93.1: Siguira’s procedure

Fig. 93.2A: Distal splenorenal shunt (Warren)

Fig. 93.2B: Operative photograph of distal splenorenal shunt: End of the splenic vein to be anastomosed to the left renal vein
with hepatic deprivation is a hazard most serious with this option. In this procedure the spleen is removed and the central end of the splenic vein is anastomosed to the side of the left renal vein (Fig. 93.3).

**Mesocaval Shunt**

In this shunt anastomosis or graft anastomosis of the side of the superior mesenteric vein to the proximal end of the divided inferior vena cava is performed as a means of controlling portal hypertension. The inferior vena cava is exposed by mobilizing the right mesocolon. The duodenum is reflected by a Kocher maneuver. After exposure the inferior vena cava is mobilized from the renal veins to below the caval bifurcation. Individual ligation of several lumbar veins is often required. A tunnel is made in the retroperitoneum and posterior mesentery, often thick and edematous, to reach the superior mesenteric vein (Fig. 93.4).

**Side-to-side Shunt**

Mitra et al have reported an extensive experience with side-to-side splenorenal shunt without splenectomy in children with noncirrhotic portal hypertension with 87% patency. The technique involves extensive mobilization of splenic vein while maintaining its medial (portal) and lateral (splenic) attachments. Reversal of blood flow from the portal to systemic circulation, which allows the vein to act as an outflow tract, remains a potential consequence (Fig. 93.5).

**Mesoatrial Shunt**

In patients with the Budd-Chiari syndrome in whom occlusion or compression of the inferior vena cava precludes the use of standard portacaval shunts for portal venous decompression, construction of a mesoatrial shunt may be the treatment of choice. This shunt is a Dacron or Goretx graft that is interposed between the superior mesenteric vein and the right atrium. The occlusion rate of these shunts is high because of their long length and slow flow rates (Fig. 93.6).
Portocaval H-Graft Shunt

Small diameter H graft portacaval shunts (HGPCSs) effectively treat bleeding varices due to cirrhosis, although the effects of such shunts on hepatic blood flow are not well established. Proponents of HGPCS believe that portal flow diverted through the shunt is regained through increased hepatic arterial inflow while others argue that this flow is never recovered; resulting in compromised nutrient flow (Fig. 93.7).

Transjugular Intrahepatic Portosystemic Shunting (TIPS)

This procedure provides the same shunting benefits as the major shunt procedures. It is carried out by an interventional radiologist. TIPS eliminates the disadvantage of altering the extrahepatic venous anatomy. By this technique, an intrahepatic communication is established between the hepatic venous outflow and the portal venous inflow. The portosystemic communication is accomplished under fluoroscopic guidance. It is dilated and the intrahepatic tract secured by insertion of an expandable stent. These procedures are routinely successful in decreasing the portal pressure and eliminating the dangerous gradient between the portal and systemic venous systems. Ascites is regularly resolved with TIPS.

The TIPS procedure has been proven effective for controlling bleeding esophageal and gastric varices even when other measures have failed. Accepted indications for TIPS include acute variceal bleeding or recurrent bleeding refractory to pharmacological measures for which sclerotherapy has failed. Contraindications to TIPS include right-sided heart failure (elevated central venous pressure) and severe hepatic failure.

Meso-Rex Bypass

The recent introduction of the meso-Rex bypass raises a possible paradigm shift in the therapeutic approach to extrahepatic portal vein obstruction (EHPVO). Long-term follow-up of patients with EHPVO has revealed a variety of complications including variceal hemorrhage, hypersplenism, biliopathy, growth/development retardation and neuropsychiatric disease. The meso-Rex bypass restores physiologic blood flow to the liver. Thus, when feasible, the meso Rex bypass should be considered in patients with clinically significant manifestations of EHPVO.

REFERENCES

Persistent hyperinsulinemic hypoglycemia of infancy (PHHI) is a challenging disease both to establish the diagnosis well in time and also to treat as PHHI can lead to brain damage or death secondary to severe hypoglycemia.

**TERMINOLOGY**

The term persistent hyperinsulinemic hypoglycemia of infancy (PHHI) is synonymous with nesidioblastosis, congenital hyperinsulinism, nesidiodyplasia and islet cell dysmaturation syndrome.

The term 'nesidioblastosis', derived from the Greek words nesidion, for islet, and blastos, for germ, was originally conceived by Laidlaw in 1938.1 Severe infantile hypoglycemia was first associated with nesidioblastosis in 1970.2

This term has now been replaced by persistent hyperinsulinemic hypoglycemia of infancy (PHHI), to describe the neoformation or neodifferentiation of islets of Langerhan's from pancreatic ductal epithelium.3,4 Hyperinsulinism is the most common cause of persistent neonatal hypoglycemia.

**EMBRYOLOGY**

The endocrine and exocrine pancreas arise from endodermal buds from which primitive pancreatic ducts and acini develop by repeated branchings.5 At birth, increased numbers of islet cells are found throughout the lobule as single cells and as clusters of cells, in addendum to the islets of Langerhans.

In PHHI, the pancreas resembles the third-trimester fetal and neonatal pancreas. This finding has also been found in teratomas.6 It has been suggested that nesidioblastosis may be the result of improper development of the endocrine pancreas progressing beyond birth and neonatal life.7

The diffuse pattern of development in the fetal and newborn endocrine pancreas makes the diagnosis of nesidioblastosis therefore rather challenging.8

**ETIOPATHOGENESIS**

1. Unknown etiology. Most cases of PHHI are sporadic. In more than 50% cases, no known genetic abnormality is found.
2. High rates of consanguinity have been noted in some series.9
3. Familial forms of PHHI have been reported.10 These involve autosomal recessive or dominant defects in Beta-cell high-affinity sulfonylurea receptor gene (SUR1). Inwardly rectifying potassium channel gene (Kir 6.2), glucokinase gene (GK) and glutamate dehydrogenase gene (GUD1).
4. The advances in molecular genetics have contributed enormously to our understanding of nesidioblastosis.11,12 The underlying genetic defects of β-cell regulation include a severe recessive disorder of the sulphonylurea receptor, a milder dominant form of hyperinsulinism, and a syndrome of hyperinsulinism plus hyper-ammonemia.
5. In the focal form, maternal loss of heterozygosity in chromosome region 11p15 in the cells of the hyperplastic area have been observed without loss in the normal pancreatic cells.13 This has not been observed in the diffuse form of PHHI.
6. Lately, the pathogenesis is now divided into K-channel disease [hyperinsulinemic hypoglycemia, familial (HHF) 1 and 2], which can mandate surgery, and other metabolic causes, HHF 3-6, which are treated medically in most patients.13
7. The diffuse form is inherited as a recessive gene on chromosome 11, whereas most cases of the focal form are caused by a sulfonylurea receptor 1 defect inherited from the father, which is associated with a maternal loss of heterozygosity on chromosome 11.\textsuperscript{13}

**PATHOPHYSIOLOGY**

PHHI may be focal or a diffuse abnormality of the islets. Abnormalities in the insulin secretory or glucose-sensing mechanism result in a failure to reduce pancreatic insulin secretion in presence of hypoglycemia. High insulin levels in turn promote hepatic and skeletal muscle glycogenesis, resulting in a decrease in the amount of free blood glucose available and suppression of the formation of free fatty acid (FFA), an alternative energy substrate for the brain. Thus a vicious cycle is established resulting in life-threatening hypoglycemia.

**EPIDEMIOLOGY**

The incidence varies from 1 in 40000 live births in northern Europe and USA to 1/2675 live births in areas where consanguineous marriages are common.\textsuperscript{9,14} The male-to-female ratio is 1.2:1 in diffuse forms and 1.8:1 in focal lesions. The overall incidence is slightly higher in males with a male-to-female ratio of 1.3:1.

**AGE AT PRESENTATION**

PHHI usually present from birth to 18 months of age, with most cases diagnosed at about one month after birth. PHHI represents the most common cause of hyperinsulinism in neonates.\textsuperscript{15-17} PHHI is usually found during the first two years of life and is unusual to find after that. Although PHHI was initially thought to affect only infants and children, various cases have been reported in adults.\textsuperscript{18,19}

**CLINICAL PRESENTATION**

The babies may present soon after birth with symptoms of hypoglycemia that include jitteriness, lethargy, apnea, seizures and hunger.\textsuperscript{20} Hypoglycemia should be documented during the symptoms. Hypoglycemia is persistent, requiring frequent or continuous glucose infusions or feedings to maintain adequate blood glucose levels.

Older children may also show diaphoresis, confusion, behavior changes or peripheral neurological symptoms like altered gait and motor weakness.

Presenting symptoms of PHHI reported in adults include confusion, headaches, dizziness, syncope, and loss of consciousness. These symptoms may be exacerbated by fasting and may improve after eating. The characteristic Wipples triad is seen in adults for diagnosing an insulinoma. This comprises of symptoms of hypoglycemia, documented hypoglycemia and subsiding of symptoms on giving glucose.

The physical examination findings are usually normal during euglycemia.

**DIFFERENTIAL DIAGNOSIS**

The presence of hepatomegaly suggests a metabolic disorder, such as glycogen storage disease, galactosemia, or fructoseemia. The presence of syndromic or dysmorphic features suggests a different diagnosis. PHHI is not usually associated with a genetic syndrome or characteristic physical features. The babies may be large for their gestational age because of the influence of chronic hyperinsulinism in utero. The differential diagnosis include hypopituitarism, transient hypoglycemia of the newborn, erythroblastosis fetalis, effects of drugs like tocolytics and quinine, infant of diabetic mother, Patau syndrome, insulinoma, ketotic hypoglycemia and Beckwith-Weidemann syndrome. Hyperinsulinism can be caused by pancreatic islet cell tumors such as insulinoma and associations with multiple endocrine neoplasia syndromes.\textsuperscript{21}

**INVESTIGATIONS**

**Blood Investigations**

1. PHHI is characterized by severe recurrent hypoglycemia associated with an inappropriate elevation of serum insulin, C-peptide, and proinsulin.

2. Serum glucose, ketone, and insulin levels should be obtained while the patient is hypoglycemic (serum glucose level < 60 mg/dL). The definition of hypoglycemia in neonates is dependent upon gestational age, and the threshold may be lower.
3. Nonketotic hypoglycemia with elevated insulin levels (>10 mU/mL) and normal levels of FFA supports the diagnosis of hyperinsulinism.
4. The insulin-to-glucose ratio may range from 0.4-2.7 (normal < 0.3).
5. Other tests for differential diagnosis include cortisol and growth hormone levels, serum metabolic screens, pH, lactate, ammonia studies, urinary ketones, amino acids, and reducing-substances. Hyperinsulinism with hyper-ammonemia and elevated levels of FFA suggests a fatty acid oxidation disorder. Hyperinsulinism with hyperammonemia and normal levels of FFA suggest the diagnosis of hyperinsulinism with hyperammonemia.
6. Requirement of sustained glucose to remain symptom free in excess of 10 mg/kg/min are consistent with exaggerated insulin activity.
7. Catheterization of the portal and pancreatic veins with venous sampling may help distinguish between focal and diffuse PHHI. Selective pancreatic venous sampling may help to identify focal lesions. Pancreatic venous sampling has been studied widely now, even in neonates.
8. Selective intra-arterial calcium stimulation has been described to a lesser extent in children. An excessive insulin response from calcium stimulation in a single artery suggests a focal lesion.22,23

**Imaging Studies**

Ultrasonography, CT scanning, or MRI are helpful to locate a focal mass in the pancreas. The focal lesion is commonly too small to be identified on imaging studies. No form of imaging currently available reveals the diffuse form of PHHI.

A preoperative PET scan with fluorodihydroxyphenylalanine has been found useful to pick up focal lesions.13

**Histopathology**

The morphologic characteristic features are ductoendocrine proliferation, numerous small endocrine cell groups and large endocrine areas.24 PHHI may be focal or diffuse.25 The diffuse form is more common (60-70% cases). The focal lesion contains islet like cell clusters with ductoinsular complexes, hypertrophic insulin cells with giant nuclei. Nuclear abnormalities include greatly increased size or crescent or ovoid shapes of beta-cells.

Immunohistochemical staining shows an increased proportion of insulin-containing cells (Fig. 94.1). The focal lesion may occur in any part of the pancreas, although the tail and body are the most common locations. The rest of the pancreas appears normal. Most patients with the focal form have a solitary lesion, though the lesions may be multifocal in 25% cases. Malignant potential based on clinical findings should be ruled out in solitary lesions.26

In the diffuse form, findings are similar throughout the pancreas with irregularly sized islets. Grossly, the pancreas appears normal (Fig. 94.2).
De novo formation of intermediate cells (acinar-islet cells) is a phenomenon which is clearly associated with nesidioblastosis. Nesidiodysplasia has been proposed to describe apparently increased and possibly maldistributed and/or malregulated endocrine cells associated with hyperinsulinemic hypoglycemia. Future classifications related to the underlying genetic defects may result in appropriate modification of the existing nomenclature.

**MEDICAL TREATMENT**

Newborns with persistent hypoglycemia should be transferred to the intensive care unit for stabilization, monitoring, and further diagnostic evaluation. Continuous feeding by a nasogastric tube may be helpful in some patients to maintain adequate blood glucose levels. Continuous feeding is particularly useful during sleep. Immediate treatment of hypoglycemia is essential as it is a life-threatening situation. Patients may require continuous IV glucose infusion. Glucagon may also be administered emergently to maintain adequate blood glucose levels.

Diazoxide, octreotide, and nifedipine are the primary medications used in long-term treatment of persistent hyperinsulinemic hypoglycemia of infancy. Some also recommend using chlorothiazide in conjunction with diazoxide for a synergistic effect. Oral diazoxide is used usually for the treatment of hypoglycemia. Diazoxide promotes opening of the potassium adenosine triphosphate channel, which inhibits pancreatic secretion of insulin, stimulates glucose release from the liver, and stimulates catecholamine release. Intravenous use may cause hypotension. Diazoxide is given in a dose of 8-10 mg/kg/d in three divided doses in neonates and infants and 3 mg/kg/d in older children, titrated to effect.

Octreotide, a long-acting somatostatin analogue inhibits insulin release but tolerance may develop over time. The dose is 1-10 mcg/kg/d SC divided 6-8 hourly.

Nifedipine has also been used successfully for ionic control of beta cell function. The doses and selection of drugs, must be highly individualized on the basis of therapeutic response and adverse-effect tolerance. Many children require years of drug therapy, and regular reassessment and dose adjustments are required besides ensuring compliance.

**SURGICAL TREATMENT**

PHHI is often poorly responsive or unresponsive to medical management, necessitating 95% or near-total pancreatectomy (Figs 94.3A and B). However, a more conservative approach is now possible after the recognition of a nonrecurring focal form, which is cured by partial surgery, and a diffuse form, which necessitates total pancreas removal only in cases of medical treatment failure. In infants, surgery is usually performed within the first 2 months of life. Laparoscopic procedures can be done in all age groups.
Indications of Surgical Intervention

1. Medical therapy fails to maintain normoglycemia.
2. A focal lesion.
3. Noncompliance to medical therapy.
4. Recurrent symptoms following partial pancreatectomy.

Identification of a Focal Lesion

The distinction between focal and diffuse lesions is critical in planning surgical intervention. Every effort should be made, pre and perioperatively to identify or rule out a focal lesion. Limited pancreatic resection prevents future development of diabetes mellitus. Most focal lesions are too small to identify by CT scanning, MRI, ultrasonography, or even intraoperative palpation. Pancreatic venous sampling or intra-arterial calcium stimulation may help identify a focal lesion. Preoperative localization of focal insulin hypersecretion by percutaneous pancreatic venous sampling has allowed to limit the amount of pancreatic resection. A routine intra-arterial calcium stimulation test with venous sampling (IACS test) may help to identify an occult insulinoma. An intraoperative ultrasound may supplement in detecting an occult lesion as it is able to identify nonpalpable lesions. Occult lesions identified by intraoperative ultrasound have been treated by 40% or 60-70% distal pancreatectomies when insulin gradients were demonstrated on calcium stimulation to the splenic or to the superior mesenteric artery, respectively. A rapid intraoperative insulin assay has been recently developed that yields results within several minutes and confirms complete resection of insulinoma. It is a valuable adjunct to determination of complete excision in complicated cases of recurrent or questionable insulinoma. Children may especially benefit from this novel assay to confirm complete resection and to differentiate multiple etiologies of hyperinsulinism in the pediatric population. Care should to taken so as not to miss multiple focal lesions. Intraoperative glucose monitoring during a trial of glucose-free IV fluids may guide the surgeon in determining the need to search for additional lesions. If there is normoglycemia without IV glucose, after removal of a focal lesion, it is unlikely that there is another lesion.

The surgical approach involves taking multiple biopsy samples from different parts of the pancreas (head, body, isthmus, and tail). Intraoperatively frozen-section evaluation helps to determine whether the pathology is diffuse or focal. Abnormal beta-cell nuclei in all specimens suggests a diffuse lesion necessitating extensive pancreatectomy. In contrast, if only one specimen contains abnormal beta-cell nuclei, a focal lesion may be present.

If no focal lesion is found a near total pancreatectomy may be performed. Varying degrees of pancreatic resection from 85-95% in infants and children have been reported. Albeit being a controversial issue, subtotal pancreatectomy or 95% or is the most widely accepted procedure for infants and children. The tail, body, uncinate process, and most of the head of the pancreas are removed, leaving a portion of pancreas to the right of the common bile duct and a thin rim along the second portion of the duodenum and the pancreaticoduodenal arteries. Resection of less than 95% of the pancreas is associated with a higher rate of treatment failure and need for reoperation. The more aggressive, 98% pancreatectomy removes all but a few small islands of pancreatic tissue along the pancreaticoduodenal arteries. This procedure is associated with a higher rate of postoperative diabetes mellitus. However, patients with even lesser degrees of pancreatic resection are at risk for development of diabetes mellitus. To remain on the safer side, some authors advocate a more conservative initial procedure, with reoperation later if hypoglycemia persists.

COMPLICATIONS

Preoperative

1. Permanent neurologic dysfunction (e.g., seizures, developmental delay, focal neurologic deficits).
2. Death secondary to severe, prolonged hypoglycemia may occur if PHHI goes untreated or is inadequately treated.
3. Adverse effects of medications.

Postoperative

Early Complications

1. Bleeding
2. Wound infection
3. Pancreatic fistula
4. Persistent hypoglycemia.
Late Complications

1. Pancreatic exocrine insufficiency and glucose intolerance.
2. Diabetes mellitus following total pancreatectomy. The risk of diabetes mellitus appears to increase with the extent of pancreatic resection; however, the risk is significant even with conservative surgical procedures. Upto 15% of children with diffuse lesions may develop diabetes mellitus, regardless of the surgical procedure performed. The mean time from surgery to development of diabetes mellitus was 9.6 years. Diabetes mellitus is extremely rare following resection of focal lesions.
3. Persistent hypoglycemia: Hypoglycemia often persists even after a 95-98% pancreatectomy. Hypoglycemia may be easier to control after partial pancreatectomy and may resolve months or years later or persist throughout life.
4. Neurological developmental delay: A high incidence of mental retardation, developmental delay, and nonhypoglycemic seizures has been reported by some, attributed to minimal brain damage from early hypoglycemic events. It has been thus suggested that patients with early, severe disease treated with early, aggressive surgery may have a better neurodevelopmental outcome.

FOLLOW-UP

Long-term follow-up is essential to prevent delay in the diagnosis of disease recurrence, glucose intolerance, or diabetes mellitus.

Regardless of the surgical procedure used, hypoglycemia may recur, and the patient may require continued medical therapy. Additional pancreatic resection may be indicated if optimal medical management cannot provide adequate glycemic control. In refractory cases, which are rare, total resection of the pancreas has been performed.

In a series evaluating the residual pancreas in children diagnosed with nesidioblastosis and who had undergone 90-95% pancreatectomy, it was reported that most patients showed complete or incomplete pancreatic regeneration during follow-up. These patients were asymptomatic and showed normal laboratory tests.

Ultrasound measurements indicated normal age-dependent growth after near-total resection in 54% of patients. The function and echogenicity of the regenerated pancreas indicated that the increase in organ size was due to normal pancreatic tissue.

PROGNOSIS

If a solitary focal lesion can be identified and excised, the patient usually remains euglycemic without medication or continuous feedings. The results following surgery for diffuse disease have not been encouraging in most series. Rates of initial failure to control hypoglycemia are high, followed by, paradoxically, high rates of subsequent development of diabetes mellitus. About half of the patients undergoing 95% or greater pancreatectomy have been cured at a mean follow up of 5 years. 40-60% of patients managed with medical therapy alone have had late remission of hypoglycemia. Later onset of disease has been correlated with a higher likelihood of being able to discontinue medical therapy. Future advances in medical therapy may provide better glycemic control with fewer side effects, permitting less radical pancreatic resection.

REFERENCES

Persistent Hyperinsulinemic Hypoglycemia of Infancy

1057

In spite of the considerable improvements in conventional diabetes therapy during the past years, insulin-dependent diabetes mellitus ranks as one of the major disease entities in the world. The life expectancy of the diabetic patient is approximately one-third less than that of the general population. Since the metabolic abnormalities that prevail in diabetes mellitus are due to non-functioning B-cells in the islets of Langerhans, it would be logical to treat this disease by the transplantation of a normally functioning pancreas. This procedure should correct the metabolic abnormalities and presumably prevent or delay the onset of severe secondary complications. Clinical application has been limited because of immunologic and technical problems, but these problems are gradually being overcome. From the 1980s the number of diabetic patients treated with pancreatic transplantation has increased rapidly and the results improved markedly.1

PATIENT SELECTION

In spite of the mortality and morbidity associated with insulin-dependent diabetes mellitus, the disease is not immediately life-threatening, and pancreatic transplantation unlike heart and liver transplantation, cannot be considered a life-saving procedure. Instead the potential benefits of pancreatic transplantation on the quality of life and on the secondary complications of diabetes must be weighed against the risks of the surgical procedure and by the immunosuppression required after transplantation. Until recently the difficult question of whether it was justifiable to try to cure diabetes by a major surgical procedure which was to be followed by long-term immunosuppressive therapy has largely been circumvented by accepting diabetic patients with end-stage renal disease for pancreatic and renal transplantation. In the diabetic patients with end-stage renal disease, pancreatic transplantation has been performed either concomitantly with a renal transplantation, with both the organs coming from the same donor, or alternatively, with a diabetic patient already having a renal graft has been given a subsequent pancreatic graft. Since end-stage renal disease usually develops after 20-30 years of insulin-dependent diabetes, these patients have been in the 25-45 years age range. Most patients have had various diabetic stigmata in addition to renal damage such as retinopathy and neuropathy.

The diabetic patients accepted for combined transplantation have been the patients who would otherwise have been accepted for renal transplantation only. When pancreatic transplantation has been carried out in diabetic patients already having a renal graft, the patient selected are those who have had few or no rejection episodes.

Uncorrectable malignancy and psychosis constitute contraindications for organ transplantation. Any acute disease, whether related to the patient's diabetes or not, should be treated and preferably corrected before transplantation. Infections are especially important in this regard. Some severe disabilities caused by the diabetes constitute contraindications to pancreatic transplantation, for instance ongoing peripheral gangrene, severe coronary insufficiency with angina or intractable cardiac in compensation and severely incapacitating peripheral neuropathy such as in the case of bedridden patients. An upper age limit in the 50-60 years range is usually applied.
PREOPERATIVE PATIENT EVALUATION

Because of the high incidence of coronary artery disease in the diabetic patient population, an exercise ECG should always be performed. If there is any indication of coronary artery disease, coronary angiography should be carried out. If a significant stenosis is found the patient should be evaluated for bypass surgery before pancreatic transplantation. Angiography of the iliac arteries, one of which is used for the anastomosis of the graft artery, is indicated if the femoral pulses are weak or absent or if the patient has significant claudication. 

If there is a history of gastroparesis or gastric candidiasis, an upper GI series or gastroscopy should be performed. If there is a history of urinary bladder dysfunction, cystoscopy should be performed. In patients with pre-uremic nephropathy, glomerular filtration rate should be determined repeatedly to establish the extent of deterioration.

To establish the effects of the pancreatic transplantation on the secondary complications of the disease a careful preoperative evaluation of the patient's neurologic and ophthalmologic status should be carried out. In patients with pre-uremic nephropathy, glomerular filtration rate should be determined repeatedly to establish the extent of deterioration.

THE PANCREATIC DONOR GRAFT

All cadaveric donors considered for kidney donation should be considered also for pancreas graft donation, providing there is no history of diabetes mellitus, chronic pancreatitis or pancreatic damage by trauma. Blood glucose and serum amylase should be examined in the donor. If a high blood glucose level exists, our practice is to give the donor a non-glucose-containing infusion solution for a few hours. If the blood glucose remains more than a twice normal, we are hesitant to use the pancreas. Valuable further information concerning the state of the endocrine pancreas can be obtained by determination of glycosylated hemoglobin (HbA1) with a rapid screening method. Hyperamylasemia may exist and some evidence has been presented that this can be a consequence of the cerebral infarction.

The final decision concerning the suitability of the pancreas for transplantation is made during its actual removal. The normal pancreas is yellowish, soft and has a homogeneous consistency. If sclerotic, calcified or markedly discolored, the pancreas should not be used.

In some instances relatives have served as donors for segmental pancreatic grafts. The rationale for using living related donors for pancreas grafts is that provides for a better immunological match, presumably reducing the risk for graft rejection.

THE CADAVERIC DONOR OPERATION

Most pancreases are obtained from multiorgan donors. The heart and liver are usually harvested prior to the removal of the pancreas and kidneys. Previously most pancreatic transplantations were performed using a segmental-body and tail-graft. Today more and more groups use a pancreatico-duodenal graft consisting of the entire pancreas and a segment of the duodenum.

The following is a brief description of the steps required for removal of pancreatico-duodenal graft. A long midline or a cruciate incision is used. The lesser sac is opened by ligating and dividing the gastrocolic ligaments from the pylorus to the short gastrosplenic vessels. The stomach is retracted cranially and the body and the tail of the pancreas are inspected and palpated. The spleen is mobilized or alternatively, the splenic vessels are ligated in the splenic hilum. The pancreatic tail is then reflected medially and the dissection is carried out towards the portal vein following the lower margin until the superior mesenteric vein (SMV) is reached. The inferior mesenteric vein is identified and ligated. At the upper margin the dissection is carried out until the trifurcation of the celiac axis is reached. The left gastric artery is ligated. The diaphragm is incised to provide access to the aorta and the roots of the celiac axis and the superior mesenteric artery (SMA).

The duodenum and the pancreatic head are mobilized by a Kocher maneuver. The common bile duct is divided and ligated, and the hepatic artery is ligated and divided distally to the gastroduodenal artery. The right gastric and gastroepiploic arteries are divided. The portal vein is then dissected free. The SMV and the SMA are ligated where they ride over the duodenum. The duodenum is divided just distal to the pylorus and the lower bend. The cut ends are usually closed with staples. Finally dissection is carried out towards the aorta behind the SMA.
The aorta is crossclamped above the celiac axis, and organ cooling and flushing are accomplished by intra-aortic infusion of a cold electrolyte solution by a tube inserted in the lower aorta. Thus, the pancreas and also the two kidneys are perfused. The pancreatic graft is then removed with an aortic patch containing the two arteries. The portal vein is divided to provide a length of 2-3 cm. If the whole pancreas and the liver are to be harvested from the same donor, the common hepatic artery is usually required for the vascular pedicle of the liver. In this case the gastroduodenal artery is ligated at its origin from the common hepatic artery, and the pancreatic head and the duodenum will then derive their arterial supply from the inferior pancreatico-duodenal artery arising from the SMA. If the celiac axis is also taken with the liver, the severed splenic artery can be anastomosed end-to-side to the SMA or a Y-extension graft (from the donor iliac artery bifurcation) can be used to join the splenic artery and the SMA.

If a segmental pancreatic graft is to be obtained from a cadaveric or living related donor, the dissection is carried from the tail to the level of the portal vein as describe above. A finger is passed between the pancreatic neck and the portal vein, and the pancreatic neck is cut with scissors. In the cadaveric donor this maneuver can be facilitated by first dividing the common bile duct and the gastroduodenal artery.

**PANCREATIC GRAFT PRESERVATION**

The techniques used for flushing, cooling and storage of the pancreatic graft have been similar to those used for kidney grafts. Thus, until recently most groups flushed the graft with electrolyte solution with intracellular electrolyte content as suggested by Collins. With these, cold storage time has usually been kept under eight hours. In 1987 the University of Wisconsin (UW) group introduced a solution containing lactobionate and raffinose as impermeable osmotic agents. This solution is also devoid of glucose and, therefore, avoids lactic acid production in the organ. It has proved to be an excellent solution for flushing the pancreas and allows storage for 24 hours and perhaps even longer.

**THE RECIPIENT OPERATION**

In the very first series of pancreatic transplantation’s performed in man, pancreatic-duodenal grafts were used. The graft duodenum was anastomosed end-to-end to a recipient Roux-loop thereby accomplishing enteric exocrine diversion. However, following the occurrence of necrosis and fistulas in the duodenum in some patients, this type of graft fell into disrepute and segmental body and tail grafts became standard from the early 1970s onwards. However, the pancreatic-duodenal graft was reintroduced by Starzl in 1990s. By now, most groups are using such grafts (Fig. 95.1). The duodenal complications previously encountered are now hardly seen, probably due to better techniques for tissue preservation and better protocols for avoiding graft rejection.

Intestinal transplant alone may also be done as a separate procedure (Fig. 95.2).

**Management of the Exocrine Pancreas**

As for the handling of the exocrine secretion of the pancreatic graft, there are three options.

1. **Pancreatic ducto-occlusion**: One technique introduced by Dubernard of France is ductal filling with a polymer. By such filling the exocrine secretion is prevented from escaping or indeed even from being formed. The procedure is appealing in that it reduces the intervention in the patient to the vascular anastomosis. However, it has recently become clear that monitoring of amylase in the exocrine secretion is crucial for the diagnosis of graft rejection. Since ductal filling makes this impossible, the interest in this technique has diminished.

![Fig. 95.1: Pancreatico duodenal graft](image-url)
2. **Diversion to the urinary bladder:** In the early 1970s, Gliedman suggested that exocrine diversion should be accomplished via the patient's ureter. In so doing, the bowel did not have to be entered and the risk for infection was thereby reduced. The concept was reintroduced in the 1980s by Sollinger, who suggested that a duodenal patch of the graft should be anastomosed to the patient's bladder instead. Today most groups favour pancreatic-duodenal grafts with bladder drainage. The graft is placed intraperitoneally with the head of the pancreas pointing downwards. Vascular anastomoses are made to the iliac vessels on the right side. The antimesenteric side of the duodenal segment is anastomosed to the top of the bladder with a two-layer anastomosis or with help of a stapler. A segmental pancreatic graft can also be anastomosed to the bladder.

A disadvantage of urinary tract diversion is that it causes a significant bicarbonate loss sometimes leading to metabolic acidosis requiring replacement therapy.

3. **Exocrine diversion to the bowel:** Diversion to the bowel offers the most physiological way of handling the exocrine secretion. The graft is placed intraperitoneally. Previously, when segmental grafts were used, a pancreatic-enterostomy was created by telescoping the cut end of the pancreas into the end of a jejunal Roux-loop. When pancreatic-duodenal grafts are used, the anastomosis consists of an entero-entero anastomosis performed either to a Roux-loop or directly end-to-side to the recipient's jejunum. The arterial anastomosis is to the iliac vessels. Since the head of the graft should point upward, the portal vein is usually anastomosed to the lower caval vein. The Stockholm group uses a pancreatic duct catheter to divert the exocrine secretion to the exterior for the first few weeks after transplantation. Pure pancreatic juice is then made available for monitoring graft function.

**POSTOPERATIVE MANAGEMENT AND MONITORING**

**Infection and Thrombosis Prophylaxis**

Most groups use prophylaxis with antibiotics during surgery and for the first 2-5 postoperative days. Also various drug protocols aimed at reducing the risk of graft vascular thrombosis are used by most groups. The treatment may consist of dextran infusion given intravenously for one or several days followed by either aspirin or warfarin sodium given for weeks or months.

**Immunosuppression**

Immunosuppression is usually similar to that used in renal transplantation although quadruple drug therapy may be somewhat more common with pancreatic transplantation.

**Monitoring the Graft**

For monitoring the pancreatic graft, blood glucose, glycosylated hemoglobin and serum amylase levels are routinely assayed. In addition, many groups assay the serum C-peptide as a measure of graft insulin production. If the graft has been anastomosed to the patient’s bladder, the amylase excretion is measured by amylase assay in the urine. If, alternatively, the pancreatic secretion has been exteriorized by means of a ductal catheter, amylase and inflammatory cells are assayed directly in the juice. If an abdominal drain is used, the amylase activity in the discharge should be measured daily. An elevated level may disclose an anastomotic leakage.
GRAFT-RELATED COMPLICATIONS

Most of the graft-related complications seen after pancreatic transplantation reflect well-known pancreatic pathophysiological conditions. Examples of such conditions are pancreatitis, peripancreatic fluid collections, anastomotic leaks, fistulas and peri- and intrapancreatic abscesses. With all these conditions, wound infections are common. Another characteristic graft-related complication has been graft thrombosis.

Pancreatitis

In almost all patients some symptoms and signs typical of pancreatitis (pain and tenderness related to the pancreatic graft in combination with hyperamylasemia) appear during the first few days after transplantation. This early postoperative pancreatitis is believed to be a consequence of injury to the pancreas which occurs during the actual transplant procedure, i.e. specifically ischemic damage. In some patients hyperamylasemia appears without any specific symptoms but in others severe pain and tenderness at the graft site appear. The longer the cold ischemia, the greater the risk of pancreatitis. Still, severe pancreatitis may appear even with relatively short ischemia time.

The treatment of graft pancreatitis is similar to that of common pancreatitis, the patient is kept fasting and IV replacement is given. In case of severe local symptoms, laparotomy should be performed with evacuation of peripancreatic fluid collections. Sometimes resection of necrotic areas on the pancreatic surface might also be necessary followed by peritoneal lavage for a few days. Usually endocrine function is unaffected even during severe attacks of graft pancreatitis. Nonetheless if the pancreatitis is very severe, graft-removal offers the safest remedy.

Pancreatic Exocrine Sweating

With pancreatitis or any pancreatic injury, a fluid high in amylase and other enzymes seeps out from the pancreatic graft and accumulates around the gland, a phenomenon often referred to as pancreatic sweating. The pancreatic sweating usually abates a few days after transplantation but may continue for 1-2 weeks. By tube drainage of the operative site, the risk for fluid accumulation will be much reduced.

Anastomotic Leaks and Fistulas

When the pancreatic graft is anastomosed to the patient's bowel or urinary tract for diversion of the exocrine secretion, an anastomotic leak may develop. This leak may give rise to a pancreatic fistula to the exterior. Also, a peripancreatic abscess usually forms. The symptoms include local pain and tenderness, fever and leucocytosis. Anastomotic leaks typically occur during the first few weeks after transplantation. If an exterior fistula develops, the high amylase content of the discharge and the skin reddening caused by the digestive enzymes usually make the diagnosis easy. If only an abscess forms the diagnosis may be difficult since pancreatitis, graft rejection and intestinal obstruction may give similar symptoms.

Early re-exploration should be considered as soon as the patient experiences unexplained abdominal pain and fever. The chances of repairing an anastomotic leak and of successfully draining fluid collections are much enhanced if the operation is performed promptly.

Intrapancreatic Abscesses

In some patients intrapancreatic abscesses have developed several weeks after transplantation. The symptoms are persistent fever, pain at the graft site and a gradual deterioration of blood glucose control. Serum amylase is unaffected. Such intrapancreatic abscesses are probably due to subacute or chronic rejection with ensuing destruction of the exocrine part of the graft. They may also be due to primary cytomegalovirus infection of the pancreas. If an intrapancreatic abscess develops, the pancreatic graft must be removed.

Graft Thrombosis

Vascular thrombosis has been observed to be responsible for 10-20% of all graft losses. One possible reason for the propensity of graft thrombosis lies in the abnormal hemodynamic situation that exists in the pancreatic graft. Arterial revascularization is achieved by anastomosing large arterial trunks, such as the celiac axis or splenic artery and the SMA, with their distal ends ligated. These large trunks are then left to drain via the small pancreatic branches thus creating
a low outflow situation. Pancreatitis with ensuing swelling of the exocrine pancreas may also be a predisposing factor. Thrombosis may be arterial or venous. It usually occurs during the first week after transplantation, and many thromboses occur within the first 24 hours.

With arterial graft thrombosis the characteristic findings are a sudden increase in blood glucose level and a fall in serum amylase levels. If a pancreatic duct catheter is used, the typical finding is a gradual decline in output and bloodstaining of the pancreatic juice. Pain and tenderness over the graft is common. Grafts that thrombose early should be removed while grafts undergoing late arterial thrombosis can be left in situ unless local symptoms occur. To prevent graft thrombosis most groups use anticoagulation therapy as primarily mentioned. With such therapy a reduction in the incidence of thrombosis has occurred, but a price has been paid since an increased incidence of bleeding has resulted. The risk of bleeding is lowest when only dextran and aspirin only are used.

**DIAGNOSIS OF REJECTION**

When rejection occurs in recipients of combined renal and pancreatic graft, signs of impaired renal function, such as increasing creatinine and BUN, usually precede signs of impaired pancreatic function by a few days. Often signs of pancreatic graft rejection may be absent. This finding may be explained by the pancreas being less prone to rejection than the kidney, or alternatively, the parameters used for diagnosing pancreatic graft rejection might be less sensitive. In patients subjected to single pancreatic transplantation and in those given a pancreatic transplantation after a renal transplantation—with the grafts coming from different donors—the diagnosis of acute rejection must been found that elevation of blood glucose is a very late sign of rejection, the rise occurring only when about 90% of the pancreatic graft has been destroyed. C-peptide assays seem to be a somewhat more sensitive marker of endocrine function, but the test is time-consuming and usually not performed on a daily basis. As a result of the above, interest has focused on measurements of exocrine function as possible rejection markers. So far, there are no reliable serum assays reflecting pancreatic graft rejection. Serum amylase levels sometimes show a transient rise during the first few days of an acute rejection episode, but the level may be unchanged or even decrease. At the present time the most widely used marker of acute pancreatic graft rejection is the amylase level in the pancreatic juice. If the exocrine graft has been anastomosed to the patient’s urinary tract, urinary amylase level reflects the amylase content in the juice. Some investigators prefer to use the 12-hour amylase output as the parameter thereby avoiding the influence of variations in urinary output. The diversion of the pure pancreatic juice to the exterior by means of a catheter also makes possible daily determinations of amylase output. In addition this technique makes possible studies of pancreatic juice cytology. During the first days after transplantation the pancreatic juice contains large amounts of granulocytes probably as a reflection of ischemic graft pancreatitis. During rejection, inflammatory cells appear in the juice. Monocytes usually appear first to be followed one or two days later by lymphocytes and lymphoblasts. Following antirejection treatment the lymphoblasts disappear and the pancreatic juice again becomes devoid of cells. The appearance of inflammatory cells has been found to precede the decline in amylase by one or two days. Thus pancreatic juice cytology is probably a more sensitive and more specific marker for rejection than the amylase content.

Various radiological examinations such as angiography, scintigraphy, ultrasonography and MRI may also aid in the diagnosis of acute rejection. On angiography acute rejection is reflected in poor staining of the parenchyma. If the rejection is severe, there are also irregularities in the small arteries. In scintigraphy a reduced perfusion index and a reduction in the staining of the graft is indicative of rejection. In ultrasonography with Doppler measurement of blood flow, an increase in the resistance index as well as swelling of the graft and peripancreatic fluid collections are taken as signs of rejection. With MRI the normal pancreas allograft has a signal intensity similar to that of normal renal cortex on T:1 weighted images and less than that of urine or kidney on T:2 weighted images. During acute rejection, the pancreatic parenchyma has an abnormal focal or diffuse signal intensity less than that of normal renal cortex and similar to that of muscle on T:1 weighted images and brighter or equal to that of urine or kidney on T:2 weighted images.
Chronic graft rejection may occur months or years after transplantation, and a slowly rising blood glucose level, indicative of a progressive destruction of the endocrine capacity, is a characteristic laboratory finding. Usually the rise is seen first in the postprandial blood glucose. At the same time there is a progressive decline in the C-peptide level.

Ultimate confirmation of rejection requires microscopic evaluation of a biopsy specimen from the graft. Characteristic findings are diffuse mononuclear cell infiltrates in the pancreatic parenchyma and acute or chronic vasculitis. Since the pancreatic graft is placed intraperitoneally among the intestines, a laparotomy is necessary for a safe biopsy. Fine needle aspiration biopsies can be carried out with little or no risk of enteric damage.

OUTPATIENT FOLLOW-UP

Patients are seen in the outpatient clinic, initially twice weekly then over longer and longer intervals. At each visit, pancreatic graft function is assessed by measuring fasting and postprandial blood glucose levels, glycosylated hemoglobin and serum amylase. In patients with graft with urinary tract diversion, urinary amylase is measured. Between visits the patients may perform home monitoring of blood glucose levels. The patients with urinary diversion are also recommended to monitor urinary pH since a reduction of the exocrine secretion from the graft is reflected in an increased pH.

Every three or six months the endocrine capacity of the pancreatic graft is examined by intravenous and oral glucose tolerance test. Retinopathy and neuropathy is reassessed every six months after transplantation. In pre-uremic patients the course of the nephropathy is followed by regular assays of serum-creatinine, BUN and EDTA clearance. The immunosuppressive treatment is tapered.

EFFECT OF TRANSPLANTATION ON METABOLIC CONTROL

Usually normoglycemia occurs within a few hours after pancreas transplantation, and exogenous insulin therapy can be discontinued. However, hyperglycemia requiring treatment with exogenous insulin may exist for days or even weeks in some patients. Such post-transplantation hyperglycemia may be due to ischemic damage to the graft, and it may be aggravated by the intravenous glucose infusions given in the early postoperative phase. When conditions have stabilized, fasting and postprandial blood glucose should be normal or almost normal. When glycosylated hemoglobin is measured, it is found normal in approximately two-third of the patients and slightly elevated in the remaining one-third. The oral glucose tolerance is normal in most of the patients while the intravenous glucose tolerance is normal only in some 50% of the patients. These abnormalities in glucose metabolism are probably mainly due to immunosuppression. Graft injury, due to sustained ischemic damage or rejection, might be a contributing factor in some patients. In spite of the difference in islet mass provided there seems to be no significant difference in blood glucose control whether pancreaticoduodenal or segmental grafts are used. It is clear that the long-term metabolic control seen after successful pancreatic transplantation is superior to that which can be achieved with any other method today.

EFFECT OF TRANSPLANTATION ON QUALITY OF LIFE AND ON THE SECONDARY COMPLICATIONS OF DIABETES

After successful pancreatic transplantation there is a distinct improvement in the quality of life of the recipient. Insulin injections can be dispensed with and all dietary restrictions abandoned. These changes have considerable social and psychological implications for most patients. Also general wellbeing is often improved and can be objectively measured in factors such as social, physical and psychological functions.

As for the effects on the secondary complications of the disease, such as retinopathy, neuropathy and nephropathy, there are some unfavourable and some more favourable findings. Thus combined renal and pancreatic transplantation in uremic recipients seems to have little or only moderate effect on established diabetic retinopathy or neuropathy. However these findings may be explained by the fact that most recipients transplanted so far, have had very advanced secondary complications, complications that could hardly be expected to be reversed or even halted. An important conclusion to be drawn from these findings is that pancreatic transplantation needs to be performed earlier in the course of the disease. So far,
only limited clinical data are available concerning the effect on the secondary complications in this situation. It has been reported however, that in recipients of combined pancreatic and renal grafts diabetic lesions in the transplanted kidney are avoided while such lesions develop after two years in diabetic patients who have received a kidney only. In addition there is some preliminary data showing that early diabetic lesions in a previously transplanted renal graft or the patient’s native kidneys can be halted or perhaps even reversed following pancreatic transplantation. Also following single pancreatic transplantation in non-uremic recipients the progression of diabetic polyneuropathy may be halted. These findings confirm several animal studies where pancreatic transplantation has been shown to prevent or reverse secondary lesions if performed early on in the course of the disease.6-8

FUTURE

Pancreas transplantation has become increasingly effective for the treatment of human diabetes. Islet cell transplants have thus far been successful only in the laboratory. Unless islet cell yield can be improved and methods to reduce immunogenicity can be made practical, pancreas transplantation is the only practical method of total endocrine replacement therapy in diabetes that can succeed. Potentially, pancreas transplantation could be applied on as large scale as renal transplantation is. Eventually, pancreas transplantation may be routinely performed at a sufficiently early stage to prevent the development of diabetic nephropathy and other complications and may supersede kidney transplants and other procedures in the management of complication-prone diabetic patients.

REFERENCES

Modern-day understanding of the role of the spleen both in health and disease can be traced back to Virchow’s detailed anatomic and histologic descriptions in the 19th century. In the hundred years that followed, little knowledge was gained about the exact function of the spleen, and as recently as fifty years ago, it was believed that the spleen could be removed with impunity. In the early 1950’s, it was recognized that removal of the spleen may have life-threatening consequences, particularly in young children. In the past 20 years, much has been learned about the important role of the spleen in the immune processes of the body. This knowledge has led to a more conservative approach in the surgical management of splenic disease. Important new aspects of splenic surgery in children include splenic preservation, laparoscopic approaches, and autotransplantation. Furthermore, more evidence has accumulated supporting a nonoperative approach in the management of splenic trauma in a majority of cases.

EMBRYOLOGY AND ANATOMY

Normal

The spleen is unique in that it is the only unilateral and completely mesenchymal organ in humans. It arises at about the fifth week of gestation from the mesenchyme of the dorsal pancreatic bud. With the normal longitudinal rotation of the stomach, the spleen is carried into the left upper quadrant where it occupies a position superior and dorsal to the stomach and anterior to the left adrenal and kidney. By the twelfth week of gestation, the spleen assumes a triangular shape, with a parietal convex surface abutting the diaphragm and a concave visceral surface directly adjacent to the stomach, kidney, and colon. The dorsal mesentery surrounding this structure gives rise to the peritoneal layer that envelops the spleen, as well as an inner capsule containing a network of connective tissue fibers. An extensive network of sinusoids develops in this capsule in the fifth to seventh weeks of gestation. During the second trimester, the spleen supplements the liver in its hematopoietic function. The weight of the spleen increases more quickly during this time than the body weight until the fetus reaches 200 grams. The rapidity of this rise corresponds with the increasing hematopoietic function of the fetal spleen. At the splenic hilum, the leaves of the dorsal mesentery coalesce to form the gastroplenic and splenorenal ligaments, providing fixation and enveloping the splenic pedicle. Other lesser attachments develop between the spleen and the colon, diaphragm, and pancreas.

At birth, the normal spleen weighs between 10 to 15 grams and measures approximately 5 cm at its greatest dimension. Its main arterial blood supply, the splenic artery, arises from the celiac trunk. Additional arterial blood supply is obtained from the short gastric arteries, branches of the left gastroepiploic artery. The splenic artery divides into several smaller trabecular arteries at the hilum. These trabecular arteries branch into smaller central arteries that supply the splenic parenchyma, named as a result of their central position in the white pulp. The central arteries send numerous radial branches into the white pulp, terminating as the penicillate arteries and arterioles in the capillaries of the red pulp. It is this radial orientation of vessels from
a central hilum that facilitates the technical performance of a partial splenectomy. These capillaries are sheathed with phagocytic cells, and communicate with the venous system either directly or indirectly in the splenic substance. The circulation of blood through the red pulp, which is lined entirely by endothelium is termed "closed circulation," whereas circulation into the phagocyte lined sinuses (Billroth's cords) is referred to as the "open circulation".

Venous drainage of the splenic parenchyma begins in the sinuses located in the red pulp. These structures empty directly into venules and veins coursing the trabecular arteries which eventually join to form the splenic vein near the hilum. Near the tail of the pancreas, the splenic vein coalesces with the inferior mesenteric vein which more medially is joined by the superior mesenteric vein giving rise to the portal vein.

The red and white pulp within the splenic parenchyma have specialized functions. The red pulp, so named because of the slow flow of blood through the sinusoids, forms the majority of splenic substance. It is composed of cords of loose trabecular tissue containing capillaries and reticuloendothelial cells interspersed among venous sinuses. The white pulp is composed of lymphoid tissue and reticular substance and surrounds the central artery and arterioles. Within the white pulp, B-cells are arranged as follicles surrounding a germinal center. T-cells are arranged densely around the central artery, and more dispersed peripherally. This precise microarchitecture is critical to the normal physiologic and immunologic function of the spleen.

Abnormal

Asplenia and Polysplenia

Asplenia and polysplenia are unusual defects arising from a failure of normal symmetric organogenesis, and are associated with other major congenital anomalies. The incidence of asplenia in man is between 1:632 and 1:3214 in series reporting on this syndrome, with a slight male predominance. Congenital asplenia (Ivemark syndrome) occurs as a result of bilateral right-sidedness. Other structures derived from the dorsal mesogastrium are also affected, including the stomach and omentum. Associated cardiac anomalies often include transposition of the great arteries, septal defects, truncus arteriosus, pulmonary artery stenosis or atresia, anomalous venous return, and atrioventricular canal defects. In most cases, both lungs are trilobed, and the stomach is located on the right with a centrally located liver. Splenic absence is suggested by examination of a peripheral blood smear in the newborn revealing Howell-Jolly bodies and siderocytes. Patients should be placed on asplenia prophylaxis (as discussed later) as soon as the diagnosis is made. Acquired asplenia is encountered after removal or sequestration of the spleen in sickle cell anemia.

In contrast, polysplenia results from bilateral left-sidedness. The multiple spleens are usually located along the greater curvature of the stomach. Cardiac defects are often present, however, not as severe as those accompanying asplenia. The lungs are usually bilobed, and the liver may be bilateral. Other associated lesions of surgical significance include a higher incidence of biliary atresia, and a preduodenal portal vein. Splenic function is usually normal.

Accessory Spleen

Accessory spleen refers to small (1 to 10 cm), functioning splenic nodules, in addition to a normal, functioning spleen. It represents by far the most common anomaly of the spleen, and one of the most common anomalies of the body overall, reportedly occurring in between 10-30% of the general population. In most cases, a single accessory spleen is present, but multiple accessory spleens have also been reported. Accessory spleens are usually found in the splenic hilum, along the curvature of the stomach, in the omentum, and adjacent to the pancreas. The nodules often resemble small lymph nodes, but may proliferate quickly if overlooked during splenectomy performed for hematologic disease, thereby allowing for recurrence of the original disorder.

Splenogonadal Fusion

Splenogonadal fusion refers to a rare developmental anomaly that results in the presence of splenic tissue in the left scrotum or adnexa. The aberrant tissue is often connected to the normal spleen by a band of fibrous tissue with or without additional splenic tissue along its course. The most-likely etiology is the adherence of the splenic anlage with the mesonephric ridge in the developing embryo.
fusion is often found in association with limb or anorectal anomalies. In males, these lesions typically present as left undescended testicle, presumed hernia or even an "acute scrotum", the latter secondary to acute congestion of the ectopic splenic tissue. In most cases, the splenic tissue can be safely removed from the underlying testicle, however, this may be complicated in cases in which there is direct fusion with the testicular tissue underlying the tunica.

**Splenic Ectopia (Wandering Spleen)**

Splenic ectopia describes a condition where the laxity of the splenic ligaments allows the spleen to be located anywhere in the peritoneal cavity other than its normal position in the left upper quadrant. The exact etiology is unknown, however, the abnormality most likely results from the failure of the dorsal mesogastrium to give rise to the major supporting ligaments of the spleen. The long splenic pedicle predisposes the spleen to torsion which can result in infarction, an acute surgical condition. A child with a wandering spleen may present with chronic abdominal pain or a painless abdominal mass, although the most common presentation is acute abdominal pain secondary to torsion and infarction. The classic physical exam findings of a notched, elliptical, freely mobile abdominal mass are highly suggestive of a wandering spleen. Diagnosis may be confirmed by ultrasound or computed tomography which demonstrates a mass with morphologic characteristics of a spleen in the absence of a spleen in its normal expected position in the left upper quadrant. Once detected, therapy is based on the indications for operation. Splenectomy is required in cases of infarction, however, if spleen viability is found at operation or if an incidentally discovered wandering spleen is discovered, it may be treated by splenopexy in which the spleen is placed into an extraperitoneal pouch. The use of polyglactin mesh as a buttress to secure the splenic capsule to the diaphragm and retroperitoneum may be a useful adjunct.

**PHYSIOLOGY**

**Normal**

**Hematologic Function**

In many mammalian species, the spleen serves as a major reservoir of erythrocytes; however there is little evidence of this role in humans. In contrast, the human spleen serves as a reservoir for platelets, with up to 50% of the platelet pool sequestered in the spleen at any given time. In hypersplenic states, this proportion is increased. As a result, splenectomy leads to loss of this platelet reservoir, and a rapid increase in the number of circulating platelets which may lead to thrombotic complications. These complications often involve the mesenteric circulation, and are exceedingly rare in children.

The spleen plays an important role in the normal homeostasis of erythrocytes. Immature erythrocytes (reticuloendothelial cells) are retained by the spleen and released into the circulation after achieving maturation. This process involves remodeling of the cell membrane, loss of reticulum, and shrinkage of cell volume. The spleen is responsible for removing intraerythrocytic inclusions such as (Howell-Jolly bodies) and Heinz bodies. The process is commonly referred to as "pitting" and is a direct result of the microarchitecture of the splenic sinusoids. Erythrocytes which have traversed the splenic cords re-enter the circulation through the fine interendothelial gap junctions of the splenic sinus. Normal erythrocytes are distensible, and traverse the small spaces with ease. Cells containing inclusion bodies become less distensible, and are unable to complete this journey intact. A small portion of the cell membrane is pinched off with the cell wall at the splenic sinus aperture, effectively removing the inclusion bodies from the circulation. Other abnormal erythrocytes (spherocytes, poikilocytes) cannot deform sufficiently to enter the splenic sinus, and are trapped in the splenic cords where they are phagocytosed by cells of the reticuloendothelial system. This includes aged red cells in which the membrane is less deformable in part as a result of diminished adenosine triphosphate activity. In addition to decreased deformability, aged erythrocytes acquire immunoglobulin G (IgG) antibody on the cell surface which is recognized by monocytes and phagocytes of the spleen. Immunoglobulin-mediated destruction of these aged erythrocytes takes place after subsequent slow passage through the splenic reticuloendothelial system.

**Immunologic Function**

Normally, the spleen serves as a major storage center for lymphoid cells, accounting for up to 30% of the
T-cell pool, and 15 to 20% of the B-cell population at
any given time.\textsuperscript{17} There is constant flux of the
circulating lymphocyte pool with those stored in the
spleen. The spleen serves as an important source for
IgM antibody, and these levels are diminished
significantly after splenectomy. In addition, factors
involved in activation of the complement system
including properdin and tuftsin are produced in the
spleen.\textsuperscript{18}

Abnormal

Hyposplenism

Hyposplenism refers to decreased splenic function and
phagocytic ability.\textsuperscript{19} Acquired hyposplenia may be
associated with a variety of conditions, and results in
the finding of increased inclusion bodies in the
peripheral smear as well as small erythrocyte
membrane defects. In children, sickle cell disease is
the most common cause of acquired hyposplenism,
and is associated with a gradual loss of splenic function
over several years.

In the normal neonate, developmental hyposplenia
exists due to the immaturity of the white pulp. As a
result, antigen processing is deficient, and intra-
erthrocytic inclusions are common in the neonatal
peripheral smear. Prematurity accentuates this normal
developmental finding in the neonate.\textsuperscript{20}

Hypersplenism

Hypersplenism refers to a state of increased splenic
destruction and sequestration of preformed blood
elements, in conjunction with a relative deficiency of
the same blood element in the peripheral blood as well
as increased production in the marrow.\textsuperscript{21} This
condition is most commonly acquired, and may or may
not be associated with splenomegaly. Portal
hypertension resulting in venous outflow obstruction
is the most common cause of hypersplenism. Other
associated conditions are listed in Table 96.1.

INDICATIONS FOR SPLENECTOMY

The main indications for splenectomy in children are
listed in Table 96.2. Absolute indications for
splenectomy are rare and splenectomy should be
performed only after careful consideration.

Table 96.1: Conditions associated with hypersplenism

- Portal hypertension
- Splenic vein thrombosis
- Congestive heart failure
- Leukemia
- Felty syndrome
- Lupus erythematosus
- Sarcoidosis
- Amyloidosis
- Gaucher disease
- Niemann-Pick disease

Table 96.2: Indications for splenectomy in children

- Chronic Hemolytic anemias
- Hereditary spherocytosis
- Autoimmune hemolytic anemia
- Thalassemia intermedia
- β-thalassemia (with increasing transfusion
requirements)

Chronic Thrombocytopenias

- Idiopathic thrombocytopenic purpura
- Thrombotic thrombocytopenic purpura (refractory to
medical therapy)

Severe Hypersplenism

- Severe cytopenias, splenic infarction
- Myeloproliferative disorders
- Myeloid metaplasia
- Chronic myelogenous leukemia
- Congestive splenomegaly
- Storage diseases
- Parasitic diseases (schistosomiasis, malaria,
leishmaniasis)

Primary Malignant Lesions of the Spleen

- Lymphoma
- Angiosarcoma

Splenic Lesions

- Cysts (congenital; post-traumatic; echinococcal)
- Hodgkin's disease

Trauma

- Hemodynamic instability secondary to splenic hemorrhage

Hematologic Disorders

Hereditary Spherocytosis

Hereditary spherocytosis is inherited as an autosomal
dominant trait, and is a hemolytic anemia that occurs
most commonly in caucasians. A cell membrane
defect causes erythrocytes to be spherical rather than
biconcave, rendering them more fragile and prone to destruction during their passage through the splenic circulation. This condition typically presents as a mild chronic anemia with periodic exacerbations causing more severe anemia. On examination, the spleen is mildly enlarged, and firm. A peripheral blood smear reveals spherocytes, and laboratory findings include an elevated reticulocyte count, increased osmotic fragility, and a negative Coomb’s test. Moderate to severe spherocytosis is an absolute indication for splenectomy, which results in complete resolution of the anemia in almost all cases. Spherocytosis persists after removal of the spleen, however, the lifespan of erythrocytes returns to normal. Since postsplenectomy sepsis is more common in very young children, splenectomy for spherocytosis is usually delayed until the age of at least five years if the underlying anemia is not severe. Most patients respond to medical therapy in this waiting period.

**Sickle Cell Anemia**

Sickle-cell anemia is a common hereditary hematologic abnormality, occurring in 1 in 625 live births in the United States. This condition results from homozygous hemoglobin S resulting in polymerization and sickling of affected erythrocytes in conditions of hypoxia, acidosis, cold, and dehydration. Abnormal hemoglobin detected during electropharesis is diagnostic of this condition. In most cases, the spleen is enlarged by six months of age as a result of increased phagocytosis of sickled erythrocytes which are less distensible and more readily destroyed during their passage through the splenic sinus, with its naturally hypoxic and acidic environment. During acute splenic sequestration crises (ASSC), sudden trapping of blood in the spleen may be substantial, and cause rapid increase in the size of the organ. The volume of blood stored in the spleen during these crises may lead to hypovolemic shock. Older children who have experienced numerous vasoocclusive crises have decreased splenic function and show evidence of splenic atrophy leading to functional autosplenectomy after approximately 10 years. This results from fibrosis and scarring of the splenic parenchyma. In some cases, the spleen persists until adulthood.

The main indication for splenectomy is the development of (ASSC), which is the leading cause of death in sickle cell patients younger than 10 years of age. Patients with severe attacks should undergo splenectomy after recovering from a severe attack, since the risk of recurrence ranges from 40-50% and carries a 20% mortality rate. In most cases, transfusion requirements dictate the severity of the attack and the need for splenectomy. Partial or subtotal splenectomy is advocated in these patients since they are especially prone to developing postsplenectomy sepsis.

**Thalassemia**

Thalassemias represent a heterogeneous group of hereditary hemoglobinopathies which vary in severity. Genetic defects range from partial to complete deletions of genes encoding for globin chains as a result of nucleotide deletions, insertions, or substitutions. The more severe forms are accompanied by diffuse deposition of iron in the splenic parenchyma which is engorged by destroyed abnormal erythrocytes. Hypersplenism results in further red blood cell sequestration and leads to increased transfusion requirements. In severe cases with escalating transfusion requirements, partial or total splenectomy may be indicted. The rate of postsplenectomy sepsis in patients with thalassemias is high, approaching 15%.

**Idiopathic Thrombocytopenic Purpura**

The etiology of idiopathic thrombocytopenic purpura (ITP) is unknown. Chronic ITP is mediated at least in part by IgG binding to platelet associated antigen resulting in phagocytosis by the reticuloendothelial system in the spleen. Acute ITP, is a transient, more self-limiting form of this disorder, and is commonly treated with activity restriction, corticosteroids, and administration of intravenous gamma-globulin. Acute ITP most commonly occurs in children younger than 10 years of age following a viral illness. Symptoms are associated with thrombocytopenia, and include formation of petechiae, ecchymoses, perianal or oral bleeding, and intracranial bleeding.

Systemic corticosteroids increase the platelet count significantly in up to 80% of these patients. The mechanism is believed to be related to inhibition of phagocytosis as well as through stimulation of platelet production. Intravenous gamma-globulin binds to Fc
receptors of the reticuloendothelial cells in the spleen, and inhibits phagocytosis. This treatment is usually reserved for cases refractory to steroids or in patients who are actively bleeding.

In 10-20% of patients with ITP, thrombocytopenia and associated symptoms last greater than six months. These patients are believed to have chronic ITP, and may also show improvement after administration of steroids and IV gamma-globulin. Approximately 20% of patients with chronic ITP will eventually require splenectomy due to medical treatment failure. In contrast, acute ITP almost always resolves after medical treatment, and splenectomy in those cases is only reserved for cases with severe bleeding complications. During surgery for ITP, a careful search for accessory splenic tissue must be conducted to avoid postoperative recurrences.28

**Splenotic Lesions**

**Abscess**

Splenic abscess is rare in children and most commonly a result of an infected hematoma or pseudocyst.29 It is most commonly seen in the immunosuppressed child who is at increased risk from seeding during bacteremia. Also, a splenic infarct resulting from a hemoglobinopathy may become secondarily infected. These patients show signs of sepsis, and complain of left upper quadrant pleuritic pain. The diagnosis is confirmed by CT scan. Solitary abscesses may be drained percutaneously, which allows identification of the organism and directed antibiotic treatment. Multiple, loculated abscesses sometimes respond to antibiotics alone. Empiric antibiotics should be aimed at the most likely organism—Salmonella species being most common in patients with hemoglobinopathies, and Streptococcal and Staphylococcal species most common in post-traumatic infection.30 Immunosuppressed patients with multiple negative blood cultures are most likely to have a fungal infection. The indication for splenectomy is failure to respond to percutaneous drainage and antimicrobial or antifungal therapy.31

**Tumors**

Splenic tumors are rare. Hemangiomas are the most common benign tumor of the spleen, and splenectomy is indicated for large, symptomatic or bleeding tumors. Other benign tumors include adenomas, hamartomas, fibromas, and dermoids all of which rarely require surgical intervention once diagnosed.32 Angiosarcoma and lymphoma represent the two primary malignant tumors of the spleen in children. Most patients have disseminated disease once detected, and often present to the emergency department in hemorrhagic shock secondary to spontaneous splenic rupture. Lymphomas represent the most common malignant lesions of the spleen. In children, non-Hodgkin’s lymphoma involving the spleen usually represents metastatic disease. Splenectomy is not indicated in these patients. In Hodgkin’s disease, chemotherapy is now used in all stages of the disease in order to reduce the dose of radiation therapy. For this reason, laparotomy/splenectomy staging is much less commonly indicated, even in cases where the spleen is directly infiltrated by tumor.

**Cysts**

Splenic cysts can be classified as either congenital, pseudocysts (without epithelial lining), and parasitic.33 Epidermoid cysts are the most common congenital variety. Pseudocysts usually arise after abdominal trauma, and are believed to result from the resolution of a subcapsular or intraparenchymal splenic hematoma. Small pseudocysts do not require further treatment; however, larger expanding pseudocysts should be followed by ultrasound and may be resected with spleen-preserving procedures with good results. Parasitic splenic cysts are rare, but may be caused by E. granulosus (Hydatid) or echinococcus34 (Fig. 96.1). Splenectomy (either total or partial) may be required for large parasitic cysts. Smaller cysts may be enucleated in order to preserve splenic function (Fig. 96.2).

**TRAUMA**

Non-operative management of splenic trauma is a concept that was first introduced by pediatric surgeons in the 1960’s who recognized the potentially life-threatening consequences of postsplenectomy sepsis. Today, this principle is widely accepted, and operative intervention in the management of splenic trauma is reserved only in cases where persisting and uncontrolled hemorrhage from the injured spleen is suspected to be the cause of hemodynamic instability.
Despite the general agreement on a conservative, non-operative approach, some disagreement exists on the acuity of care necessary for the child with an isolated injury to the spleen. Some pediatric surgeons have advocated the monitoring of children with moderate grade splenic injuries in the intensive care unit (ICU) in order to facilitate the early diagnosis of complications including delayed hemorrhage and associated hollow visceral injury. The validity of this approach has been questioned by others who believe that delayed secondary hemorrhage from the injured spleen is a very uncommon event, and such bleeding is almost always associated with a delay in diagnosis or an underlying pathologic condition such as a pseudoaneurysm of the splenic artery. In addition, the incidence of associated hollow-viscus injury appears to correlate with the presence of hemodynamic instability, and not with the grade of splenic injury.

Recently, the American Pediatric Surgical Association (APSA) Trauma Committee sought to define evidence-based guidelines for resource utilization in these patients. A contemporary, multi-institution database of 832 children with isolated liver or spleen injuries was established and analyzed with the ultimate goal of standardizing treatment and promoting consensus among surgeons. Guidelines for intensive care unit (ICU) stay, length of hospital stay, use of pre- and postdischarge follow-up imaging, and length of physical activity restriction were proposed (Table 96.3).

In a follow-up study, these guidelines were prospectively applied to 312 patients at 32 pediatric trauma centers across North America. The authors found that compared with the previously studied 832 patients, the 312 patients who had prospective application of the proposed guidelines had a significant reduction in ICU stay, hospital stay, follow-up imaging, and interval of physical activity restriction within each grade of splenic injury (Table 96.4). This study has led to the belief that safe early discharge from the hospital with fewer limitations on activity can be achieved in children who are hemodynamically stable regardless of the severity of injury to the spleen.

In cases when operation is unavoidable, partial splenectomy or a splenorrhaphy should be attempted if at all possible, particularly in younger children.

OPERATIVE TECHNIQUES

The technique used in splenectomy varies, largely depending on the diagnosis and the indications for the operation. The importance of splenic salvage has been emphasized, however, splenectomy continues to be the operation of choice for certain disorders. Laparoscopic techniques have gained popularity recently and have presented the surgeon with another option for the operative approach to this organ.

Open splenectomy is performed with the child in the supine position and the stomach decompressed with a nasogastric tube. The operation may be performed through either a midline incision or a left upper quadrant transverse incision extended to the flank. A midline incision is appropriate in cases where the operation is being performed for trauma or as part of a staging laparotomy for Hodgkin’s disease. A thorough search for accessory spleens should be conducted during elective splenectomy in patients with hemolytic anemias to prevent recurrence of the disease postoperatively.

In cases of splenic trauma, all efforts should be taken to at least partially preserve the spleen. This can be accomplished more effectively after division of the lateral peritoneal reflection which allows for delivery of the spleen into the surgical wound where splenic repair and salvage can be attempted. Total splenectomy following trauma should only be performed in cases of extreme fragmentation, where the blood supply is entirely interrupted, or when the patient’s hemodynamic status precludes an attempt at splenic salvage. Whether splenic fragment autotransplantation should be considered as an alternate therapy in this latter circumstance remains controversial.

In cases of marked splenomegaly, embolization of the splenic artery and its branches preoperatively can be utilized as a means to reduce the size of the organ, and make attempts at open or laparoscopic removal possible or at least safer.

POSTSPLENECTOMY SEPSIS

Postsplenectomy sepsis (also referred to as overwhelming postsplenectomy infection OPSI) is the most feared complication of splenectomy, particularly in children. Morris and Bullok were the first to propose that splenectomy increases the risk of infection, and this proposal was later verified by King.
and Schuler in 1952 who documented the clinical relationship between splenectomy and infection. The risk of infection is significantly higher in patients undergoing splenectomy for a hematologic disorder. Specifically, the incidence of overwhelming post-splenectomy infection approaches 15% in children with thalassemia compared to 1-2% in patients undergoing splenectomy after trauma. Considering all patients undergoing splenectomy, the incidence of overwhelming infection is approximately 4%, and carries a 50% mortality. Typically, the infections are caused by encapsulated organisms, including Pneumococci, Hemophilus influenzae B, Gonococci, and Escherichia coli. The predominance of infections with encapsulated organisms is attributed to the spleen being the major site of antibody production against these bacteria. For this reason, total splenectomy should be avoided when possible, especially in children younger than two years of age due to the high incidence of postsplenectomy sepsis in this group. In cases where elective surgery is indicated, polyvalent Pneumococcal and H influenza B vaccines should be administered preoperatively. The most effective way to prevent infection is to administer the vaccine 2 to 4 weeks before operation. In all patients, postoperative antibiotics should be administered prophylactically. Penicillin is the most widely prescribed antibiotic for prophylaxis against overwhelming postsplenectomy sepsis. The appropriate duration of prophylactic antibiotic therapy is controversial and ranges between two years and a lifetime. The risk of developing postsplenectomy infection decreases significantly two years and a lifetime after the operation. Education of patients and families about early recognition of postsplenectomy infection is vitally important. A patient who has undergone a splenectomy should be examined by a physician at the onset of any febrile illness. In cases where postsplenectomy sepsis is suspected, the early and liberal use of intravenous antibiotics and supportive treatment are essential for a good outcome.

REFERENCES

Hemangiomas of infancy are the most common vascular tumors of childhood. They affect 1 in 10 Caucasian infants in North America and are less commonly seen in children of African or Asian descent. Although review of the English-language literature published over the past four decades shows no population-based studies that specifically address hemangioma incidence in the Indian subcontinent, my personal experience in visiting medical centers throughout India indicates that these lesions commonly occur.

Hemangiomas of infancy usually present cutaneously in the cervicofacial region (60%), and may appear as focal, segmental, solitary or multiple lesions. They can also involve any anatomic site and may affect the extremities, thoracoabdominal walls and cavities, solid organs, hollow viscera, and brain. Lesions undergo a phase of proliferation and subsequent gradual spontaneous regression. In light of this natural history, many smaller uncomplicated hemangiomas are best left untreated. Less common, lesions can cause function- or life-threatening complications or serious aesthetic concerns, having a serious impact on a child's quality of life. This chapter presents an overview of hemangiomas, describing recent insights into pathogenesis, complex clinical presentations, diagnostic approaches, and treatment strategies. I have prefaced my discussion with a concise nosologic summary of vascular anomalies.

NOSOLOGY OF VASCULAR ANOMALIES

In 1996, a consensus resolution of the International Society for the Study of Vascular Anomalies (ISSVA) designated a classification system of vascular lesions that is currently used worldwide by most experts in the field. Based on the pioneering work of Mulliken and Glowacki, this system comprises two categories of lesions—vascular tumors and vascular malformations (Table 97.1). Within the category of vascular tumors, there are a number of distinct lesions, including hemangioma, kaposiform hemangioendothelioma (KHE), tufted angioma, pyogenic granuloma, and hemangiopericytoma.

Hemangiomas are the most common vascular tumor. They are typically observed at birth or during the first several weeks of life. They undergo an active period of growth characterized by endothelial proliferation and hypercellularity and a subsequent involutive phase that occurs over several years (Fig. 97.1A to D). In contrast, vascular malformations are structural anomalies believed to be caused by errors in vascular or lymphatic morphogenesis. They are subdivided according to their predominant channel type as capillary, venous, lymphatic, arterial, or combined lesions. Unlike hemangiomas, vascular malformations have normal levels of endothelial turnover, are present at birth, never involute, and grow commensurate with the child.

Despite the valiant efforts of the ISSVA to standardize the classification and nomenclature of vascular anomalies, the literature remains replete with outdated terminology that continues to hamper communication among specialists and often results in inappropriate management. Particularly important for clinicians to note, the term "hemangioma" is often misused to label a spectrum of vascular lesions with varying etiologies and natural histories. More specifically, lesions with large blood-filled spaces are sometimes incorrectly termed 'cavernous hemangiomas'; such lesions are generally venous or lymphaticovenous malformations.

HEMANGIOMAS OF INFANCY

Pathogenesis

Hemangiomas of infancy are benign vascular lesions that expand rapidly during infancy and gradually involute during childhood; tumor involution can last for up to 5 to 10 years. Expanding hemangiomas of infancy are composed of proliferating endothelial cells and large numbers of pericytes, mast cells, and fibroblasts. As lesions spontaneously involute, apoptosis of endothelial cells increases and fibrofatty tissue gradually replaces the vascular network.

Although the molecular pathogenesis of hemangioma of infancy is largely unknown, over the past several years new insights have been gleaned from basic and translational research. Numerous investigations have focused on possible molecular factors that control the natural course of hemangiomas, and various cellular markers that distinguish the phases of hemangioma growth and regression have been identified. Studies of the cellular and molecular factors involved in lesion expansion indicate that endothelial progenitor cells are present predominantly in proliferating hemangiomas. Endothelial progenitor cells coexpress the endothelial cell marker KDR and CD133-2, a stem cell-progenitor cell marker. Such findings demonstrate that endothelial progenitor cells comprise a cell population that plays a role in hemangioma expansion.

Proliferating hemangiomas have been shown to have increased expression of type IV collagenase, vascular endothelial growth factor (VEGF), and basic fibroblast growth factor. In involuting hemangiomas, the high expression of basic fibroblast growth factor persists, while the level of expression of VEGF substantially diminishes. Also, as compared to proliferating lesions, involuting lesions show increased expression of apoptosis-associated proteins. Gene-expression analysis comparing proliferating vs involuting has revealed that insulin-like growth factor 2 (IGF-2) is highly expressed during proliferation, but is substantially decreased during involution.

Analysis of messenger RNA expression patterns of genes required for angiogenesis in hemangioma tissues and in hemangioma-derived EC reveal strong expression of the VEGF receptor family and the angiopoietin-Tie family (Tie-1, Tie-1, and angiopoietin 2), Tie-2 in particular, is increased in hemangioma tissues and hemangioma EC compared to normal EC, suggesting that the angiopoietin-Tie-2 system is a molecular regulator of hemangioma of infancy.

Results of a number of studies aimed at determining possible mechanisms of hemangioma involution indicate that an immune-mediated process is involved. DNA microarray analysis has identified indoleamine 2,3-dioxygenase as a potential modulator of the immune response in hemangiomas. Indoleamine 2,3-dioxygenase messenger RNA is present in high levels in proliferating hemangiomas and decreases significantly during involution.

There is compelling evidence that infantile hemangioma derives from placental EC. North and colleagues have identified four markers of hemangioma vessels that are coexpressed in placental vessels; these EC markers include GLUT1 (a glucose transporter enzyme), merosin, Lewis Y antigen, and Fcγ-RIIb. GLUT1 is strongly expressed in infantile hemangiomas, placentas, and the blood-brain barrier though not in normal surrounding vascular endothelium and not in vascular malformations. Other authors have reported hemangioma and placental vessel coexpression of type III iodothyronine deiodinase, indoleamine 2,3-deoxygenase, and IGF2. With the exception of the central nervous system, no other tissue jointly expresses these markers. These studies raise the possibility that vascular precursor cells (angioblasts) aberrantly differentiate toward the placental vascular phenotype at sites of hemangioma development in the fetus. An alternative possibility is that placental EC embolize into the fetal vascular system, becoming a source of hemangioma where they lodge and implant. Corroborating evidence for a placental origin of hemangiomas is the 3-fold higher incidence of hemangiomas in infants born after transcervical chorionic villus sampling, which may cause placental injury and intravascular shedding of placental cells. Data derived from a recent study using molecular profiling indicated a common genetic program between placental and hemangioma endothelium, further supporting the idea of a placental origin of
hemangioma. The positive expression of GLUT1 persists throughout the hemangioma life cycle, making this histochemical marker a valuable tool in distinguishing hemangiomas from other vascular tumors and from vascular malformations.

Dadras et al have shown that lymphatic endothelial hyaluronan receptor-1 (LYVE-1), a marker for both normal and tumor-associated lymphatic vessels, is strongly expressed in proliferating hemangiomas but absent in involuted lesions. These authors propose that vessels from hemangiomas of infancy are arrested at an early developmental stage of vascular differentiation.

**Presentation**

Most hemangiomas of infancy present singularly. About one third of tumors are observed at birth, appearing as erythematous macules, some with a pale halo or a telangiectatic path. Most lesions, however, become evident during the first several weeks of life. Based on anatomic depth, lesions are categorized as superficial (50 to 60%), deep (15%), or combined (25 to 35%), with each of these categories showing a characteristic appearance. Superficial lesions are usually soft, red, and raised and only rarely telangiectatic. Deep lesions, which are sometimes difficult to distinguish from venous or lymphatic malformations, may show a spectrum of appearances and consistencies, ranging from soft and supple to raised and firmer warm masses that are bluish in color. Combined lesions appear as red dermal tumors with epidermal and dermal components, along with a subcutaneous mass that is either blue or flesh colored.

The proliferative phase of these tumors begins in the first few weeks of life and continues for 4 to 10 months. During this time lesions rapidly expand and the superficial component becomes more erythematous or violaceous. The proliferative phase of deep hemangiomas is typically longer, lasting for up to 2 years. Following this phase, the growth rate of lesions stabilizes and lesions grow in proportion to the child. This quiescent period is followed by an involuting phase during which hemangiomas become gray in color. This phase varies in duration, sometimes lasting as long as 5 to 6 years (Figs 97.3A and B). Maximum involution occurs in approximately 50% of children by age 5 years and in 90% of children by age 9 years. In most patients, tumor regression results in restoration of normal skin; however, 20 to 40% of patients exhibit residual skin changes such as laxity, discoloration, telangiectasia, fibrofatty masses or scarring.

**Ulceration**

The most common complication of proliferating hemangiomas is ulceration (Figs 97.4A to E). This complication occurs in 10-15% of superficial lesions and usually leaves behind some degree of scarring.
Ulcerations can become infected and are often quite painful. In rare instances, they can lead to non-fatal hemorrhage. Lesions in perioral and perineal locations are especially prone to ulceration, with factors such as recurrent friction and moisture playing a role. Ulceration can significantly distort or even destroy a facial feature such as the eyelid, nose, ear, or lip.

**PATTERNS OF PRESENTATION AND PROBLEMATIC ANATOMIC LOCATIONS**

Hemangiomas that occur in developmental segments are termed "segmental" lesions. These lesions are less common than localized lesions and have a higher risk of being life or function threatening and of having associated structural anomalies. Large cervicofacial segmental lesions, especially those on the forehead, temple, upper cheek and around the periorbital area can be accompanied by a constellation of anomalies.
that is referred to PHACES association.\textsuperscript{29,30} This association is characterized by a group of anomalies, including posterior fossa brain malformations (e.g., Dandy-Walker malformation), hemangiomas that are typically plaque-like and segmental in the cervicofacial area, arterial abnormalities (especially of arteries supplying the face and central nervous system), cardiac and aortic arch defects (e.g. coarctation, aneurysms, and congenital valvular aortic stenosis), eye anomalies (e.g. optic atrophy, congenital cataracts, and retinal vascular abnormalities), and sternal clefts or supraumbilical raphes (Fig. 97.5A to E). More than 50\% of these patients are affected by various neurologic sequelae, including seizures, stroke, developmental delay, and migraines.\textsuperscript{31} When there is an index of suspicion, it is prudent to refer patients for an ophthalmologic examination, screening echocardiogram, and either magnetic resonance imaging (MRI) or magnetic resonance angiography (MRA). If a central nervous system abnormality is found on imaging, patients should undergo follow-up imaging every 3 months until 18 months of age.

\textbf{Figs 97.5A to E}: Infant with PHACES association. \textbf{A}. At 4 weeks of age had subglottic airway involvement and obstruction. She required a tracheostomy and was treated aggressively with steroids. \textbf{B}. Supraumbilical median raphe and sternal cleft. \textbf{C}. Patient at 14 months; When patient was weaned of steroids, the lesions continued to grow. Weekly vincristine therapy was required to stabilize lesions. \textbf{D}. Posterior fossa Dandy-Walker cyst in a child with PHACES association. \textbf{E}. MRI 3 dimensional reconstruction of aortic arch coarctation of the in a child with PHACES association
In that 65% of patients with lesions that cover a beard distribution (i.e., the chin, jawline, and preauricular areas) have associated airway involvement, such patients should be closely followed and treatment should be initiated if airway involvement is suspected.32

**Periocular and Orbital Hemangiomas**

Periocular hemangiomas can involve the upper lid, lower lid, and or retrobulbar space; amblyopia is reported in 40-60% of cases.33 Because of pressure from the hemangioma on the globe, astigmatism often occurs. Strabismic amblyopia occurs when a hemangioma affects the movement of extraocular muscles. Deprivation amblyopia occurs when there is partial or complete eyelid closure. When this occurs in the first few months of life, it can cause profound visual impairment. Periorbital hemangiomas that impair vision or create pressure on the globe require immediate treatment (Figs 97.6A to D). This may include medical approaches such as topical high-potency steroids, intralesional steroids, systemic steroids, or surgical resection. Ophthalmologic care such as patching the contralateral eye and monitoring the need for corrective lenses is imperative.

**Tip of Nose, Lip and Ear Hemangiomas**

Proliferation of hemangiomas on the tip of the nose can distort normal anatomy and cause splaying of the
nasal cartilage, resulting in what is referred to as "Cyrano nose" deformity (Figs 97.7A and B). Lesions on the pinna of the ear can also deform normal structures and result in ulceration with focal destruction of the auricle. Lesions obstructing the auditory canal can cause temporary conductive hearing loss. Lip hemangiomas frequently regress quite slowly, sometimes leaving residual skin changes. Additionally, lip ulcerations can result in feeding difficulties, secondary infection, and significant scarring (Fig. 97.8).

**Subglottic Hemangiomas**

Hemangiomas can occur anywhere within the tracheobronchial tree, however, they are most commonly seen in the subglottis. More than 50% of patients with subglottic hemangiomas also have cutaneous hemangiomas, which provide an indication for the presence of subglottic lesions. Female infants are twice as likely to be affected as males. Most patients present during the first six months of life, and the earlier the presentation, the higher the likelihood that surgical intervention will be required.

Characteristic symptoms include progressive stridor and retractions. Diagnosis is made on rigid bronchoscopy, and though radiological evaluation (MRI with contrast enhancement) is indicated, it rarely demonstrates extension of the lesion beyond the confines of the subglottis. Lesions are typically asymmetric and usually covered by a normal smooth mucosa (Figs 97.9A and B).

**Lumbosacral Hemangiomas**

Lumbosacral lesions can be associated with underlying spinal cord abnormalities (e.g., tethered spinal cord, lipomeningocele, and diastematomyelia) and with genitourinary malformations, including imperforate anus, recto-scrotal fistula, and renal anomalies (Figs 97.10A and B).

**Multiple Cutaneous Hemangiomas**

Up to 20% of affected infants have multiple cutaneous lesions, and such lesions increase the risk of visceral hemangiomas. The term "disseminated neonatal hemangiomatosis" is used to describe the uncommon
Hemangiomas

presentation of several to hundreds of small, multifocal cutaneous hemangiomas with associated visceral hemangiomas (Fig. 97.11). Most children have numerous hemangiomas, though no specific number of lesions must be present for systemic involvement to occur.

Visceral Hemangiomas

Symptomatic hemangiomas of the viscera are extremely uncommon. Lesions can occur anywhere in the gastrointestinal tract, though the liver is the most common visceral site. As mentioned above, the presence of multifocal cutaneous hemangiomas increases the likelihood of visceral lesions. Important to note, however, visceral lesions can exist without cutaneous involvement.

Hepatic hemangiomas follow a natural history similar to that of cutaneous lesions. Hepatomegaly, anemia, and high-output cardiac failure may be
present. In severely affected patients, an abdominal compartment syndrome may arise from massive liver enlargement. In these patients, the diaphragms are elevated to such an extent that unassisted ventilation becomes impossible. Ultrasonography (US) of the liver in patients with multiple cutaneous lesions sometimes detects a hepatic hemangioma early in the proliferative phase (Fig. 97.12A and B). Such lesions are also occasionally detected on an antenatal US. Rarely, a hepatic hemangioma may parasitize the duodenal or colonic blood supply, leading to significant gastrointestinal bleeding from the transmural tumor. In such cases, endoscopy is important in confirming the bleeding site; however, endoscopic hemostasis is unlikely to be achieved.

In some patients, a small hemangioma that is detected on imaging studies may remain asymptomatic throughout the proliferative phase, requiring no particular intervention. Such lesions warrant clinical vigilance and sequential US studies, with treatment reserved for patients in whom symptoms are apparent.

Hemangiomas of the stomach, small intestine, and colon are rare. As with liver lesions, they are often associated with multifocal cutaneous hemangiomas and become evident only when symptomatic. Mild to life-threatening gastrointestinal bleeding may occur, necessitating repeated blood transfusions. Since an intestinal hemangioma rarely bleeds after the proliferative phase has ended, such a lesion would not be a likely cause of bleeding beyond the first two years of life. Another possible presenting symptom, though less commonly seen, is intestinal obstruction.

Detailed treatment options for visceral lesions are presented in my discussion of management strategies.

**CONGENITAL HEMANGIOMA**

Congenital hemangioma is currently considered a distinct type of vascular tumor. Lesions do not resemble hemangiomas of infancy nor do they exhibit the same clinical behavior. In contrast to hemangiomas of infancy, congenital hemangiomas are fully 3-dimensional at birth. Lesions fall into two major subgroups: rapidly involuting congenital hemangioma (RICH) which regresses by 6 to 14 months of age, and noninvoluting congenital hemangioma (NICH). Based on negative GLUT1 staining results, these lesions together comprise less than 3% of all hemangiomas seen in infancy. They are occasionally diagnosed in utero.

Both RICH and NICH usually present as solitary lesions at birth and rarely coexist in a patient with a typical infantile hemangioma. The most common location for RICH is on the limb, head, or neck. Most NICH occur in the head and neck, trunk, or limbs. These two tumor types share similar morphology and present with a violaceous color and with either fine or
coarse telangiectasias. There is often a pale halo encircling the lesion, and in some lesions there is a central ulceration, linear scar, or central nodularity (Fig. 97.13A to C). Unlike infantile hemangiomas, RICHs leave behind a residual patch of thin skin with prominent veins and little, if any, subcutaneous fat. Both RICH and NICH exhibit fast flow on US and may show flow voids on MRI.40 Both can be misdiagnosed as arteriovenous malformations.

**Diagnostic Evaluation**

Prenatal US has detected congenital hemangioma as early as the 12th week of gestation. Both congenital tumor types (RICH and NICH) initially exhibit fast flow by US and MRI.

The diagnosis of hemangioma of infancy is based on clinical presentation, history, and physical examination. Lesions exhibit varying degrees of compressibility to the limits of their underlying fibrofatty architecture. If lesions are complicated or if surgical intervention is necessary, additional investigation is generally required to determine the extent of involvement and to confirm the diagnosis. US with color flow Doppler is helpful in distinguishing hemangiomas from vascular malformations that may have a similar appearance. On US, hemangioma of infancy appears hypoechoic, well-defined, and heterogeneous in texture, with small cystic and sinusoidal spaces. In most proliferating lesions, a fast-flow pattern is visualized by Doppler US.

Computed tomography (CT) can reveal the extent and involvement of the hemangioma. Additionally, it can be useful in differentiating hemangiomas from lymphatic malformations; however, it can only indicate qualitative differences in blood flow. In the proliferative phase, a hemangioma appears as a well-circumscribed tumor with homogeneous parenchymatous density and intense enhancement. In the involutive phase, it appears heterogeneous with distinct lobular architecture and large draining veins in the center and the periphery.

MRI and MRA are especially valuable in showing the extent of involvement with tissue planes as well as rheologic characteristics. Conventional angiography can provide information about the size of lesions and feeding vessels and can also differentiate hemangiomas from other vascular anomalies; nevertheless, it is reserved for patients who may undergo embolization or surgical intervention.

Differential diagnosis primarily includes other vascular tumors within the ISSVA classification system and malignant tumors such as infantile fibrosarcoma, rhabdomyosarcoma, neuroblastoma and angiosarcoma. Biopsy is indicated only when the diagnosis is uncertain or when the threat of malignancy must be excluded.

![Figs 97.13A to C: Congenital hemangioma, A. At birth B. 6 months of age. C. Age 5](mebooksfree.com)
Management Strategies

As discussed, most uncomplicated hemangiomas spontaneously regress without the need for intervention. In some patients, however, rapidly proliferating lesions can cause a wide spectrum of complications, including infection, hemorrhage, necrosis, airway obstruction, loss of vision, and cardiac failure. As such, these patients almost always require multimodal therapy. Decisions as to possible intervention entail consideration of the size and location of the hemangioma, the presence of complications at diagnosis, the age of the patient, and the rate of tumor growth. Large segmental lesions and life-or function-threatening lesions are likely to mandate immediate treatment. In many patients, the possibility of permanent disfiguration or scarring warrants early intervention.

Therapeutic options include pharmacotherapy, chemotherapy, laser therapy, and surgical excision. Depending on anatomic location and severity of the lesion, these approaches are sometimes combined. Optimally, management strategies for complicated lesions should be individualized and collaboratively planned by a multidisciplinary team of clinicians with expertise in treating vascular anomalies.

Treatment of Ulcerations

The treatment of ulcerations should focus on (1) decreasing pain, (2) preventing secondary infections, and (3) promoting reepithelialization. Topical antibiotics are frequently used. Dressings such as DuoDERM® or Mepilex® that cover the ulceration can provide immediate relief of pain and promote healing. When ulcerations are painful, oral medications such as acetaminophen or acetaminophen with codeine may be necessary. When an associated cellulitis occurs, oral systemic antibiotics are given. Ulcerations on localized cervicofacial lesions and lesions on the trunk and extremities are amenable to surgical resection, which generally results in excellent cosmetic outcomes. When resection is not feasible or desirable, the pulsed dye laser can be used to promote reepithelialization and decrease pain. This approach is particularly useful in anatomic areas that are not amenable to resection, such as extensive facial lesions or lesions of the perineum. Newer products such as imiquimod, an immune modulator that stimulates endogenous interferon production, and becaplermin gel, which promotes wound healing, require further study to assess their usefulness in treating ulcerated hemangiomas.41,42

Pharmacotherapy

Corticosteroids

Corticosteroids are the first line of therapy for the management of complicated hemangiomas of infancy. These agents may be administered topically, intralesionally, or orally. High-potency topical agents such as clobetasol propionate (0.05%, applied twice daily) are useful in treating problematic localized craniofacial lesions.43 Unlike orally administered systemic corticosteroids, these agents have only a limited degree of systemic absorption and are not associated with significant adrenal pituitary axis inhibition. One limitation, however, is that rapidly expanding lesions at the tip of the nose or upper lip may develop ulcerations in response to topical steroid application. Intralvesional corticosteroids are effective in treating smaller localized, problematic lesions, particularly those in the periorbital region. Whereas some surgeons and ophthalmologists prefer to perform this procedure with the patient under general anesthesia, others prefer the use of a topical anesthetic on an outpatient basis. A long-acting steroid such as triamcinolone can be used together with a short-acting steroid such as cortisone acetate or betamethasone acetate, in a total volume that generally does not exceed 2.5 mL. The dose and volume are dependent on the size of the lesion. A 26-30 gauge needle is used and injections are made directly into the hemangioma in different directions through the same needle hole. Direct pressure is subsequently applied for 2 to 10 minutes to prevent bleeding. Although this approach is associated with a 70-90% response rate, a known complication is the risk of retinal artery embolization and thrombosis, with resulting blindness. To diminish this risk, funduscopic retinal examination should be performed as the lesion is slowly injected so to recognize evidence of imminent retinal artery involvement. Although this approach is associated with a 70-90% response rate, a known complication is the risk of retinal artery embolization and thrombosis, with resulting blindness. To diminish this risk, funduscopic retinal examination should be performed as the lesion is slowly injected so to recognize evidence of imminent retinal artery involvement. Although we have observed some Cushingoid features in patients treated with intralesional steroids, the systemic effects of intralesional and topical steroid therapy have not been well studied.
Oral corticosteroids are commonly the first line of treatment for lesions that threaten life, limb, vital function, or significant tissues. As with intralesional corticosteroids, they are associated with a 70 to 90% response rate (Fig. 97.14A and B). Although their specific mechanism of action is unclear, it is believed to be an antiangiogenic effect that decreases endothelial cell expansion and causes endothelial cell apoptosis. Because there are no prospective randomized controlled studies that have investigated dosing or efficacy, current dosing strategies are based on retrospective studies. The general recommendation for oral steroids is a starting dose of 2 to 4 mg per kg daily of prednisolone as a single morning dose. Typically, an assessment of response is performed 2 weeks after this regimen is initiated. If the response is positive, this high dose is maintained for 4 to 6 weeks and then tapered over 4 to 6 months. Ranitidine or other antiacid medication is given concomitantly to diminish the risk of gastric irritation. For patients who undergo steroid therapy over an extensive period of time, some clinicians prescribe trimethoprim/sulfamethoxazole to prevent *Pneumocystis carinii*.

Reported short-term side effects of systemic corticosteroids include irritability, gastric irritation, diminished linear growth and weight gain, nonsystemic fungal infections, and Cushingoid appearance and suppression of the hypothalamic-pituitary axis. Potential side effects of steroid use include immunosuppression, hypertension, significant but reversible suppression of the hypothalamic-pituitary-adrenal axis, hyperglycemia, ophthalmologic changes, myositis, osteoporosis, cardiomyopathy and neurologic changes.

Patients undergoing systemic glucocorticoid therapy should be monitored for potential side effects. Close monitoring of height and weight, blood pressure, developmental milestones, and adrenal suppression at the end of treatment should also be done. Live vaccines should not be given to these patients. If exposure to varicella occurs, a physician should be called immediately and the administration of VZIG should be considered. Patients should be seen for significant fevers and followed regularly. They should be instructed to increase their dosages during stresses related to illness or surgical procedures.

**Chemotherapy**

**Vincristine**

For patients who have failed or are unable to tolerate other medical therapies, chemotherapy with vincristine is an option. It interferes with mitotic spindle microtubules and induces apoptosis in tumor cells *in vitro*. Vincristine has a known side effect profile that includes peripheral neuropathy, constipation, jaw pain and irritability, electrolyte disturbances, and neurological problems. Because it is a vesicant, it is best delivered through central venous access. Only two studies have been reported pertaining to chemotherapy with vincristine following failed steroid therapy or significant complications from steroid therapy. In one study, Enjolras and colleagues initiated vincristine in 10 patients with a mean age of 8 months and continued for a mean duration of 6 months. Nine of 10 patients had a significant response; the remaining patient had a partial response. The average time to response was 3 weeks. Adams et al. reported similar findings.

**Interferon-alpha**

Interferon-α is an antiangiogenic agent that decreases endothelial cell proliferation by down-regulating basic fibroblast growth factor (bFGF). It is used as a tertiary therapy for life-threatening hemangiomas. Studies have reported the efficacy of interferon alpha-2a and
interferon alpha-2b, showing a complete response rate ranging from 40 to 50% with doses between 1 and 3 million Units/m²/daily.\textsuperscript{49,50} Nevertheless, neurotoxicity resulting in spastic diplegia and other motor developmental disturbances has been reported with the use of all interferon preparations in 10 to 30% of patients. Moreover, some patients experience permanent spastic diplegia.\textsuperscript{51} It is thus prudent for clinicians to conduct neurologic examinations prior to therapy and every month during the course of therapy. Laboratory evaluations should be done twice a month.

**Laser Therapy**

Laser treatment of hemangiomas has long been controversial. Although there is no substantial body of evidence indicating that pulsed-dye laser (PDL) therapy prevents the growth of hemangiomas or causes involution to occur significantly faster, it is commonly used to treat small lesions. The results of a prospective, randomized controlled study conducted Batta et al has shed light on this debate.\textsuperscript{52} These authors compared outcomes of patients who underwent PDL laser therapy to those of patients who received observation alone. They found that the number of children whose lesions showed complete clearance or minimum residual signs at 1 year was not significantly different from the number in PDL-treated and observation groups. Moreover, PDL-treated infants were more likely to have subsequent skin atrophy and hypopigmentation. The only objective measure of resolution with PDL treatment was a more rapid decrease in hemangioma redness.

There are, however, a number of specific indications for PDL treatment. It is advocated for the treatment of ulcerated hemangiomas in that it decreases pain and promotes more rapid reepithelialization. The PDL is also effective for treating the residual telangiectasias that remain after lesion regression. In a small number of patients, particularly those with segmental lesions, ulceration may worsen after laser treatment.

Since the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser system has a greater depth of penetration than the PDL, several authors have reported its successful use in treating the deeper component of hemangiomas. The Nd:YAG laser is also used for intralesional photocoagulation. Both the carbon dioxide (CO\textsubscript{2}) laser and the erbium (ER:YAG) laser are useful for resurfacing wrinkled and scared skin following involution.

**Surgical Excision**

If feasible, surgery is indicated in a number of clinical circumstances: (1) when hemangiomas present a threat to function or are associated with complications (e.g., persistent ulceration, significant hemorrhage, or infection) and do not respond to pharmacotherapy or other less invasive alternatives; (2) when they have a high probability of leaving a bag-like fibrofatty residuum, such as seen in pedunculated hemangiomas; (3) when required to revise residual scars after lesions have involuted; (4) when lesions persist beyond a reasonable period of time or grow atypically; and (5) when there is a perceived emotional burden on the child or family and the lesion can easily be removed, leaving no significant cosmetic deformity. The timing of surgery remains controversial, particularly in regard to performing early surgery on disfiguring hemangiomas with post-involution outcomes that are difficult to predict. In such cases, the potential risks must be weighed against numerous factors, including the likely prognosis, the rate of involution, and parental expectations and desires. For example, nasal tip hemangiomas commonly require surgical intervention. They are usually medically managed in infancy with intralesional steroids for smaller lesions and systemic steroids for larger lesions. Staged resection should be contemplated in early childhood. If surgical excision is required to avoid the psychosocial consequences of a visible hemangioma, the operation should be performed during the preschool period, when the child is beginning to develop a defined body image.

The surgical approach is highly dependent upon the size and location of the hemangioma. Although lenticular excision enclosure is an established approach for localized lesions, the length of scarring is a major drawback (Fig. 97.15A and B). A particularly useful technique for localized lesions in most anatomic sites is circular excision and pursestring closure.\textsuperscript{53} This technique can be used at any phase in the clinical course of a lesion. It reduces both the longitudinal and transverse dimensions and converts a large circular lesion into a small ellipsoid scar. No other excision and
Hemangiomas

1093

The closure technique results in a smaller scar (Fig. 97.16A to D). Because normal skin and subcutaneous tissue are relatively lax, this technique is unlikely to result in significant distortion of surrounding structures. In addition, the scar can be readily revised and made even smaller or placed in desirable skin crease if necessary.

TREATMENT FOR SPECIFIC LESIONS

Subglottic Hemangioma

Traditional management of a subglottic hemangioma has thus been placement of a tracheostomy tube, with the expectation of decannulation between 1 to 2 years.
of age. In children with mild to moderate symptoms, high-dose systemic steroids may cause involution of the lesion and prevent the need for other surgical intervention; however, their prolonged use is strongly discouraged. Although a number of alternatives to tracheostomy placement have been used (e.g., intralesional steroids, prolonged intubation, CO₂ and KTP laser ablation, and microdebrider resection), they are associated with drawbacks such as inadequate removal of the hemangioma and the development of subglottic stenosis. For children with moderate to severe symptoms, surgical resection of the localized subglottic hemangioma is the preferred intervention of some surgeons. This is at least in part due to the association of subglottic hemangioma with mild to moderate congenital subglottic stenosis in the majority of cases. This approach permits removal of the hemangioma and simultaneous repair of the congenital subglottis stenosis if present. Segmental hemangiomas associated with subglottic hemangiomas are treated with systemic agents such as steroids or vincristine. Tracheostomy should be reserved for patients who fail medical therapy.

Parotid gland hemangiomas can be superficial and deep and can grow rapidly, causing extrinsic compression of the upper pharyngeal airway. These lesions can proliferate for up to 12 to 16 months and require systemic treatment if the airway is compromised.

Visceral Hemangiomas

Liver Lesions

Patients with asymptomatic liver hemangiomas detected on imaging studies should undergo both routine sequential physical examinations and imaging studies. Treatment should be reserved for patients in whom symptoms are apparent or there is significant liver enlargement (Fig. 97.17). Larger lesions or those causing heart failure require immediate treatment. Systemic corticosteroids are the preferred initial therapy; however, unresponsive lesions may necessitate the use of vincristine or interferon. For patients in whom heart failure persists or worsens, performing a hepatic arteriography may have to be considered. Embolization is likely to be useful when there are direct macrovascular shunts through the lesion. Both angiography and embolization are associated with significant rusk of injury to the femoral access vessel or embolized visceral vessels, and should be performed only by an interventional radiologists who are highly skilled in using these techniques in infants.35

Surgical resection of the hemangioma is generally not indicated. Liver transplantation should be considered only when tumors are unresponsive to therapy, involve the entire liver, and are associated with unremitting abdominal compartment syndrome.54 Many of these large lesions are associated with profound acquired hypothyroidism.55 Some hemangiomas have been shown to express type 3 iodothyronine deiodinase, which inactivates circulating thyroid hormone; thyroid hormone may thus be destroyed by the tumor more rapidly than the thyroid can produce it. Such patients require large doses of exogenous hormone replacement. Since hypothyroidism may not develop until the hemangioma undergoes significant growth, repeated thyroid testing in the presence of such growth is indicated.

Other Lesions of the Gastrointestinal Tract

Treatment of hemangiomas of the stomach, small intestine, or colon is based on severity of symptoms, with gastrointestinal bleeding varying from mild to life threatening. If symptoms can be managed with persistent and aggressive blood replacement and pharmacotherapy, these are often the most prudent
treatment strategies. Bleeding will diminish and cases after lesions enter the involution phase, which in many cases can be accelerated with angiogenesis inhibitors. A small isolated hemangioma of the stomach or colon can be banded endoscopically, but this is not without risk of perforation or increased hemorrhage. Occasionally, a focal lesion may be amenable to treatment with other endoscopic techniques such as multipolar thermocoagulation or argon plasma coagulation. For lesions visible by endoscopy, intralesional injection with corticosteroid may also be considered. Indications for excision include complications such as intussusception or obstruction, uncontrollable ulceration with hemorrhage or perforation, or infection. A surgical approach is not indicated when there is diffuse multifocal involvement of the gastrointestinal tract. Such lesions are more appropriately treated with corticosteroids, interferon alpha 2a, or other antiangiogenic agents.

**Congenital Hemangiomas**

In a patient with lesions that rapidly involute (RICH), observation is generally the first line of treatment. Involution may begin very early in the neonatal period, causing crusting and scaling on the surface of the lesion. Preventing ulceration is often accomplished by applying a petroleum-based emollient to the surface of the lesion several times daily. In patients in whom ulceration does occur, adherence to good wound care practices, pain control, and treatment of secondary infection is essential. Once spontaneous tumor regression is complete, residual fibrofatty tissue and scarred skin can be excised to improve cosmesis. Noninvoluting congenital lesions (NICH) require excision. For larger lesions, preoperative embolization may be required to reduce intraoperative bleeding.

**OTHER VASCULAR TUMORS**

The classification of vascular tumors encompasses several other less commonly seen tumors, including kaposiform hemangioendothelioma, tufted angioma, and angiosarcoma.

**Kasabach-Merritt Phenomenon and Kaposiform Hemangioendothelioma**

Kasabach-Merritt (K-M) phenomenon is a coagulopathy characterized by profound thrombocytopenia (a platelet count of 300 to 50,000 per cubic millimeter) caused by platelet trapping and disseminated intravascular coagulation that leads to profound fibrinolysis and hypofibrinogenemia. Until the 1990s, this condition was mistakenly thought to be a life-threatening complication of some hemangiomas. However, it is now recognized as distinct from classic hemangioma and is associated primarily with kaposiform hemangioendothelioma (KHE), and far less commonly with tufted angioma.

KHE is an aggressive vascular tumor, presenting at birth in about 50% of cases and usually appearing within the first year of life in most other cases (Figs 97.18A and B). The tumor is usually solitary and...
multifocal lesions rarely occur. In contrast to hemangiomas of infancy, KHE has no female preponderance and typically occurs in the proximal arms and legs and the trunk (including the retroperitoneum); craniofacial lesions are uncommon. KHE is typically manifested as a plaque-like mass with a deep red-purple hue. It is associated with surrounding subcutaneous edema and induration, the degree of which depends upon the amount of trapped blood elements and the extent of intralesional bleeding in tissue. KHE does not completely regress and can involve adjacent muscle and bone, but does not metastasize. The mortality rate of this tumor is high, ranging from 20 to 37%, with bleeding being the primary cause of death.\(^5^9\) Retroperitoneal involvement has been associated with a particularly poor outcome. A number of therapies have been reported in the treatment of K-M phenomenon, but none have been uniformly effective.\(^5^8^-^6^1\) Treatment involves the use of steroids, interferon-alpha, antifibrinolytic agents, and chemotherapeutic agents, including cyclophosphamide, vincristine and actinomycin.

**Tufted Angioma**

Congenital and acquired tufted angioma usually present as an erythematous, slightly tender, indurated macule or plaque in a child younger than age 5. As with KHE, tufted angioma is typically located along the midline axis of the neck, upper trunk, and extremities. Unlike KHE, it is characterized by rounded nodules or tufts of densely packed capillaries and pericytes in the mid-dermis, which bulge into and compress large, thin-walled vessels at the periphery of the nodules. MRI imaging scans have demonstrated that tufted angioma invade the skin and subcutaneous fat and muscle.

Tumors exhibiting gradations between KHE and tufted angioma and containing elements of both lesions have been described. Since both can be associated with K-M phenomenon, they may represent variations of the same tumor.

ARTERIOVENOUS MALFORMATIONS

Classification and Pathology

Vascular malformations, are errors in morphogenesis and are populated by mature vascular endothelium, with normal endothelial turnover, and normal numbers of mast cells. These lesions are present at birth, though not always apparent, grow with the child and do not involute.

Vascular malformations need to be differentiated from hemangiomas. In a series, quantitative assessment of mast cells was done in cellurally dynamic and adynamic vascular malformations. There was an increased number of mast cells in growing stages and during initial involution of strawberry hemangiomas that decreased in the later involuting stages. However, the mean number of mast cells in cellularly adynamic lesions, i.e. port wine stains was 4.8, and in congenital arteriovenous malformations, it was 3.6, comparable to that in normal skin where the mean number of mast cells was 3.2.

Vascular malformations are further classified as capillary, venous, arterial (with or without fistula) or lymphatic anomalies.

A recent revision of Mullikan and Glowacki’s classification has broadened the category of vascular tumors of infancy to include hemangiopericytoma, pyogenic granuloma, tufted angioma, and kaposiform hemangioendothelioma.

As in the case with hemangiomas, the terminology used to describe malformations has been very confusing. Many authors continue to use terms like port wine stain when describing capillary malformations. The incidence of arteriovenous malformations is 1-4%.

Port wine stains, intradermal capillary malformations, are seen in 0.3% of newborns Figure 98.1. Approximately 25% of affected individuals have a positive family history of other vascular anomalies. These lesions are found frequently on the face in the distribution of the trigeminal nerve. When associated with the trigeminal nerve there is an 8% incidence of ocular and central nervous system disorders. The variance in color of port wine stains is attributable to ectatic postcapillary venules.

Presentation and Clinical Course

Unlike hemangiomas, malformations are present at birth and grow as the child grows. Table 98.1 outlines the clinical stages of a hemangioma (Figs 98.1 to 98.4) Table 98.2 gives the differences between a

hemangioma and malformation. One distinguishing feature of venous malformations is that they are emptied of blood with compression. The most important distinguishing feature is that malformations do not involute. Vascular malformations have no predilection for either sex and may demonstrate sudden growth secondary to trauma, infection or hormonal modulation. The appearance of malformations is dependant on the type of vessel involved. Venous malformations appear bluish and can be confused with subcutaneous hemangiomas. Vascular malformations are categorized based on the types of vessels involved (capillary, venous, arterial, lymphatic, or mixed) and flow characteristics. Arteriovenous malformations and fistulas are high flow lesions that present with pulsations, bruits, or thrills and can expand with rises in blood pressure. 

The two types of congenital arteriovenous malformations are macrofistulas and microfistulas. Macrofistulas occur as solitary lesions in the head and neck and can result in distal ischemia. Microfistulas are usually multiple, occur in the lower extremity and do not cause distal ischemia. Low flow lesions are lymphatic, venous, capillary or combined. Doppler ultrasonography is useful in delineating microfistulas. Vascular malformations on CT present as tissue heterogeneity. Magnetic resonance imagery (MRI) demonstrates both the extent of involvement within tissue planes and rheologic characteristics. During the proliferative phase, T1 and T2 weighted MRI images demonstrate a lobulated soft-tissue mass with feeding and draining vessels. Angiography can be utilized to define the anatomy and hemodynamics of these malformations and is utilized in patients requiring therapeutic embolization.

In contrast to hemangiomas, arteriovenous malformations can be complicated by consumption coagulopathy. Stasis with dilated ecstatic venous channels precipitates the coagulopathy. Port wine stains are intradermal capillary malformations that are present at birth and persist throughout life without regression. Sturge-Weber syndrome is the most common disorder associated with port wine stains. The port wine stain in Sturge-Weber is in the V1 and V2 distribution of the trigeminal nerve and is associated with leptomeningeal venous malformations, and atrophy and calcification of the underlying cerebral cortex. Consequently these patients may demonstrate mental retardation, focal motor seizures, hemiparesis, visual field defects and glaucoma. It is recommended that children with facial port wine stain should undergo fundoscopic examination and CT scan. In addition, reflectance spectroscopy can delineate the level and degree of ectatic vessels and aids in the planning of laser therapy.

Klippel-Trenaunay syndrome is a complex congenital malformation that may affect the upper or lower extremities, and less commonly the trunk, head or neck. The three main components are varicosities and venous malformations, port wine stains, and hypertrophy of the bone and soft tissue. Venous drainage is abnormal because of persistent embryonic veins, agenesis, hypoplasia, vascular incompetence, or aneurysms of the deep veins. An important distinction is the absence of significant arteriovenous shunting.

Treatment

Unlike hemangiomas, the endothelium of vascular malformations is not hyperplastic and exhibits normal turnover and is not susceptible to anti-proliferative treatments like steroids, interferon, or radiation/chemotherapy. Prior to surgical management of arteriovenous malformations any underlying consumptive coagulopathy should be treated. The treatment of venous malformations includes elastic compression garments for lower extremity lesions with analgesia for pain control. Sequential compression devices must be used with caution because of the risk of embolism. Intervention is mostly indicated with large lesions or with venous malformations of the head and neck. Lesions of the head and neck often involve neural structures and resection may be difficult. Good results have been reported with percutaneous injection of the sclerosing agent sodium tetradocyl sulfate at doses of 2-4 ml. Others report favorable results with injection of 95% ethanol, however alcohol should be used with care since it can pass through arteriovenous shunts into normal tissues causing necrosis. Cavernous sinus thrombosis has also been seen with injection of sclerosing agents therefore low doses are recommended. Ethibloc has been used with good results. It is biodegradable and more viscous than ethanol and less likely to diffuse into nearby tissues. The argon, YAG, and nd:YAG lasers have all shown
good results particularly with intraoral lesions. Repeated treatments may be necessary because these lesions tend to recur after photocoagulation. The treatment of choice for port wine stains is laser photocoagulation. The flashlamp-pumped pulsed-dye laser has been used to successfully lighten these lesions.

Management of Klippel-Trenaunay syndrome is primarily nonoperative. Those patients with patent deep veins can be considered for excision of symptomatic varicose veins and venous malformations. Preoperative evaluations should include MRI and contrast venography.

LYMPHANGIOMAS

Classification and Pathology

Lymphangiomas are a heterogeneous group of benign malformations of the lymphatic system that consist of localized or generalized anomalous lymphatic channels and cysts. Lymphangiomas can present in any lymphatic bed and in order of decreasing frequency occur in the cervicofacial region, axilla, thorax, and extremities. There are two morphologic types, macrocystic and microcystic, which are often combined. Macrocystic lymphatic malformations are soft, large, smooth translucent masses under normal or bluish skin. Microcystic lymphatic malformations are firm, tiny cutaneous vesicles that permeate the skin and muscles and give the impression of brawny edema. Classification of congenital abnormalities of the lymphatic system has been based on pathology and on clinical presentation.

Presentation and Clinical Course

Overall, lymphangiomas account for 6% of the benign tumors found in the pediatric population. Both sexes are affected equally. Approximately 65% of lymphangiomas present at birth, and 90% appear by the second year of life. The size of a lymphatic malformation may increase due to intralesional hemorrhage, cellulitis, or increasing fluid accumulation noted with viral or bacterial infections. Pure lymphatic malformations or combined lymphaticovenous malformations, such as Klippel-Trenaunay syndrome, can be associated with soft-tissue and skeletal hypertrophy. Disfigurement is the principal reason patients seek medical attention. Spontaneous regression is rare, and malignant degeneration is unlikely.

History and physical examination usually suggest the diagnosis of lymphangiomas. The differential diagnosis includes lipoma, dermoid cyst, branchial cyst, thyroglossal duct cyst, teratoma, thyroid tumor, neurofibroma, and meningoencephalocele. Plain films are useful to evaluate the airway. Ultrasound and CT scan can determine whether the lesion is cystic or solid. MRI is useful to assess extension of the lesion (Figs 98.5 to 98.7).

Treatment

Surgical excision is indicated for lesions that interfere with function, cause major cosmetic disfigurement, or become easily infected. Lymphangiomas that obstruct the erodigestive tract may require aspiration, incision and drainage, tracheostomy, or feeding tube
conditions. Expectant management is also advised initially for recurrent lesions; spontaneous regression was noted in 12% of patients who had a recurrence after initial complete excision. They also noted that the type of procedure and the site of the lesion were important factors in the recurrence rate. Neck lesions had a fairly low recurrence rate after complete excision (12%) and internally located lesions, other than head, trunk, and extremities, had the lowest recurrence. Aspiration, intrallesional injection of bleomycin, Ethibloc, or OK-432, and laser excision were associated with high recurrence rates.

CYSTIC HYGROMA

Presentation and Clinical Course

Cystic hygromas classically appear in the cervical, axillary, and inguinal areas. These macrocystic lymphangiomas are dysplasias that arise from the sequestration of lymphatic tissue that fails to communicate with the vascular tree. Grossly, these lesions are multilobular and multilocular cystic masses. Microscopically, the cyst wall consists of a single layer of flattened endothelium. In children afflicted with this condition, the cystic hygromas are present in 50-60% of infants at birth, and at least 90% are present by the end of the second year of life. They occur equally in males and females, except for inguinal hygromas, which are five times more common in males.

The lymphovascular system begins to develop at the end of the 5th week of gestation, approximately 2 weeks after the cardiovascular system. There are 6 primary lymph sacs: 2 jugular sacs near the junction of the subclavian veins with anterior cardinal veins (the future internal jugular veins); 2 iliac lymph sacs; 1 retroperitoneal lymph sac near the root of the mesentery; and the cisterna chyli dorsal to the retroperitoneal lymph sac. The connection of the embryonic lymph system to the venous system is completed at 8 weeks gestation. Maternal-fetal ultrasound has allowed cystic hygromas to be identified early in gestation and to be followed. Nuchal cystic hygroma, when present at the time of a second-trimester scan, has a strong association with aneuploidy, 45X, trisomy 21 and trisomy 18. When a normal karyotype is present, the cystic hygroma may signal the presence of a single gene disorder such as Noonan syndrome, Robert’s syndrome, or polysplenia.
syndrome. It is likely that many cystic hygromas associated with both Turner’s and Noonan’s syndromes regress; this regression may explain the webbed neck observed in children with these conditions.21

Cervical cystic hygroma presenting late in gestation, generally is not associated with hydrops or other anomalies. Patients should be advised about the prognosis according to category: (1) 1st trimester diagnosis with karyotypic abnormality-59% chance of poor outcome; (2) 1st trimester diagnosis without karyotypic abnormality-89% chance of reaching viability with dysmorphic sequelae occurring in 20%; (3) 2nd and 3rd trimester diagnosis (before 30 weeks) guarded; and (4) 3rd trimester diagnosis after 30 weeks gestation - good prognosis.21 Seventy five percent of cystic hygromas are seen in the neck, 20% in the axilla, and the remaining 5% are distributed throughout the body in the mediastinum, retroperitoneum, and groin. The majority of cystic hygromas affecting the neck occur in the posterior triangle. Those occurring in the anterior triangle are often associated with intraoral lymphangiomas, and are the ones most prone to cause pharyngeal compression and airway compromise. The presenting complaint is a soft mass in the posterior triangle of the neck. They are transilluminant unless intracyst hemorrhage has occurred. The characteristic location and consistency of these lesions allow easy differentiation from other cervical masses.

Hayward et al reported 2 cases in which infants presented with congenital cervicothoracic masses. Both were initially diagnosed as having lymphatic malformations (cystic hygroma) based on history, physical findings, radiologic assessment and in one instance, biopsy. Subsequent excision showed both lesions to be congenital fibrosarcomas. These cases emphasize that rare congenital tumors can mimic the clinical and radiological appearance of the relatively common lymphatic malformation. The authors concluded that a congenital lesion that does not fit the classic history and physical findings of a vascular or lymphatic anomaly should be imaged radiologically and biopsied.22

Lymphatic malformations generally grow at a rate proportionate to that of the child. These lesions can enlarge suddenly due to infection or intralesional bleeding. Of all cervical hygromas, 2-3 % are associated with mediastinal extension. All patients with cervical cystic hygromas should have a preoperative chest X-ray to determine mediastinal involvement.19 (Figs 98.9 and 98.10).

Treatment

Prenatal ultrasound and MRI provide information regarding compression and obstruction of the fetal airway by neck masses.23 This information is useful in determining if a controlled delivery with ex utero intrapartum treatment is necessary. The EXIT (ex utero intrapartum treatment) procedure was designed initially for reversal of tracheal occlusion performed in fetuses with severe congenital diaphragmatic hernias. This procedure ensures a stable fetal

Fig. 98.10: CT scan showing mediastinal extension of a cystic hygroma

Lymphangioma is an entity caused due to anomalous lymphatic channels that are in close proximity to the vital structures like major vessels and nerves. Surgical excision in toto is associated with a high risk of damage to the facial nerves that leaves behind a disfigured face that is not acceptable by the patient as well as the surgeon. This has led to development of alternative methods of treatment of which OK-432 is one. The other aspects of management of lymphangiomas have been discussed in the previous chapter.

**LAUNCH OF OK-432**

OK-432 was launched after its approval for cancer by the Japanese Ministry of Health and Welfare in 1975, and was approved by this Ministry for the additional indication of lymphatic malformation in 1995.

OK-432 contains Lyophilized powder of Strep-tococcus pyogenes (A group, type 3) Su strain cells treated with benzylpenicillin. As components of culture medium in the manufacturing process, materials derived from bovine heart, bovine skeletal muscle, bovine bone marrow, bovine fat tissue, bovine connective tissue, and bovine milk, and materials derived from porcine heart, porcine pancreas, and porcine stomach are used. It was recognized as a potent biological response modifier.1

**OK-432 IN LYMPHANGIOMA**

In 1986, Professor Shuhie Ogita* used OK-432 in cystic lymphangioma and published their results in 1987.2 (Fig. 99.1). Most of the published work on the use of OK-432 in lymphangioma has been accredited to him.3-6

**MECHANISM OF ACTION IN LYMPHANGIOMA**

The local administration of this product into lymphangioma induces inflammatory reactions, causes the induction of macrophages and induces the production of cytokines such as TNF. All inflammation mediated cytokines are involved. OK-432 increases the permeability of endothelial cells. This series of events accelerates the excretion of lymph, thus reducing the size of lymphatic vascular lumen (humans). The sclerosis of the cyst wall causes decreased production of cyst fluid and increased permeability of the endothelial cells causes increased collateral lymph drainage. The seepage of fluid thus causes shrinkage of the cyst. There is a difference in the response rate between cystic and cavernous lymphangiomas (Fig. 99.2). Figure 99.3 depicts the mechanism of action.

---

*This chapter is dedicated to Late Dr Shuhei Ogita, the man who is credited with the use of OK-432 in pediatric lymphangioma.
Dosage and Administration of OK-432 for Treatment Lymphatic Malformation

OK-432 is suspended in isotonic sodium chloride solution to prepare 0.05-0.1 KE/ml solutions. As a general rule, the dosage equals the amount of aspirated fluid collected from lymphatic malformation. The maximum dosage is 2 KE/injection. The dosage may be adjusted depending on the patient’s age and symptoms. In this context, generally, 1-5 KE Picibanil injection is enough for a course of treatment per lymphatic malformation patient. [1.0 KE (Klinische einheit/clinical unit) = 0.1 mg (dried bacterial cells)]

It is usually supplied in 1 KE vials of OK-432, and the 5 vials/box package. The expiration date is two years from production.

Some have given the injection under ultrasonography guidance to yield good response without complications. Depending on the size, location, and anatomical relationship of the airway while others have even used general anesthesia.7,8

PRECAUTIONS

Due to the known sensitivity toward OK-432, it is advisable to start treatment with a low dose and gradually increase the dose while monitoring the patient’s condition.

As shock may rarely occur, the patients or their relatives should be well informed and a consent taken before administration. Facilities for emergency care should be available to ensure that patients can be treated immediately after the onset of shock. It is advisable to perform a skin test with a diluted solution of benzylpenicillin before the administration of this product. During administration, the general condition of patients should be closely monitored. If any abnormalities are observed, the administration should be immediately discontinued and appropriate measures taken.

OK-432 is a preparation of whole bacterial cells that are incapable of growing in any culture media, and is to be administered repeatedly. Therefore, it should be administered with care while monitoring for the onset of adverse reactions. The dose should be minimized and the patient carefully observed since postinjection local swelling may cause a compression of the trachea or stridor (especially injection into the neck).

The injection should not be injected at innervated sites. If insertion of the injection needle evokes intense pain, or if blood flows back into the syringe, the needle should be withdrawn immediately and injected at a different site. Intramuscular injection to infants and children should be kept to the absolute minimum.

After administration of OK-432, the patient should be carefully monitored. After a drug-free period, OK-432 should be administered with care starting with a low dose. The risk of malign diseases has to be excluded before the commencement of the Picibanil treatment.9

CONTRAINDICATIONS

OK-432 is contraindicated in patients with a history of shock caused by OK-432 or benzylpenicillin. A history of hypersensitivity to OK-432 or other penicillin antibiotics is a relative contraindication. OK-432 should be administered carefully in patients with
cardiac or renal diseases or in patients with a personal or familial predisposition to allergic reactions such as bronchial asthma, rash or urticaria.

**ADVERSE REACTIONS**

The reported adverse reactions during treatment of Lymphangioma include swelling and redness, fever, pain and tenderness. The major abnormal laboratory values were increased WBC in 64% and increased CRP in 71.8%.

**Major Adverse Reactions**

1. **Shock:** Since shock may occur, patients should be closely monitored. If any abnormalities are observed, the administration of this product should be discontinued and appropriate measures taken.

2. **Interstitial pneumonia:** Since interstitial pneumonia may occur or be exacerbated, patients should be closely monitored. If abnormalities such as fever, cough, dyspnea and abnormal chest X-ray findings, are observed, the administration of this product should be discontinued and appropriate measures taken (e.g. administration of adrenocorticotropic hormone).

3. **Acute renal failure:** Since acute renal failure may occur, patients should be closely monitored. When abnormalities such as increased BUN or creatinine, or decreased urinary output are observed, the administration of this product should be discontinued and appropriate measures should be taken.

4. **Delayed shock occurring up to several hours after high-dose administration by intralesional or intracavity injection has been reported.**

**Minor Adverse Reactions**

When the following adverse reactions are observed, appropriate measures such as dosage reduction or discontinuation should be taken.

- **Hypersensitivity**—Purpura, itching, rash, local reactions
- **Regional**—Pain, swelling/redness, feeling of warmth, induration.
- **Fever**
- **General**—malaise, headache, arthralgia,
- **Hematologic**—Leucocytosis, Thrombocytosis, increased CRP, anemia
- **Hepatic**—Increased enzymes
- **Gastrointestinal**—Anorexia, nausea/vomiting, diarrhea, etc.
- **Renal**—Increased BUN, increased creatinine, decreased urinary output, etc. Proteinuria.

**RESULTS**

The application of OK-432 (Picibanil) has been described as safe and effective primary method for sclerotherapy of benign cervical cysts by many with excellent results. Intraleisonal OK-432 therapy is effective for most unresectable lymphangiomas. Local swelling should be anticipated, especially when treating lesions near the upper airway.

The rate of effectiveness in treating patients of lymphangioma with 0.5 KE/10 ml or 1.0 KE/10 ml, two months after administration has been reported as 53-75.5% and six months after administration as 85.4%.

The use of OK-432 has been found to be better than other available sclerosing agents that has often resulted in disfigurement due to extensive scarring, thus rendering secondary surgery even more difficult. The local inflammation did not cause any damage to the overlying skin and did not lead to scar formation.

There are many reports of excellent cosmetic outcome. Some authors have grouped lymphangiomas according to radiological appearance into 4 types: single cystic, macrocystic microcystic, and cavernous. In a series of 128 patients with lymphangioma treated with OK-432, the effectiveness was 90.9%, 100%, 68.0%, and 10.0% for single cystic, macrocystic microcystic, and cavernous types respectively. Thus they recommended OK-432 injection therapy alone for single cystic, and macrocystic types and surgical excision after pretreatment with OK-432 for microcystic and cavernous types.

Cystic lymphatic vascular malformations are benign lesions that can cause disfigurement and functional impairment. Complete surgical resection is often difficult, and clinical recurrence is common. Sclerotherapy has been used as an alternative to excision. OK-432 is an excellent treatment for patients with macrocystic lymphatic malformations. However, it is ineffective for microcystic lesions. 86% of patients with predominantly macrocystic lymphangiomas had a successful outcome in a multi institutional study.
AIIMS EXPERIENCE WITH PICIBANIL\textsuperscript{16,17}

From 1996 to 2001, 54 patients were treated with OK-432. Of these, 47 cases had the cystic variety of lymphangioma. The age range was between day 1 of life up to 10 years.

The investigations done prior to injection of OK-432 included an ultrasound and a CT scan or MRI. A cavitogram was done to see the presence of hemangiomatous component. The response was described as excellent: Complete Response, Good: > 50% response, Fair: < 50% response and Poor: no response. The site of the lymphangioma is given in Table 99.1.

Response

There was an onset of fever that started after 6 hours of injection and lasted for 2-4 days. There was local inflammatory reaction with pain and local erythema that subsided in few days. If there was no response to the first dose, a repeat dose was given on the seventh day. If there was local inflammatory response that was seen in 80% cases, the dose was repeated, if necessary, after 6 weeks. A maximum of 3 doses was given. The adverse reactions noted is given in Table 99.2.

Results

At 4 weeks after treatment, 16 cases had excellent results (Fig. 99.4). At 8 weeks after treatment, 21 cases had excellent results. At 24 weeks after treatment, 37 cases had excellent results. One patient was lost for follow up.

The best results were seen for single large cystic lymphangioma with a response rate of 80-100%. A poor response was noted in the multicystic variety, cases that were postsurgery, if there was hemangiomatic component or a history of other sclerosants previously.

Conclusions

The response is better if OK-432 is used as an initial therapy. When used as a secondary therapy for postoperative lesions, only 36% showed response. Surgical adhesions prevent diffusion of OK-432 throughout the lesion. No special problems encountered during surgery following failure of OK-432. The advantages over other sclerosants is that there was no skin damage or scar formation.

RARE SITES

Other rare sites where OK-432 has been used for lymphangioma include Orbital and perineal area.\textsuperscript{18,19}

Orbital Lymphangioma

Surgical excision of orbital lymphangiomas is difficult, and almost always incomplete due to the diffusely infiltrative pattern of these tumors. Successful use of intraliesional OK-432 administration to treat two children (1 and 3 years old) with intractable hemorrhagic proptosis due to orbital lymphangiomas has been reported. In both cases, intracystic administration of 0.05 mg of OK-432 in a 1 ml volume resulted in a successful outcome. The adverse effects were minor (mild transient fever and lid swelling), and rebleeding and intraocular pressure elevation did not occur. Proptosis and eyelid swelling gradually improved over 1 month, and completely resolved within 3 months of treatment. Although this drug concentration is higher than in previous reports, there were no major adverse effects.18

OTHER DISEASES WHERE OK-432 HAS BEEN USED

Malignancy

OK-432 has been used to prolong survival in patients with gastric cancer or primary lung cancer in combination with chemotherapy, reduction of cancerous pleural effusion or ascites in patients with gastrointestinal cancer or lung cancer, head and neck cancer (maxillary cancer, laryngeal cancer, pharyngeal cancer, and tongue cancer) and thyroid cancer that are resistant to other drugs.20 Local injection of OK-432 has been reported to be effective as a palliative therapy for recurrent carcinoma esophagus.21 An 85-year-old man with a massive recurrent tumor of mediastinum 3 years after esophagectomy for squamous cell carcinoma of the intrathoracic esophagus was given endoscopic local injection of OK-432 and lived for two years and three months after recurrence without severe side effects.21

Ranula

Intracystic injection therapy with OK-432 is relatively safe and can be used as a substitute for surgery in the treatment of ranulas.22-24 It has been used both in intraoral type and plunging type of ranula. Aspirated mucus of ranula was replaced with an equal volume of OK-432 solution.23,24

Thoracic Duct Cyst

OK-432 therapy has been successfully used for a cervical thoracic duct cyst.25

Warts

Warts, recalcitrant to various treatment, including cryotherapy, have been successfully treated with OK-432 injection.26 The injection has been given both subcutaneously and intraliesionally.26 Complete clearing of the warts has been reported in 75% patients.

Chronic Wound Healing Impairment

OK-432 has been used effectively for the treatment of chronic wound healing impairment. It was used successfully in a 13-year-old girl who suffered a polytrauma with a displaced fracture of the sacrum which required neurosurgical decompression of the sacral plexus that led to a seroma with recurrent fistulation postoperatively.27 OK-432 was instilled into the wound.27

Ganglia

OK-432 injection has also been used as a safe, convenient, and effective alternative to surgical treatment for either symptomatic or recurrent ganglia.28

Simple Renal Cysts

Percutaneous treatment of simple renal cysts with OK-432 sclerotherapy was found to be a safe, effective and minimally invasive procedure in a series of 20 patients with 25 symptomatic or large simple cysts.29 The average reduction was 93.0%. Complete and partial resolution occurred in 44.0% and 52.0% cysts, respectively. Renal pain improved in all patients, regardless of complete or partial resolution. Minor complications occurred in 3 patients, 2 developed leukocytosis and 1 had mild fever following aspiration and sclerotherapy.29

Dislocation of the Temporomandibular Joint

Dislocation of the temporomandibular joint has also been treated injection of OK-432 as a sclerosing agent.30
Experiment

The author has experience of creating cholangitis-induced liver damage in rats by intraductal injection of OK-432, and studying the response of oral, low-dose methotrexate.31

REFERENCES

HISTORICAL BACKGROUND

Hydrocephalus has been described by Hippocrates, Galen, and by early medieval Arabian physicians, who believed that this disease was caused by an extracerebral accumulation of water. Historically, hydrocephalus has been treated by primitive and totally ineffective measures like venesection, tight head bandages, leeching and purgatives. These methods have now been condemned. Evacuation of superficial intracranial fluid in hydrocephalic children was first described in detail in the tenth century by Abulkassim Al Zahrawi. In 1744, LeCat published findings on a ventricular puncture. Effective therapy required aseptic surgery as well as pathophysiological knowledge—both unavailable before the late nineteenth century. In 1881, Wernicke performed a sterile ventricular puncture and external CSF drainage. These were followed in 1891 by serial lumbar punctures (Quincke) and in 1893, by the first permanent ventriculo-subarachnoid-subgaleal shunt (Mikulicz), which was simultaneously a ventriculostomy and a drainage into an extrathecal low pressure compartment. Diversion of the cerebrospinal fluid (CSF) from head into various body cavities was first attempted as early as 1898 and almost all known body cavities have been tried for the same though none seems to be perfect for the purpose.

Between 1898 and 1925, lumboperitoneal, and ventriculoperitoneal, -venous, -pleural, and -ureteral shunts were invented, but these had a high failure rate due to insufficient implant materials in most cases. Ventriculostomy without implants (Anton 1908), with implants and plexus coagulation initially had a very high operative mortality and were seldom successful in the long term, but gradually improved over the next decades. In 1949, Nulsen and Spitz implanted a shunt successfully into the caval vein with a ball valve. Between 1955 and 1960, four independent groups invented distal slit, proximal slit, and diaphragm valves almost simultaneously. Around 1960, the combined invention of artificial valves and silicone led to a worldwide therapeutic breakthrough. After the first generation of simple differential pressure valves, which are unable to drain physiologically in all body positions, a second generation of adjustable, autoregulating, antisiphon, and gravitational valves was developed, but their use is limited due to economical restrictions and still unsolved technical problems. At the moment, at least 127 different designs are available, with historical models and prototypes bringing the number to 190 valves, but most of these are only clones. In the 1990s, there was a renaissance of endoscopic ventriculostomy, which is now widely accepted as the method of first choice in adult patients with aquired or late-onset, occlusive hydrocephalus; in other cases the preference remains controversial.

Hydrocephalus is an entity that has till date no satisfactory treatment in terms of cure and long-term good outcome. The indications for surgical intervention with the insertion of a shunt, the shunt related complications and the ultimate long-term prognosis are still far from satisfactory.

DEFINITION

Hydrocephalus is defined as the dilatation of the cerebral ventricle/s due to accumulation of fluid under pressure caused by an imbalance of CSF production.
and absorption. This does not include conditions where there is excessive accumulation of CSF within the cranial cavities due to decrease of the cerebral substance resulting in an increase in ventricular size, as in patients with cerebral atrophy (hydrocephalus ex vacuo).

**INCIDENCE**

The condition is not uncommon with an estimated incidence of infantile hydrocephalus around 3-4 per 1000 live births. Congenital hydrocephalus comprises about 30% of all congenital malformations of the nervous system and is often associated with spina bifida and meningomyelocele (70%).

**PHYSIOLOGY OF CSF FORMATION**

The choroid plexus appears as a mesenchymal invagination of the roof of the ventricles at 35 days of gestation. CSF circulation begins at 50th day of gestation.

The amount of CSF is around 150 ml in adults and the amount of CSF produced is 20 ml/hour irrespective of age amounting to around 500 ml/day. 65-80% of this fluid is produced by choroid plexus and 15-30% is secreted by ependymal surfaces of ventricles and arachnoid membranes. Small amount is produced from the brain itself through the perivascular spaces surrounding the blood vessels entering the brain. The rate of CSF production is around 0.02 ml/minute in neonates and the total “ventricular” CSF volume varies between 5-15 ml.

CSF is formed by the choroid plexuses of the lateral, third and fourth ventricles by an active transport process, across the endothelium of capillaries in the villous processes of the choroid plexus. Each villus is lined with a single layer of cuboidal epithelium and has a central stromal core. The apical tight junctions represent the blood-CSF barrier. Na-K ATPase located in the microvilli extrudes sodium ions into the ventricles which osmotically draws water along with it. Na⁺ transport is balanced by counter transport of K⁺ and/or H⁺ ions. Carbonic anhydrase catalyses the formation of bicarbonate inside the cell, with the H⁺ ion being fed back to the Na⁺ transporter as a counter ion in exchange of K⁺.

Acetazolamide and furosemide are diuretics that also decrease secretion of CSF at the level of the choroid plexus. **Carbonic anhydrase** catalyzes a reversible reaction in which carbon dioxide becomes hydrated and carbonic acid dehydrated. Acetazolamide is a noncompetitive reversible inhibitor of enzyme carbonic anhydrase, which catalyzes the reaction between water and carbon dioxide, resulting in protons and carbonate. This carbonic anhydrase inhibition in central nervous system retards abnormal and excessive discharge from CNS neurons and thus decreases CSF secretion by choroid plexus (Fig. 100.1). Acetazolamide is also a weak natriuretic which non-competitively inhibits carbonic anhydrase in the proximal convoluted tubule, preventing the reabsorption of bicarbonate and the excretion of hydrogen ions. The paucity of hydrogen ions in the tubular fluid for exchange with sodium ions prevents the reabsorption of filtered sodium. Hence, an alkaline diuresis rich in sodium and bicarbonate results in hyperchloremia (normal ion gap).

Various osmotic agents like glycerol also have ICP-lowering effects. The solute must be relatively restricted in its entry across the blood brain barrier. An osmotic gradient is necessary to draw water from the brain cell to the site of higher osmolality, the plasma. Once the solute has reached equilibrium in plasma and brain cell, the intracellular volume returns to its initial state and the intracranial pressure returns, to its initial level.

Mechanism of action proposed for Furosemide for lowering ICP include; lowering cerebral sodium uptake, affecting water transport into astroglial cells by inhibiting cellular membrane cation-chloride pump, and decreasing CSF production by inhibiting carbonic anhydrase.
Furosemide, a loop diuretic is a potent, short acting natriuretic which inhibits sodium reabsorption in the medullary portion of ascending limb of the loop of Henlé by blocking the sodium-potassium-chloride (Na⁺K⁺2Cl⁻) cotransporter. This leads to the excretion of 30% of the filtered sodium, as the sodium concentration in the distal nephron is increased; moreover, the sodium concentration in the renal medullary interstitium and peritubular capillaries is decreased, impairing the concentrating ability of the countercurrent multiplier mechanism. The co-dependent reabsorption of calcium and magnesium are inhibited. Potassium and hydrogen ion exchange for sodium in the distal convoluted tubule is increased. Loop diuretics also increase and redistribute renal blood flow and have a systemic venodilatory effect.

CSF FLOW

The CSF secreted in the lateral ventricles passes into the 3rd ventricle and then along the aqueduct of Sylvius into the fourth ventricles. It then passes out of the fourth ventricle through two lateral foramina of Luschka and the midline foramina of Magendie into the Cisterna Magna (Fig. 100.2).

This is continuous with the subarachnoid space that surrounds the entire brain and spinal cord. From the subarachnoid space, the CSF is absorbed into the large sagittal venous sinus and other sinuses by multiple arachnoid villi projecting into the sinuses. Transepipendymal CSF absorption into capillaries and the lymphatic channels associated with cranial nerves also act as alternate channels for CSF absorption. The optic nerve, the olfactory nerve sheaths and the choroid plexus have also been demonstrated as probable sites of CSF flow and absorption.

The rate of CSF absorption is pressure dependent over a wide physiologic range. CSF formation is independent of pressure whereas the CSF absorption increases linearly after 6.8 cm H₂O pressure. The formation and absorption rates become equal beyond 11.2 cm H₂O pressure. The CSF formation does not diminish significantly until the cerebral perfusion pressure is markedly reduced. It is the change in resistance to CSF absorption that determines CSF pressure and progression of the hydrocephalus.

Ongoing research has continued to improve our understanding of the cerebral water circulation and is starting to provide insight into the pathogenesis and potential treatment options of this common group of disorders.

PATHOPHYSIOLOGY

Regardless of the etiology, obstruction of CSF pathways results in a wide spectrum of changes that depend on the age of the patient and the expansibility of skull as well as the duration of the hydrocephalus.

Ventricular enlargement is caused by undamped pulsewave generated by the choroid plexus. The subarachnoid channels are the first CSF compartments to dilate and reduce CSF pressure. Later with progressive dilatation of the subarachnoid channels, the increase in CSF pressure is transmitted to the ventricular system resulting in ventriculomegaly. Ventricular enlargement causes displacement of the primary cerebral arteries and a reduction in the caliber and number of the secondary and tertiary vessels, causing diminished blood flow and ischemia.

Ventriculomegaly causes changes throughout the cerebral cortex and affects the periventricular white matter. The deeper cortical layers are more affected than the superficial laminae, some of these changes may be permanent. Raised intracranial pressure (ICP) increases ventricular size in a newborn child as the brain is incompletely myelinated and the parenchyma is soft and pliable.
The effects of raised ICP on the developing brain include:
1. Atrophy of white matter.
2. Stretching and denuding of ependymal epithelium with formation of ventricular diverticula.
3. Spongy edema of the brain parenchyma surrounding the ventricles.
4. Fenestration of the septum pellucidum
5. Thinning and elongation of the interhemispheric commissure.
6. Fibrosis of choroid plexus.

The atrophic process in hydrocephalus involves primarily a destruction of the axons, secondary loss of myelin and chronic astrogliosis. Neurons are selectively spared as grey matter enjoys a more luxuriant blood supply. Thus cerebral mantle thickness is not a reliable prognostic criterion in hydrocephalus. White matter ischemia and periventricular edema can cause porencephalic cavities. Porencephalic cavities and disappearance of the tertiary branches of the anterior and middle cerebral arteries represents irreversible brain damage. CSF drainage has a beneficial effect only till the stage when edema of the white matter and enlargement of the extracellular spaces begins.

**ETIOLOGY AND CLASSIFICATION (TABLE 100.1)**

**Genetic Factors**

The most common inherited form of hydrocephalus, X linked hydrocephalus is characterized by mental retardation, adducted thumbs and spastic paraplegia.

**Environmental**

The incidence of congenital hydrocephalus was more in mothers who received oral contraceptives in first trimester and in families with parental consanguinity.

mebooksfree.com
Hydrocephalus, depending on the site of obstruction, is classically described as:
(i) **Non-communicating:** Blockage of CSF pathway at or proximal to the outlet foramina of the fourth ventricle (Figs 100.3A and B). In non-communicating hydrocephalus CSF flow can take place via the blood vessel adventitia and extracellular space of the cortical mantle to reach the subarachnoid space on the brain surface. These alternate pathways are established with time and lead to an equilibrium between CSF production and absorption.
(ii) **Communicating:** Obstruction located in the basal subarachnoid cisterns, subarachnoid sulci or arachnoid villi (Figs 100.3A and B).

Hydrocephalus can arise as a result of:
1. Obstruction of CSF pathways
2. Impaired venous drainage
3. Overproduction of CSF.

**Impaired Venous Drainage**
(i) Thrombosis of sinuses, jugular vein or superior vena cava
(ii) Tumor invading the sinuses
(iii) High flow arterio-venous malformation.

**Overproduction of CSF**
(i) Choroid plexus: Papilloma, Carcinoma
(ii) Hypervitaminosis A

In a nationwide survey conducted in Japan to assess the etiology and associated conditions of prenatally and postnatally diagnosed congenital hydrocephalus, destructive cystic lesions, holoprosencephaly, and agenesis of the corpus callosum were found significantly predominant in fetal hydrocephalus. Arachnoid cyst was somewhat predominant in infantile hydrocephalus.

**CLINICAL PRESENTATION**

There may be a positive history of congenital hydrocephalus in the family or an history of fever in the first trimester or if the child has other associated congenital anomalies like myelomeningocele or spina bifida. There may even be an obstructed labor due to giant hydrocephalus in the fetus.

The signs and symptoms related to hydrocephalus depend on the age of the patient, causative factor, associated malformations and the severity and progression of the disease. Baby may have a big head with no symptoms at all while others may have normal sized head with severe headache.

**Infant**

The infant with hydrocephalus presents with large head, a full or a bulging anterior fontanelle, poor feeding and lethargy (Fig. 100.4). The anterior fontanelle is examined in the upright position or at a
45° incline. The infant may have sutural diastasis particularly the squamo-parietal suture. This suture should close early after birth and its diastasis after birth suggests presence of hydrocephalus. The other signs of hydrocephalus include thin scalp with visible veins, Parinaud’s phenomenon (sun set sign caused by pressure on the tectal plate) and Macewan’s sign (cracked pot resonance). Vascular lesions can be suspected if cranial bruits are audible. The infant will have delayed milestones and difficulty in head control. Apneic bouts and bradycardia are usually associated with posterior fossa anomalies and with an increase in intracranial pressure (ICP).

During the first three months of life, normal head growth velocity is 2 cm per month. Macrocrania is defined as head circumference higher than 2 standard deviation above normal, or with an increase in the head circumference by more than 2 cm in any month before the fusion of sutures. Head circumference more than 97th percentile for gestation age is suggestive of hydrocephalus. Transillumination can be appreciated in cases of hydrancephaly and in infants less than 9 months of age with a cerebral mantle less than 1cm. Bobble head doll syndrome with forward and backward nodding movements may be seen. Cranial nerve palsies especially lateral gaze palsy (VI nerve involvement) and stridor may also be seen in infants. Visual tracking disorders seen in hydrocephalus could be caused by oculomotor palsy. There may also be cortical blindness as a result of stretching of the optic radiations by the lateral ventricles. The discrepancy between head and chest circumference may suggest hydrocephalus. Normally the head measures about 1 cm more than the chest circumference until late in the first year when it reverses. An older child up to 2 years of age may present as an irritable child with alteration in the development of intelligence, affecting verbal capabilities more than nonverbal ones.

Older Child

The inability of the fused cranium to expand causes the older children more than 2 years of age, to have a more acute presentation. The triad of severe headache, vomiting and lethargy is commonly seen. The headache at first sporadic may become persistent and severe enough to awaken the child from sleep. It may be accompanied by typically early-morning abdominal pain with nausea and vomiting. Visual disturbances and papilledema is commonly seen in children unlike infants. Delayed motor and cognitive development and subtle behavioral changes are noted. A mild spastic diplegia with positive Babinski sign can also be elicited. A decline in school performance as well as memory loss may be seen. The presence of frank neurological signs usually reflects a primary pathologic condition. The other indicators of hydrocephalus include decreased active leg motion, poor placing and positive support reflexes. Gait disturbance may occur in late stages with spasticity involving the lower limbs. Endocrine disorders though rare may occur due to distraction of hypothalamus and pituitary stalk by dilated third ventricle. It may be in the form of obesity, small stature, precocious puberty, adiposogenital atrophy, primary amenorrhea or diabetes insipidus. Seizures are a common presentation due to raised ICP.

The shape of the skull may give some clue to the cause of the hydrocephalus. The expansion of the supratentorial compartment with a small posterior fossa, is characteristic of Aqueductal stenosis while the ballooning of the whole head with predominance of posterior fossa is suggestive of the Dandy – Walker syndrome.
The sunset sign is most commonly seen in acqueductal obstruction in juxtaposition to the mesencephalic tectum.

**DIFFERENTIAL DIAGNOSIS**

1. Familial big head or constitutional macrocrania
2. Hydrancephaly—Transillumination may be marked in hydrancephaly
3. Subdural fluid—Hygroma, Hematoma, Effusion
4. Brain edema
   - Toxic, e.g. Lead encephalopathy
   - Endocrine, e.g. Galactosemia
5. Gigantism
6. Achondroplastic dwarfism
7. Leukodystrophy, e.g. Alexander’s disease
8. Lysozymal disorders
9. Aminoaciduria
10. Thickened skull, e.g. Thalassemia, cranioskeletal dysplasia.

**INVESTIGATIONS**

The investigations are done to establish the diagnosis, evaluate the etiology of hydrocephalus and assess the progress with treatment. From a pediatric surgeon’s point of view, based on the history and clinical examination, it is vital to judge whether the hydrocephalus has an infective origin or not. If there has been a history of meningitis associated fever in the past, an infective pathology is suggested.

**Ultrasoundography**

Routine prenatal ultrasonography is an effective measure for antenatal detection of hydrocephalus.

A transfontanellar ultrasound is the first investigation for an infant with accessible anterior fontanelle, being simple and noninvasive way of visualizing the ventricular dilatation. It can pick up the size of the ventricles as well as the presence of debris in infected cases. It is also useful for follow up screening. Ultrasonography is less accurate for evaluating posterior fossa anomalies, vascular lesions and neoplasms. The foramen magnum has been suggested as an alternative window besides the anterior fontanelle to evaluate posterior fossa lesions.

**Doppler Studies**

Doppler USG studies are very informative to assess the severity of the hydrocephalus by measuring the flow resistance index.

Transcranial doppler flow studies have shown a correlation between intracranial pressure and resistive indices in the middle cerebral artery and anterior cerebral artery. The normal mean resistive index in a newborn is 0.75 and found to be significantly higher in hydrocephalics (0.80). The resistive index returns to normal after an effective shunt surgery.

PET scanning has shown that cerebral blood flow and regional cerebral metabolic rate of oxygen values indicate decreased metabolic activity in the developing hydrocephalic brain. The values increase following shunt surgery.

Trans-systolic time (TST) is a new Doppler index used to evaluate intracranial pressure. TST is the width of the systolic peak at the level of the mean of the peak systolic and end diastolic velocity. An increase in intracranial pressure results in a decrease in TST and vice versa.

**Fundus Evaluation**

This is an important tool to assess severity of the raised intracranial pressure. This is especially good for follow up for cases kept on medical management. It is useful in older children as a screening tool and may defer the repeated CT scan examination done during follow up. Changes on fundal examination are an indication for shunt placement for a patient on medical management. Fundus changes may occur in the form of papilledema, temporal pallor and primary optic atrophy.

Papilledema is a non-inflammatory passive swelling of the optic disk, produced by raised intracranial tension. It occurs as a result of interrupted axoplasmic flow in the optic nerve due to transmitted elevated cerebrospinal fluid pressure in the subarachnoid space around it. This in turn causes venous congestion. Papilledema is one of the causes of “disk-edema”, and they are not synonymous.

As a rule, papilledema does not develop if the optic nerve has already become atrophic, in congenital absence of arachnoidal sheath and in opto chiasmatic arachnoiditis or other forms of basal meningitis due to tuberculosis, etc.

Any intra-cranial tumor may induce papilledema. It is most evident with tumors in the posterior fossa which obstruct the aqueduct of Sylvius, and least with pituitary tumors. The site of the tumors is, thus, more important than its nature, its size and rate of growth.
The Ophthalmoscopic features in the different stages of the disease are:

(a) Early papilledema: Earliest change is disc hyperemia and dilated capillaries. Blurring of disc margins, spontaneous venous pulsation is absent (this may be absent in 20% of normal population.) Splinter hemorrhages at or just off the disk-margin.

(b) Established papilledema: Disk margins become indistinct and central cup is obliterated. Disc surface is elevated above the retinal plane (more than +3D (1mm) with direct ophthalmoscope). Peripapillary edema.[Paton’s lines, present temporal to the disk]. Venous engorgement. Flame-shaped hemorrhages and ‘cotton-wool’ spots around the disk. Hard exudates in radiating pattern around the macula, [macular star]

(c) Chronic papilledema: Disk edema resolves, but margins are blurred. Hemorrhagic and exudative components gradually resolve. Optik disk appears pale like a champagne cork. White spots–corpora amylacea may be seen on the disk.

(d) Atrophic papilledema: Peripapillary retinal vessels are attenuated and sheathed. Dirty-white appearance of the optic disk, due to reactive gliosis-leading to secondary optic atrophy.

CSF Evaluation

CSF examination is warranted only if an infective pathology is suspected. CSF examination for protein and cell content is important prior to shunt placement in post meningitic hydrocephalus. Fat laden cells are indicative of brain damage in post infection states and can also be evaluated by CSF examination. Experimentally, CSF biogenic amine, myelin basic protein, lactate:pyruvate ratio and cyclic nucleotide levels have all been used as indicators of cerebral injury implying progressive hydrocephalus.

Computed Tomography

CT scanning is useful to evaluate macrocrania or signs of raised intracranial pressure for comparisons during the course of the disease. The cause and site of obstruction can usually be defined and with contrast enhancement tumors as well as vascular lesions can be visualised. Dilatation of the temporal horns is a sensitive indicator of raised intracranial pressure. The presence of periventricular edema or ooze suggests high intracranial pressure but this sign may be absent in cases of shunt failure associated with high intracranial pressure. CT scan imaging gives a quantitative assessment of ventricular dilatation and its topography (Figs 100.5A and B). Aqueductal stenosis can be appreciated with dilatation of the lateral ventricles and third ventricle without dilatation of the fourth ventricle. Presence of periventricular lucency representing egression of fluid from the ventricles is an important sign (Fig. 100.6). CT scan also helps to differentiate other causes of macrocrania like hydrancephaly and also identify cases with leucodystrophy that give a picture of dilated ventricles simulating hydrocephalus (Figs 100.7 and 100.8).

The earliest sign of neonatal or infantile hydrocephalus is dilatation of occipital horns and atria of the lateral ventricles, followed by blunting of the dorsolateral angles of the ventricles above the caudate nuclei and the thalami. The diagnosis of hydrocephalus is established when the bifrontal ventricular width expressed as a percentage of the brain width (ventricle skull ratio (VSR)) exceeds 35 percent. Calcification in tumors or periventricular cytomegalovirus inclusions and toxoplasmosis can be diagnosed (Figs 100.9A and B). The risk of repeated CT Scans for these children has been studied. The mean effective dose, lens dose and brain dose to children over 6 months of age were 1.2 mSv, 52 mGy and 33 mGy, respectively, and the corresponding doses to younger children were 3.2 mSv, 60 mGy and 48 mGy. The effective dose per CT examination varied by a factor of 64. However, since the threshold for radiation-induced damage is not known with certainty, alternative modalities such as US and MRI should be used whenever possible.

Magnetic Resonance Imaging

MRI is considered by some as the investigation of choice as it enables a pathophysiological approach to understanding the hydrodynamic disorder through the analysis of CSF fluid and the volumes of different intracranial components. MR measurement of total intracranial CSF volume may function as the “Gold standard” when making comparisons is time. The axial, coronal and saggital images available with MRI provide a more exact position and extent of the
Hydrocephalus

Fig. 100.5A: NCCT head of a child with congenital hydrocephalus showing dilated lateral and third ventricles.

Fig. 100.5B: CT scan of a child showing dilated lateral and third ventricles. The fourth ventricle was also dilated suggestive of communicating hydrocephalus.

Fig. 100.6: CT scan of a child showing presence of periventricular lucency representing egression of fluid from the ventricles.

Fig. 100.7: CT scan of a child showing very poor cortical tissue and almost the whole cranial cavity filled with cerebrospinal fluid suggestive of hydrancephaly.

lesion (Fig. 100.10). More subtle findings such as white matter pathology and dysmorphic anatomy can be demonstrated. The advent of magnetic resonance angiography has made it the ideal investigation to evaluate vascular lesions. Phase contrast cine magnetic resonance imaging technique is used to study CSF flow dynamics and is particularly useful to evaluate CSF flow following third ventriculostomy. The diagnosis of aqueductal stenosis made earlier by exclusion can now be confirmed on a 2D cine phase contrast MR.\textsuperscript{9,17} MRI can also locate small tumors in the upper cord and brainstem which may be missed on a CT scan.
ICP Measurement

This investigation is not recommended as a diagnostic tool in children. It is an invasive technique and may be performed in children only preoperatively in the operating room to measure the ventricular pressure and thereby decide the type of shunt required. In normal pressure hydrocephalus ICP monitoring showed that children who benefited with shunt placement demonstrated plateau waves and episodic increases in ICP during REM sleep. Progressive hydrocephalus is suggested if ICP monitoring shows prolonged pressure waves, frequent short term waves and augmented pulsatile indices which basically imply poor ventricular compliance.  

Noninvasive ICP monitoring involves assessment of ICP via a transducer placed over the anterior fontanelle. Recently it has been demonstrated that
Hydrocephalus

tympanic membrane displacement correlates well with intracranial pressure and this can severe as an easy, noninvasive method to measure intracranial pressure.19

Proton Magnetic Resonance Spectroscopy

It has been studied that premature infants and neonates with hydrocephalus have elevated lactate, glutamine and alanine concentrations compared with age-matched controls.20 Proton magnetic resonance spectroscopy has been reported to be of limited value in predicting outcome in infants with hydrocephalus. However, this test may be useful in identifying subsets of hydrocephalic neonates that, in fact, have severe neurologic disease and poor prognosis. Patients with dramatically reduced N-acetyl-aspartate and elevated Lac had poor neurologic outcome and were found to have neurologic disease that had not been identified with prior diagnostic tests.20

Ventriculography

It has been used previously for differentiating communicating and non-communicating hydrocephalus. Neutral Phenosulfonaphthalein dye was injected into the lateral ventricles, and if the chemical was recovered within 20 minutes from the spinal subarachnoid space it was termed as ‘Communicating’. Ventriculography and cisternography were used for evaluating patients with suspected ventricular loculation and for mass lesions extrinsically compressing the ventricular system. The role of these investigations has diminished following the advent of same and no invasive investigations like ultrasonography, CT scanning and MRI imaging.

GOALS OF MANAGEMENT

The management of a patient with hydrocephalus would depend upon the rate of progression of the hydrocephalus and the etiology of the hydrocephalus. The goals in treatment of hydrocephalus include decreasing the intracerebral pressure to safe levels, allowing the increase in the volume of brain parenchyma to maximize the child’s neurological development, minimizing the likelihood of complications, detect and aggressively treat any complications and maintain the integrity of CSF pathways to prevent ventricular cooptation and preserve the potential for life without shunt dependency.

ANTENATALLY DETECTED HYDROCEPHALUS

Congenital hydrocephalus may be diagnosed as early as 13 weeks of gestational age by USG and amniotic fluid tap. The treatment of antenatally detected hydrocephalus has been a subject of controversy in the past. The incidence of associated anomalies with antenatally detected hydrocephalus is very high and many of these anomalies can be missed on antenatal sonography. In utero, ventricular drainage had been reported two decades earlier between 1982 and 1985. This procedure did not gain popularity as the procedure related mortality rate was 10%, 53% had severe deficits and gross developmental delays while 12% were moderately handicapped. There has been a high rate of complications associated with the ventriculo-amniotic shunt and need for multiple revisions secondary to dislodgement and blockage. Serial cephalocentesis requires multiple punctures and does not allow consistent reduction of intracerebral pressure. The overall mortality in fetuses with antenatally detected ventriculomegaly is around 70% while only 50% of the survivors show normal intellectual development. It has been found that fetus who had demonstrable ventriculomegaly in-utero were managed postnatally by shunt insertion quite

Fig. 100.10: CT scan of a child showing dilated ventricles and a calcified locus in the right cerebral hemisphere
effectively. In modern day practice, in-utero surgery for hydrocephalus has no role. The authors feel that fetal interventions should not be advocated for hydrocephalus if the baby is to be delivered alive and with a fairly mild to moderate hydrocephalus that does not interfere with the delivery of the baby.

MEDICAL MANAGEMENT

Medical management is beneficial for slowly progressive hydrocephalus. The goal in treating hydrocephalus medically is to decrease ventricular size and decrease the intracranial pressure to normal levels with fewer side effects than that associated with shunt surgery. Also to stabilize the patient so that a shunt is not required or to temporize the patient until a shunt can be done more safely. The modes of medical therapy are removal of CSF, by decreasing CSF production, by decreasing cerebral water content and increasing CSF absorption. In the past head wrapping was also used with the principal being that CSF absorption increases with ICP. By this method, ICP’s of 500-700 mm water could be generated that could lead to transependymal CSF absorption.

The potential for spontaneous arrest of hydrocephalus exists in infants because of the linear increase in CSF absorption seen with increase in ICP.

Medical treatment is advocated as the initial line of management for all cases of hydrocephalus due to the growing reservations against shunt surgery. Shunt insertion represent a life time commitment to an imperfect device that may require frequent revisions. Conditions associated with a treatable etiology fair well with medical treatment alone. Hydrocephalus associated with hypervitaminosis A, if treated appropriately after diagnosis will resolve with medical management alone. Appropriate antibiotics are added if there is evidence of infection leading to ventriculitis or meningitis.

Pharmacological agents like Acetazolamide 50-100 mg/kg/day, Glycerol 2 mg/kg every 6 hours and Isosorbide 2-3 gm/kg are used for medical treatment. Some authors have also used Furosemide 1 mg/kg/day, but the authors do not advocate its routine use. As the mechanisms of action of these drugs are different, these can be given in a cyclic manner at 3-4 hour intervals to maintain high efficacy of the drugs with minimal doses.

Acetazolamide is a potent inhibitor of carbonic anhydrase which is involved in the active secretion of water and ions by the choroidal epithelium into the ventricles. Furosemide also inhibits choroidal CSF production. The inhibiting action of furosemide is around 10-100 fold less than acetazolamide but the overall decrease in CSF production is the same as with acetazolamide. This suggests alternate undefined sites of action of furosemide. Both the drugs can reduce CSF flow by 50-60% at sufficient doses. Acetazolamide also acts by causing preferential vasoconstriction of choroidal arteries. There is a high incidence of metabolic acidosis especially in the newborns and small infants with acetazolamide doses if given above 60-75 mg/kg/day. In that case, this should be recognized and treated well in time by either reducing the dose or stopping the same temporarily. There has been some concern regarding the toxicity of high dose of the acetazolamide on myelin.

Authors had an unusual experience with the prolonged use of acetazolamide. This was the case of post-spina Bifida Hydrocephalus and had been on acetazolamide for almost 6 months after surgery. Baby was hospitalized for running continuous low grade fever of 2 month duration with loss of weight and milk intake. There was no evidence of raised ICT. Baby was investigated in detail but no cause could be found. Electrolytes remained normal. Finally, it was decided to stop the medical management (Acetazolamide) and insert the VP shunt. Once the shunt was inserted, fever disappeared with in hrs and remained so thereafter. It was possibly due either to dehydration disturbing the cellular transport mechanism or affecting the temperature control system in the brain. Furosemide is also known to cause metabolic alkalosis and nephrocalcinosis and should be considered in selected cases in addition to acetazolamide and not as a substitute to it.

Osmotic diuretics decrease the brain water content by increasing the outflow of water from the interstitial space into the capillaries. The transependymal CSF flow in hydrocephalus can be then cleared by osmotic diuretics. Additionally there may also be a small flow of water back into the choroidal capillaries from the ventricles as a result of osmotic gradient. These agents are not effective if there is little residual brain parenchyma to extract water from. Osmotic diuretics are effective temporarily in reducing ICP but
prolonged use can lead to a rebound effect with an increase in interstitial water. Isosorbide, mannitol, urea and glycerol are the common agents which have been used and can be given orally. Isosorbide is a sorbitol derivative.

Hyaluronidase, urokinase, streptokinase and tissue plasminogen activator have been used experimentally to lyse fibrin blocking the subarachnoid villi following hemorrhage. Steroids decrease the inflammatory response following subarachnoid hemorrhage and meningitis but do not inhibit fibroblast proliferation. Head wrapping that was done previously was believed to increase the ICP and hence increase in transependymal CSF absorption to cause a decrease in ventriculomegaly. It is no more recommended in the scientific world.

Presently, acetazolamide and glycerol are the most frequently used agents in pediatric patients for the effective medical management of hydrocephalus.

**Postpyogenic Meningitis Hydrocephalus**

Meningitis is the most common cause of acquired hydrocephalus which produces obstruction to CSF flow usually at the subarachnoid level. The incidence of hydrocephalus following meningitis ranges between 1-5%. Intrauterine viral infection with cytomegalovirus, rubella, mumps, varicella and parainfluenza are also responsible for congenital obstructive hydrocephalus of the noncommunicating variety. *Toxoplasma gondii* is a cause of congenital infection and presents as hydrocephalus, chorioretinitis and intracranial calcification in the newborns.

The early use of antibiotics in the treatment of local infection of the middle ear and paranasal sinuses has decreased the incidence of meningitis secondary to these infections. Presently blood borne infections are the primary cause of meningitis and the organism involved depends on the age of the patient. The commonly involved organisms include *E. coli, Staphylococcus aureus*, gram negative enteric bacilli in neonates and babies upto 3 months, and *Hemophilus influenzae, Pneumococcus, Meningococcus, Streptococcus and Staphylococcus aureus* in older children.

In the acute stages of meningitis the subarachnoid space is engorged with pus and the leptomeninges are hyperemic and edematous. The exudates of *streptococcal* and *pneumococcal* infection accumulate over the cerebral convexities whereas meningococcus exudates aggregate at the base. In meningitis secondary to *Hemophilus*, the exudate is copious and diffuse. In the chronic stage there is fibroblast proliferation and the subarachnoid space is gradually obliterated by an adhesive scar. Communicating hydrocephalus results secondary to obliteration of the subarachnoid space but the 4th ventricle outlet may also be blocked leading to noncommunicating hydrocephalus as well.

**Post-tubercular Meningitis Hydrocephalus**

Tubercular meningitis is the commonest manifestation of CNS tuberculosis and constitutes almost half of the cases of childhood tuberculosis. Communicating hydrocephalus may result due to blockage of basal cisterns by the tuberculous exudate in the acute stage and adhesive leptomeningitis in the chronic stage. Non-communicating hydrocephalus may be caused by blockage of the aqueduct or outlet foramina of the fourth ventricle.

Intraluminal subependymal tuberculoma or a plug of ependymal exudate may also block the aqueduct. The meningeal exudate may also cause circumferential compression of the brainstem and cause aqueductal obstruction. Tubercular meningitis may be associated with damage of lenticulostriate vessels, vessels of the circle of Willis and the middle cerebral artery in the sylvian tissue. There may be damage to cranial nerves 2nd, 3rd, 4th, 6th and 7th leading to multiple cranial nerve palsies.

Fungal meningitis can lead to hydrocephalus in up to 20% of cases if early and aggressive treatment is not instituted. Communicating hydrocephalus is an ominous complication and has an associated mortality of around 50-70%.

**Posthemorrhagic Hydrocephalus in the Premature Infant**

Hydrocephalus following intraventricular hemorrhage (IVH) is still one of the most serious complications of premature birth. Posthemorrhagic hydrocephalus is secondary to a fibrous thickening of the meninges with an obliterator arachnoiditis and obstruction of CSF flow through the normal subarachnoid pathways. An acquired acqueductal stenosis can also occur.
because of cellular debris and red blood cells. The predisposing factors for intra ventricular hemorrhage leading to hydrocephalus include preterm neonates less than 1500 gm, respiratory distress syndrome, vigorous resuscitation, rapid volume expansion, soda bicarbonate administration, hypoxemia, hypercarbia and acidosis. The diagnosis may be picked up on a routine cranial ultrasound performed on postnatal day 2 or 3 followed by a repeat examination during the second postnatal week to screen preterm neonates of < 1500 gm or less than 34 gestational weeks. Post-hemorrhagic hydrocephalus presents with increasing occipito frontal head circumference, tense anterior fontanelle, lethargy, feeding difficulty, bradycardia and ventilator dependency the other manifestations include SIADH, persistent metabolic acidosis, abnormal eye movements and hypertonia. Diagnosis is confirmed on ultrasonography or documentation of raised intracranial pressure.

The ultrasonographic grading of intraventricular hemorrhage is as follows:

- Grade I: Germinal matrix hemorrhage;
- Grade II: Blood in lateral ventricles, no dilatation of ventricle;
- Grade III: Blood in ventricles with ventricular dilatation;
- Grade IV: Hemorrhage with parenchymal involvement.

Cases with Grade I and II are managed with observation alone. For higher grades the treatment is begun with medical management with acetazolamide (50-100 mg/kg/day) and furosemide (2 mg/kg/day) with careful electrolyte and acid base status monitoring. Ventricular taps or the insertion of ventricular catheters with reservoir for repeated tapping have been advocated in the past. There role is not much as there is a risk of porencephaly. Flexible ventriculoscopes for irrigation, evacuation of blood or to lyse intraventricular septations, have also been tried to decrease the need for shunt surgery. Children with posthemorrhagic hydrocephalus are more likely to become shunt independent on follow up though the ultimate prognosis would depend on the grade of intraventricular hemorrhage.

Ventriculoperitoneal shunt surgery cannot be carried out early and permanent dependence on a shunt is associated with several serious complications. Streptokinase has been used, based on the hypothesis that multiple blood clots in the cerebrospinal fluid (CSF) are the initial cause of posthemorrhagic ventricular dilatation and lysis of clots could reopen the pathways of circulation and re-absorption of CSF. No information on the effect of intraventricular streptokinase on disability is available. There is cause for concern about meningitis and secondary intraventricular hemorrhage, but numbers are insufficient to quantify the risks. On comparing intraventricular streptokinase with conservative management of post-hemorrhagic ventricular dilatation, the numbers of deaths and babies with shunt dependence were similar in both groups. Thus it has been concluded that intraventricular fibrinolytic therapy with streptokinase, given when post-hemorrhagic ventricular dilatation is established, should not be recommended for neonates following IVH. A conservative approach with CSF drainage applied only to symptomatic raised intracranial pressure seems appropriate.

**Emergency Temporary Treatment**

Temporary treatment measures like external drainage and repeated percutaneous taps are only to be condemned due to a high risk of infection. Their use has been only to tide over the crisis in a moribund baby in emergency unfit for anesthesia or to wait till the infection subsides with the help of antibiotics prior to shunt placement. Instillation of thrombolytic agents has been tried for intracranial hemorrhage though the results have been the same with or without this treatment.

**SURGICAL MANAGEMENT**

A shunt operation is the most commonly performed surgery for Hydrocephalus. The studies by Young have demonstrated that a cerebral mantle of 2.8 cm is adequate to achieve normal MPQ status in follow up. It is believed that the goal for treating a child with hydrocephalus is to achieve a cerebral mantle of 3.5 cm by the age of 5 months. Cases diagnosed to have removable etiological factors mandate other appropriate procedures. These include radical resection of a mass lesion, or correction of a malformation.

The various shunt procedures include:
- Ventriculoperitoneal shunts
- Ventriculoatrial

mebooksfree.com
• Ventriculopleural
• Lumboperitoneal
• Ventriculocisternostomy (Torkildsen operation).
A recent development that is slowly gaining popularity is the “Third Ventriculostomy”.

**Indications for Shunt Insertion**

It is difficult to outline the definite indications for the shunt surgery in children with hydrocephalus. Many of them can still be managed with medical decompression therapy while others may have too advanced a disease and may not benefit from any surgery. A broad based clinical approach is advisable. Commonly the indications for shunt surgery include:

a. Rapidly progressive hydrocephalus, uncontrolled with medical management even after 3-6 months therapy.
b. Symptomatic patients with established hydrocephalus, and raised ICP.
c. Head size > 2SD above normal at initial presentation.
d. Evidence of falling MPQ values during follow-up.
e. Evidence of papilledema and features of raised ICP like peri-ventricular ooze on CT scan.
f. Child develops serious side effects with medical management.
g. Hydrocephalus is caused by postnatal causes—post-meningitic, once infection is under control.
h. The value of the cortical mantle is very confusing in deciding in favour or against the shunt surgery. Patients even with the paper thin mantle can have normal intelligence while children with thick cortical mantle may not be so. In general, cortical mantle of ≤ 1 cm on initial radiological investigation or thinning of the cortical mantle on follow-up studies suggest the need for surgical intervention.

**Contraindications for Shunt Surgery**

1. Ventriculitis
2. Acute intraventricular hemorrhage
3. Hydrocephalus due to treatable obstructive lesions
4. Extreme brain pathology
5. Ventriculomegaly without elevated ICP
6. Asymptomatic nonprogressive hydrocephalus
7. Established irrecoverable optic atrophy with gross hydrocephalus.

**SHUNT SYSTEMS**

There are a many kinds of shunts available and there is no ideal one. The choice of the shunt depends upon the characteristics of the patient and the choice of the surgeon. The system characteristics that minimize shunt failure include a one piece system, a non-flanged ventricular catheter, a proximal non-slit valve and open ended distal tubing. The surgeon should adapt to using a particular type of shunt so that he may be aware of that particular shunt properties and would be well conversant in handling the complications that develop with it in the postoperative period. Most shunts are made of silicon (medical grade silastic) material. The advantages include flexibility, non-immunogenicity and blood does not clot to its inner surface and hence lesser chance of early obstruction.

All ventricular drainage systems feature three components (Fig. 100.11):

(i) A ventricular catheter
(ii) A one–way valve
(iii) Distal catheter.

**Ventricular Catheter**

They provide direct access to the ventricle and are placed via a twist drill (burr hole) and are made of silastic material and are impregnated with barium for radiographic visualization. The tip may be a right-angled catheter with multiple tip perforations, a right-angled catheter with a molded, in-line reservoir.

---

**Fig. 100.11**: The usual three parts of a shunt system include: a ventricular catheter, a one–way valve and a distal catheter (Upadhyaya shunt)
and multiple tip perforations, a grooved tip design or a flanged tip design. Although a straight catheter gives maximum flexibility vis-a-vis desired length, it requires some type of connection to the remainder of the system. The right-angled catheter although fixed in terms of functional length connects to the rest of the system via its side arm, eliminating possibility of ventricular catheter separation and migration into the enlarged ventricles. It also allows a valve or flush chamber to be placed any where in the system.

**Valves**

Two types of valves are currently available, e.g. differential pressure valves and the newer variable resistance flow regulated valves.

**Differential Pressure Valves**

They provide constant resistance and allow CSF flow when the proximal hydrostatic pressure exceeds valves present closing pressures.

Closing pressures are generally used for valve identification. The valves can be divided according the closing pressures as:

1. **Low pressure (20-40 mm H₂O) shunt**: The valve opens when CSF pressure rises even marginally over the normal range. It is used for normal pressure hydrocephalus. This type of shunt is not used commonly. There is always an inherent disadvantage that it might over drain the ventricles causing subdural hygroma, specially if the patient happened to be the newborns.

2. **Medium pressure (40-70 mm H₂O) shunt**: This is the most commonly used shunt to reduce the intracranial pressure and decompress the ventricles. However, the CSF pressure is never brought to normal.

3. **High pressure (80 – 100 mm H₂O)**: This shunt valve opens at high CSF pressure. The indication to use the high pressure system, is acute obstructive hydrocephalus so that the fluid is drained slowly against resistance to avoid sudden decompression.

Differential pressure valves come in four designs:

a. Holter valve (Slit)

b. Hakim valve (ball-in-cone)

c. Upadhyaya (Diaphragm), Pudenz valve, Chhabra, Ceredrain

d. Miter valve

- **Holter valve (Slit)**: It is the simplest valve type. When the pressure builds up inside the tubing, the slit is forced open and CSF is allowed to flow outward. The pressure at which the valve open is determined by thickness of tubing wall. The advantage is easy placement and accessibility. It can be placed anywhere in the shunt system and do not require direct connection to the ventricular catheter. This allows for valve replacement without manipulation of ventricular catheter. However, it is bulky. It can be easily blocked by turbid fluid and debris.

- **Hakim valve (Ball-in-cone)**: Similar to the Holter valve but differs in its mechanism. A synthetic ruby ball is held in place by a stainless steel spring. Depending on CSF flow rate, the ball moves back and forth within the cone under the control of calibrated spring. It is less vulnerable to obstruction by viscous, proteinaceous CSF and particulate matter.

- **Upadhyaya (Diaphragm), Pudenz valve, Chhabra, Ceredrain**: Upadhyay shunt has a diaphragm valve above and a slit valve at the lower end (Figs 100.12 and 100.13). Pudenz valve utilizes a thin diaphragm against a seat to control flow. It is usually designed to attach directly to a ventricular catheter so that it is “seated” in a burr hole. Horizontal type constitutes the Chhabra shunt. Upadhyay shunt and Ceredrain (Sri Chitra shunt) also work on the same principle.

- **Miter valve**: It is constructed from two thin sheets of silicon rubber that are bound together at one end and open at the other to regulate pressure. Each leaflet act as a spring so that, as the pressure increases at the inlet end, the leaves are pushed apart.
Variable Resistance Flow Regulated Valves

These valves take care of over-drainage by varying valve resistance and keeping CSF flow constant. They are two types:

a. *OSV valve (Orbis-Sigma valve):* The valve resistance of this valve varies by changing the cross sectional area of the valve outlet area depending on the hydrostatic inlet pressure.

b. *Delta valve:* This is a simple diaphragm valve coupled with an antisiphon device. Two silicon leaflets cover the outlet port. This unit acts as a differential pressure valve but when negative pressure is in the distal tubing (i.e. when the patient is in erect posture), suction on the distal diaphragms occlude the outlet ports preventing CSF flow.

Programmable valves have been successfully put in preterm and term babies (< 2 months of age). The valve settings can be readjusted at different pressure levels as required. Several external adjustments of the valves apparently avoided several surgical shunt revisions.26

Distal Catheter

It is similar to ventricular tubing. It may come open-ended or closed end with a slit valve. It may have a metal spring or be made of heavier guage silicone to prevent kinking.

Additional Devices

- *Flush Chambers and reservoirs:* The basic tripartite shunt system consisting of a ventricular catheter, a unidirectional valve and a distal catheter does not allow access to the ventricular CSF. At times, it may be necessary to withdraw CSF for culture or administer antibiotic, chemotherapeutic agent or radiographic contrast medium directly into the ventricle. For direct ventricular instillation, reservoirs or flush chambers can be added to shunt system.

- *On-off device:* Can be used to provide intermittent shunting or to access shunt function.

- *Shunt filter:* It is used when ventricular obstruction is caused by tumor. The filter serves to stop the dispersal of tumor cells throughout the body via the distal shunt tubing.

- *Antisiphon device:* This is another approach to the problem of ventricular over drainage. The device closes when there is negative pressure within the shunt tubing, acutely raising resistance to CSF flow and preventing ventricular over drainage.

SHUNT INSERTION

Each surgeon adopts to a particular type of shunt and adopts a method most suitable for its insertion. The equipment used for shunt insertion also varies from surgeon to surgeon however the principles of strict asepsis and avoiding skin contact of the shunt to prevent contamination with staphylococcus epidermidis remain the same. It is also better to use the system with a minimum number of connections to avoid the postoperative complications.

Procedure for Placing the Upadhyaya’s Shunt

Preoperative preparation includes combination of antibiotics (covering the gram-positive and gram negative organisms), shaving the head, removing the oil from scalp, cleaning the ears and the skin creases in the neck and behind the pinna, and painting of the part with betadine or mercurochrome a day before the surgery. The patient, like any other neurosurgical procedure, deserves high attention to be put as the first case in the list observing strict aseptic precautions. Insertion of Upadhyaya’s ventriculo-peritoneal shunt,
requires at least three skin incisions – in scalp, neck and abdomen. The shunt assembly is checked for its patency and placed in saline with antibiotic solution. Any contact of the shunt assembly with skin should be avoided as much as possible.

**Positioning the Patient**

It is the right ventricle which is used for shunt insertion routinely. However, it is only occasionally that the left ventricle would be utilized for shunt insertion either as a first choice (if it is too much enlarged) or the right ventricle is not available for use (bleeding, adhesions, sclerosis, localized infection). The right hemisphere is preferred because most commonly it is the non-dominant hemisphere. The patient is placed supine with the head turned to the left, with suitable roll/s placed between the scapulae and the neck so that the neck is extended and rotated on the thorax. Care should be taken that the ventricular end, the distal end and the shunt tract, are all in a single straight line to prevent unwanted injuries and kinking. External ear should be temporarily plugged. The pinna is brought forward and strapped in front of the tragus to assist in cleaning the area behind it.

**Skin Incision**

Curvilinear skin incision, about 4-5 cm in length, is planned over the most prominent part of the scalp to expose standard burr hole site, to allow passage of shunt catheter from the scalp incision to the abdomen with only one additional intermediary incision in the neck to negotiate a curve and avoid any injury to the thorax, permitting final seating of the shunt away from the incision line.

**Insertion of Ventricular Catheter**

The ventricular catheter which has multiple holes near its end (and with the suitable sized stylet in situ) should be placed in the frontal horn, keeping the direction of the tip of the ventricular catheter towards the nasion while inserting the catheter. The tip of the catheter should be away from the choroid plexus. The stylet is withdrawn gradually while keeping the catheter inside the ventricular system. The CSF pressure is noted and the catheter is clamped to avoid CSF loss. To minimize blockade with choroids plexus, late fractures, disconnections and tethering of the shunt in the subcutaneous tissue, it is advisable to insert an additional length of the shunt for about 2-3 cm beyond the level of the “give way feel” in the choroids plexus or when the CSF starts coming out. The catheter is placed in the lateral ventricle ideally, anterior to the foramen of Monro. This is because the anterior extent of the choroid plexus is present up to this foramen and it is believed that anterior placement would decrease the incidence of blockage of the ventricular catheter by the choroid. The two accepted approaches used are:

1. Parieto-occipital placement into the frontal horn of the lateral ventricle.
2. The more direct anterior approach through the frontal lobe at the area of the coronal sutures.

The posterior placement is sited 3 cm above and behind the tip of the ear or approximately around 2-3 cm lateral to the highest point of the occiput. From the posterior parietal site, catheter should be aimed at the glabella in both the axial and sagittal planes. The advantages of this approach are (i) shorter subgaleal tunnel for the external catheter (ii) longer ventricular segment for drainage. The disadvantages include the potential damage to the visual cortex if the lateral ventricles are grossly dilated and the cortex is thinned out.

The anterior approach is sited 3 cm lateral to the sagittal suture and just anterior or posterior to the coronal suture and the brain cannula is directed towards the inner canthus of the ipsilateral eye. The advantages of the anterior approach are shorter distance through the brain parenchyma and better chances of achieving correct positioning.

The disadvantage of the anterior approach is that the catheter has to travel a longer distance subgaleally and as the child grows there is traction and risk of damage or disconnection. CSF is usually encountered at a depth of 2-4 cm in children. The CSF pressure may be measured at this point to decide the type of shunt to be placed. Once free flow is ensured, catheter is snapped into a right-angled clip that prevents kinking at the burr-hole and secured with a silk ligature. The extracranial portion of the shunt system is pulled taut from the abdominal end to eliminate kinks. The valve with the shunt assembly must come to rest on the surface of the skull.
**Insertion of Distal Catheter**

Abdomen is opened along the right sub-costal, (or alternately by a right paramedian or midline incision) upto the peritoneum. In the abdomen, a subcutaneous tunnel is created about 2 cm proximal to the skin incision. This tunnel is also created along the subgaleal plane above the pericranium, over the clavicle upto the peritoneum. An introducer may be passed from the abdominal side. This guides the distal shunt tubing from the subgaleal space into the abdomen. The distal tube is then placed into the abdominal cavity. The length of the distal tube left in abdomen is usually about 4-6 inches and placed either over the right dome of the liver with a gentle curve or deep in the pelvis to minimize omental adhesions. The wound is finally closed in layers, with the peritoneum around the catheter.

**Connection of the Shunt Assembly**

The shunt assembly is connected with the connectors. Care should be taken that the valve overlies the mastoid bone so that it can be felt to check its function. One of the connectors is fixed to the pericranium.

**SHUNT COMPLICATIONS**

**Complications Related to Ventricular Related End**

1. Shunt infection
2. Shunt Obstruction (Ventricular end, valve, distal end)
3. Shunt disconnection or fracture
4. Shunt migration
5. Overdrainage — Slit ventricle syndrome
6. Subdural/Extracerebral CSF collections
7. Craniosynostosis
8. Seizures
9. Penumocephalus
10. Isolated ventricle syndromes.

**Complications Related to Peritoneal End**

1. Inguinal hernia and hydrocele
2. Ascites
3. Pseudocyst formation
4. Intestinal volvulus and obstruction
5. Bowel perforation, bladder perforation
6. Peritonitis.

**Shunt Infection (10-20% of Shunt Insertions)**

This is the most important complication of shunts and difficult to establish (Fig. 100.14). Unequivocal evidence of shunt infection requires demonstration of the organism on Gram staining or culture from material in, on, or around the shunt, or from fluid withdrawn from the shunt. Shunt infection occurring within the first 2 months after surgery are usually caused by skin flora and indicate poor surgical aseptic technique. Infection occurring after this period are caused predominantly by Gram-negative bacilli. The risk factors for shunt infection include young age with relatively immature immune system and vulnerability of the skin, poor skin hygiene, long duration of operation, presence of CSF leak and increased number of OT personnel.

Acute shunt infection presents with fever, redness around the skin incision or the shunt tract and in later stages discharge of pus from the incision. Chronic infection may present with exposure of the shunt, CSF leak from the incision site or frank signs of meningitis. The diagnosis may be supported with leukocytosis and CSF examination. Gram staining will confirm the diagnosis 95% of cases.

Ventriculoperitoneal (VP) shunt is one of the commonest procedures in neurosurgical practice. A significant problem encountered in shunt procedures is infection, with infection rate ranging from 2 to 27%, often with poor outcome. Shunt associated infections are most frequently (65%) caused by coagulase
negative Staphylococcus (CoNS). 27,28 Gram-negative bacteria are the next most frequent pathogens, e.g., *Pseudomonas aeruginosa*, *E. coli* and *Klebsiella pneumoniae* accounting for 19-22% of cases. 29 Most of the infections occur within 30 days of the shunt procedure. 29

Shunt infection has been defined as isolation of the organism from the ventricular fluid, shunt tube, reservoir, and/or blood culture along with the clinical signs and symptoms suggestive of shunt infection or malfunction like fever, peritonitis, meningitis, signs of infection along the shunt tract, or nonspecific signs and symptoms of headache, vomiting, change in mental status, or seizures. 29 Fever and vomiting have been reported as the most common clinical symptoms. Altered sensorium, abdominal tenderness and seizures were less common manifestations. 29 In gram positive shunt infections, majority of the organisms are commensals of the skin, a result of direct wound contamination during surgery.

The treatment depends upon the severity of the infection. If the CSF is turbid, more active treatment is initiated. The site of infection is to be identified. If the tract of the shunt is infected and there is leakage, removal of the shunt is warranted.

The treatment options include:

1. Antibiotics alone. It is useful in shunts infected with organism such as *Hemophilus influenzae*, meningococcus and gonococcus. Failure of the fluid to clear within 48 to 72 hours should prompt removal of the shunt equipment. Antibiotic treatment is recommended for a duration of 2-3 weeks and preferably the same antibiotic should be instilled intraventricularly at least once daily.

2. Antibiotics, with shunt removal and the immediate replacement with a new shunt, if the ventricular CSF is relatively sterile but the shunt taps have been positive for culture (suggestive of shunt colonization). It contemplates the need for a subsequent operation.

3. Shunt removal combined with antibiotic treatment is an alternative method to treat shunt infection. However, this requires to be supplemented with the adequate medical decompression (acetazolamide, glycerol, furosemide, alone or in combination). If the CSF leak is persisting from the shunt tract or the ventricular system is grossly infected with the positive CSF cultures, then an external ventricular drainage is preferred. This should be achieved preferably with a new shunt catheter discarding the previous one in place. This procedure is ideal and carries the highest cure rate once the shunt is found to be infected and not being cured by antibiotics alone. Many of these children with repeated surgeries in the past, produce gradually reducing amount of CSF each day suggestive of developing ventricular sclerosis or the status of the arrested hydrocephalus. These children may not require a shunt at all in future as they may well be managed with the medical decompression alone.

4. Shunt removal combined with antibiotic treatment, interval external ventricular drainage and shunt placement on the opposite site once the CSF is clear. This is the preferred procedure in children who would require shunt drainage once the infection has been cleared however, the ventricular system used so far has multiple loculi with septae due to previous surgeries and the repeated infection. Even if the shunt has been placed effectively, it may fail to drain the ventricular system effectively. Thus the choice for placing the shunt on the opposite virgin site to drain larger surface area of CSF production. Besides, a 30-40% mortality reported in some series with shunt infection, the survivors risk psychomotor retardation as a result of the infection and alteration in CSF circulation.

**Shunt Obstruction**

It may be a proximal or the distal obstruction.

(a) **Proximal Shunt obstruction:** This is the most common cause of shunt obstruction in pediatric age group. It can be blocked by adherent choroid plexus, by debris, embedding of proximal catheter in periventricular ependymal and neural tissue or blood in the ventricular system which occludes the catheter lumen, by brain tissue adherent to the catheter, or in certain cases by another pathologic process such as tumor tissue growth around the catheter tip. The decision for shunt revision is based on clinical as well as radiological findings and has to be prompt. In three piece systems the neck connector is opened to check and confirm the blocked end. At surgery, the ventricular catheter may be tethered to the choroid plexus and in such a situation saline irrigation may be tried to free it.
The ventricular catheter obstruction is diagnosed by observing no flow or only a drop or two of the CSF exiting from the isolated ventricular catheter. It should be removed and replaced by a new catheter. Sometimes, the catheter may be struck and attempts to remove can cause intraventricular bleeding which may be difficult to control. Gradual traction on the catheter or cauterization of the plexus by using ventricular stylets may be considered in these situations. If the CSF is blood tinged, it is imperative to wait for in 3-5 minutes to allow the blood to form a clot. The clot gravitates to the recumbent portion of the ventricle and the shunt tubing floats to the superior portion of the ventricle. A formed clot, hence does not obstruct the ventricular catheter whereas fresh continuing bleeding does as it clots within the tubing. Persistent flow of fresh blood is an indication for exteriorization. It is best to use the same shunt tract, unless loculated, in revisions of the ventricular catheter.

(b) Distal obstruction: With the advent of silastic catheters, this complication is rare. The common causes are malposition of the catheter that typically results from placement of the distal end into pre-peritoneal fat rather than the peritoneal cavity proper and low-grade peritoneal infection by anaerobic organisms, causing encystment and loculation of the peritoneal contents around the catheter tip, leading to pseudocyst formation and shunt obstruction. Other rare causes of distal shunt malfunction include distal slit valve occlusion by debris, migration of the tip of peritoneal catheter into an area where absorption is limited, e.g. hernial sac, embedding in the wall of the bowel, shortening of the catheter as the child grows and the catheter pulling out of the peritoneum.

Over drainage phenomenon is directly responsible for several complications like orthostatic hypotension, subdural CSF collections, slit ventricle syndrome, and loculation of ventricles. This complication can be minimized by addition of Siphon-resistive devices to the shunt systems.

Slit Ventricle Syndrome

The term slit ventricle syndrome is applied to a subset of shunt dependent patients who develop chronic, recurring headaches associated with features of raised intracranial pressure in the presence of persistent small slit like ventricles. The incidence of this syndrome ranges between 0.9-3.3%. Its hallmark is presence of definite elevation of ICP which may be as high as 50 to 60 cm H₂O in the face of small ventricle on CT scan.

Children with this syndrome often have functioning shunts throughout the period of rapid head growth, and their skulls are thus tightly configured to underlying brain with very little CSF space over the convexities. Any event which subsequently elevates CSF pressure even for brief periods such as viral infections will result in ICP rise that is not buffered by extraventricular CSF displacement as in the patient without shunts and symptoms associated with sustained rise in ICP develops.

Pathogenesis and Proposed Mechanisms

1. CSF over drainage due to siphoning effect of the peritoneal catheter.
2. Periventricular fibrosis.
3. Intermittent proximal catheter malfunction.
4. Decreased intracranial compliance and intracranial hypotension.

Clinical Features

The patient presents with chronic, intermittent and recurrent headaches with or without vomiting. Minor viral illnesses may precipitate the headache and patients with chronic intracranial hypotension may have headaches with increased activity and in an upright position. The symptoms in this disorder are much more prominent than the signs which can be elicited. Papilledema is rare though venous pulsations in the retina are diminished during symptomatic
periods. An examination will confirm the shunt chamber is filling slowly. Bradycardia, obtundation and hypertension are ominous and late signs.

**Diagnosis**

A CT scan done during the symptomatic period and compared to a baseline scan shows unchanged ventricular size. A radionuclide shunt patency study will confirm normal CSF flow and rule out partial shunt obstruction. ICP monitoring with a portable monitor is useful to record periods of increased ICP or intracranial hypotension which can then be correlated with the patient's symptoms.

**Treatment**

1. Patients with mild symptoms associated with a systemic stress and unchanged CT scan from baseline are treated with corticosteroids and acetazolamide.
2. Shunt revision is indicated for patients with increased ventricular size or evidence of shunt obstruction. While revising such a shunt, care must be taken not to allow the CSF to drain out. Rather, the proximal catheter is revised by dilating the ventricles with 10-15 cc of saline prior to the removal of the old catheter and insertion of a fresh ventricular catheter is done via the old shunt tract.
3. In patients with severe headaches, normal shunt function and dangerously high ICP levels, “cranial expansion” is an alternative. Craniotomy with morcellation of the posterior calvarium from the coronal suture to the inion and laterally to the squamosal suture is the preferred procedure.
4. Treatment of symptomatic intracranial hypotension requires addition of an antisiphon device to the shunt assembly with or without upgrading of the shunt to a higher valve pressure. The antisiphon device counteracts the siphoning action of the hydrostatic pressure of a fluid column between the head and the abdominal cavity.

**Shunt Disconnections and Dislodgements**

A disconnection is diagnosed frequently by palpating the shunt apparatus and detecting a gap in the tubing. The gap may be distended by fluid collection and the presence of a lump over the shunt tubing may be the initial complaint of the parents or the patient. This discontinuity can be confirmed by X-rays which may reveal discontinuity if it was a barium impregnated shunt. The neck is a common site of such fractures because of the frequent movements leading to the material fatigue and routine wear and tear. Due to slow leakage of the CSF in the neck, a pseudo sheath may be formed around around the shunt tubing. This may be draining the CSF to the abdominal cavity, albeit not satisfactorily, if the lower end of the shunt is blocked and not able to drain it effectively.

The most frequent cause of shunt disconnection is the improper use of connectors distal to the valve apparatus. To avoid repeated disconnections, all distal revisions of peritoneal shunts entail the replacement of the entire tubing distal to the cranial valve.

Tubing can also crack secondary to trauma and to deposition of calcific deposits around the subcutaneous tubing as it ages. Skiagrams may show the discontinuity of the shunt. In questionable cases of shunt malfunction, radioisotope study can be performed by injecting small volume of radioisotope usually 0.5 to 1 ml into the shunt reservoir while occluding the distal valve to direct the isotope into the ventricles.

Valve incompetence is rarely a cause of shunt dysfunction and can be ruled out by meticulous testing before shunt placement. Though, it is believed that a high CSF protein content predisposes to shunt obstruction, many studies have shown that there is no direct correlation between the incidence of shunt dysfunction and CSF protein content.

Seizure disorders can be secondary to shunt malfunction or secondary to ventriculitis following a shunt injection. There have been many studies which have demonstrated EEG abnormalities in shunted patients who could develop an epileptogenic focus after surgery. Routine use of anticonvulsant therapy is not required but high risk patients with intraventricular hemorrhage and porencephalic cysts require serial EEG evaluation following a shunt especially during the first 2-4 years.

Subdural hygromas are seen in patients with gross hydrocephalus associated with cortical atrophy following CSF diversion. Subdural hematomas and effusions are usually asymptomatic but may cause focal neurological deficits due to midline shift. Extracerebral CSF collections usually recur after aspirations or simple drainage. Definitive treatment has to be directed towards increasing the intra-
ventricular pressure relative to the subdural space. Temporary ligation of the shunt system or drainage of the extracerebral CSF collection into the shunt system below the level of the valve of the ventricular catheter, are the available options.

Pneumocephalus occurs in patients because of air entering through the enlarged congenital bony and dural defects after a shunt has decompressed the ventricles and the tamponade effect of the brain on these defects is lost. These patients are difficult to treat because the site of air ingress is unusually located and difficult to diagnose in the presence of CSF diversion.

Perforation of a viscus, bowel can happen rarely and after dislodgement may come out of the abdominal wound, anus or vagina. Spontaneous bowel perforation can present with shunt infection or obstruction. The shunt is replaced or externalized till the infection clears and the perforation repaired.

Craniosynostosis is another reported complication of CSF shunting and is seen frequently with the use of a low pressure valve. In most cases besides the cosmetic effect there is no restriction in brain growth. Cephalocranial disproportion is another rare complication of shunting in which there is cerebellar and brainstem herniation into the upper spinal canal. This is believed to be due to secondary craniosynostosis causing herniation of the brainstem to accommodate the growing brain.

**Shunt Revision**

When a part of the shunt system becomes non-functional, exploration of that end with repair or replacement is known as shunt revision.

**Shunt Dependency and Independency**

Recurrence of symptoms in individual once the shunt is blocked is known as shunt dependency. If the symptoms do not occur in the patient even in the presence of a blocked shunt, it is known as shunt independency. However, there is a dictum that “once a shunt, always a shunt”. Even if the shunt is not needed in routine life, it should be left in situ so that it could serve the purpose if the need be.

**VENTRICULOATRIAL SHUNT**

Ventriculoatrial shunts are less preferred to ventriculoperitoneal shunts as the severity and consequences of the complications are more frequent and more serious with the use of vascular shunts. Peritoneal shunts required fewer revisions and proximal revisions are more common unlike vascular shunts which require distal revisions more often. The second major advantage of VP shunts is that, unlike VA shunts, an unlimited length of distal catheter can be left behind to accommodate to catch up with the growth of the child and lessen the incidence of distal catheter revisions. However, there are conditions in which the peritoneum cannot be used like previous abdominal surgery with adhesions, unrecognized cryptic infections leading to recurrent pseudocyst formation and chemical content of the CSF may be irritating to the peritoneal surface as in post-hemorrhagic hydrocephalus.

Ventriculoatrial shunts are thus less performed with the absolute indication being a premature infant with necrotizing enterocolitis. The confluence of facial with internal jugular vein is exposed by incising the skin and either retracting the anterior border of sternocleidomastoid laterally or going in between the sternal and the clavicular head of the same muscle. Either the facial or the internal jugular vein is used. If the facial vein is preferred, then it is ligated proximally and the atrial catheter is passed through the facial vein into the internal jugular and into the right atrium. Alternately, if the internal jugular vein is to be used, then it is first isolated from the carotid sheath between two stay sutures. The vein is ligated proximally and the catheter is then inserted distal to it with a small incision to reach the atrium. Catheter is fixed with another suture around the internal jugular vein including the catheter. Alternately, a purse string suture is applied in the anterior wall of the internal jugular vein and about a 2 mm incision is made in its center. The atrial catheter is then negotiated through the incision into the internal jugular vein to reach the atrium. The purse string suture is then tightened making sure not to obliterate the lumen of the catheter, thus maintaining the blood flow to the heart along the side of the catheter.

Several techniques have been utilized to control catheter tip placement in the atrium. These include fluoroscopic control, catheter tip filled with 3% normal saline and used as ECG electrode (‘p’ wave becomes biphasic at entry into the atrium) and trans-esophageal ECHO that is the simplest. The simplest way is to
measure the distance between the sternal notch and the xiphisternum. The atrial catheter equal to the length of the “upper one third of this distance” would be enough to place the same in the atrium from the sternal notch. This coincides with the upper border of the fourth intercostal space.

The disadvantages include frequent revisions due to growth of the child, migration into it ventricle, cardiac arrhythmias and embolization into pulmonary artery. The other complications include mural thrombosis, endocarditis, cardiac tamponade secondary to right atrial perforation, superior vena cava obstruction, pulmonary hypertension, cor pulmonale and shunt nephritis.

LUMBOPERITONEAL SHUNTS

This is a good site for the placement of the shunt between the theca space in the lumbar region and the peritoneal cavity in patients with communicating hydrocephalus. The common indications for the lumboperitoneal shunt include CSF leaks following the MMC repair (not responding to the medical therapy), pseudotumor cerebri and CSF fistulas at the base of the skull.

The major advantages of this site are that it preserves the integrity of the CSF pathways and does not cause secondary aqueductal obstruction. Lumbar shunts are less likely to cause collapse of the cortical mantle than that seen with the VP shunts. The ventricular walls do not collapse around the catheter and this decreases the incidence of blockage. This procedure can also be performed percutaneously using a Touhy needle. The disadvantages related to this procedure are associated risks of chronic symptomatic cerebellar tonsillar herniation, kyphoscoliosis due to arachnoiditis and nerve root damage.

INTRACRANIAL SHUNTING

(a) Ventriculovenous shunting - Cannulation of the aqueduct of Sylvius has been performed after suboccipital craniotomy for the treatment of aqueductal stenosis. In occlusion of one of the foramina of Monro, an open cannulation has also been attempted.

(b) Ventriculocisternostomies.

(i) Third ventriculostomy – This was proposed by Dandy in 1922. This may be performed either by an open or closed technique. Nowadays perforation of the floor of the III ventricle is performed by ventriculoscopic techniques. Stereotactic guided puncture of the lateral ventricles is done either through the subfrontal or subtemporal approach. The ventriculoscope is passed through the lateral ventricles to the floor of third ventricle and an opening is made in the floor of third ventricle and communicating the ventricles to subgaleal space.

Although ventriculoperitoneal shunt remains the treatment of choice for many children with hydrocephalus, advances in endoscopic technology have greatly expanded the treatment options for these patients. For selected patients with obstructive hydrocephalus, endoscopic third ventriculostomy and other endoscopic techniques offer substantial advantages over shunt surgery, with a higher success rate being reported in the recent series. As with any surgical procedure, appropriate patient selection is critical to successful outcomes.

Ventriculostomy has been reported as an effective treatment in cases of obstructive hydrocephalus that is caused by aqueductal stenosis and space-occupying lesions. Early clinical picture after the operation plays an important role in predicting patient’s outcome after endoscopic third ventriculostomy. In cases of intraventricular tumors, in addition to ventriculostomy, biopsy was performed that successfully helped the patient management.

The disadvantages are the patient has to be reoperated if the opening gets blocked. However, the chance of shunt related infection is abolished in this procedure.

The overall results (shunt-independent patients with clinical remission or improvement) who had undergone endoscopic third ventriculostomy for obstructive hydrocephalus was very good in 87.1%. As postoperative failures occur early, clinical and radiological control studies, particularly in the first year after the neuroendoscopic procedure, have been recommended. Simultaneous
endoscopic third ventriculostomy and ventriculoperitoneal shunt group has also been recommended as the first choice of action for the hydrocephalic patients less than 1 year old. The success rate was 83.9% in the endoscopic third ventriculostomy plus ventriculoperitoneal shunt group and 68.9% (31 of 45) in the ventriculoperitoneal shunt only group. The complications; like infections and obstructions were much less in the endoscopic third ventriculostomy plus ventriculoperitoneal shunt group.

(ii) Torkildsen procedure–This is a redundant procedure now and had involved the cannulation of both the lateral ventricles into the cisterna magna. The Ventricular catheter cannulates the lateral ventricle via occipital burr hole and the distal catheter is placed into the cerebral subarachnoid space following a cervical laminectomy. The indication is obstruction of third ventricle or aqueduct of Sylvius. It is not to be considered as an alternative to a ventriculoperitoneal shunt.

(iii) Fourth ventriculocisternostomy–This procedure has been attempted to treat the Dandy Walker cyst by establishing communication between the fourth ventricle and the perimedullary and pontocerebellar cisterns.

NORMAL PRESSURE HYDROCEPHALUS

Normal pressure hydrocephalus (NPH) may be defined as a state of chronic hydrocephalus in which the prevailing CSF pressure has returned to a physiologic range but in which a slight pressure gradient is moderate, the ventricles enlarge gradually, accompanied by a slow, progressive wasting of the white matter. In well compensated cases, the ventricles may not continue to enlarge, but the existing pressure gradient is sufficient to keep the CSF system inflated and results in a sustained stretching of neurons and associated fibers. This circumstance cannot be regarded as normal.

In normal pressure hydrocephalus, also known as occult hydrocephalus, there is dilatation of the ventricles without the rise in the ICP.

A salient pathologic feature of normal-pressure hydrocephalus is an incomplete block of the CSF pathways. This permits compensatory changes of occur, which, in time, retard the hydrocephalus process and equilibrate CSF pressure to within a normal range. Whereas the majority of cases of NPH involve an obstruction of the distal subarachnoid pathway, approximately 20 percent of the cases are of the noncommunicating type. The most common cause of communicating NPH are head trauma, meningitis and subarachnoid bleeding. Noncommunicating types are most often seen in patients with aqueductal stenosis and/or the Arnold-Chiari malformation.

The clinical syndrome of normal-pressure hydrocephalus is insidious and is characterized in adults by the classic triad of dementia, incontinence, and a disturbance of gait. Since the syndrome is disarmingly free of overt symptoms, and because signs of increased intracranial pressure are generally absent, the diagnosis can go undetected for a prolonged time. The differential diagnosis includes all the presenile and senile dementias, post-traumatic cerebral atrophy, and cerebral arteriosclerosis. CT scan shows the enlargement of the ventricles with the periventricular lucency along with Sylvian fissures. The MRI scan shows decreased cerebral flow. Treatment is the insertion of the low pressure VP shunt. In a study, the caudate and corpus callosum ROI measurements revealed diminished caudate nuclei volume in the NPH group.

Gait abnormalities are the early clinical symptom in normal pressure hydrocephalus, and the subjective improvement in gait after the temporary removal of CSF is often used as an indication to perform shunt surgery. There are significant, quantifiable changes in gait after CSF drainage that corresponds to improvement after shunt surgery for patients with NPH.

ARRESTED HYDROCEPHALUS

Arrested hydrocephalus is a state of chronic hydrocephalus in which the CSF pressure has returned to normal and in which the pressure gradient between the cerebral ventricles and brain parenchyma has been dissipated. Under these conditions, the size of the cerebral ventricles remains stable or decreases, new neurological signs do not appear and there is evidence of advancing psychomotor development with increasing age. This definition is consistent with the findings in patients with surgically treated hydrocephalus.
Spontaneous arrest of hydrocephalus is most likely to occur when the CSF obstruction is incomplete and when the block is distal (extraventricular) rather than proximal (intraventricular). Patients with this diagnosis should be followed for at least 1 year with periodic neurological examinations. IQ test and CT or MRI scans to rule out the insidious development of normal-pressure hydrocephalus. It is important to point out that if the hydrocephalic process is truly arrested, continuing damage to the brain ceases and, in the case of children, normal developmental processes such as myelinization and neuronal maturation resume. Clinically, these changes are manifested by resumption of psychomotor development, albeit as a subnormal level. It is my personal opinion that spontaneously arrested hydrocephalus is not an optimal physiologic state is the cerebral ventricles are significant enlarged, and if it can be established on the basis of clinical and neuroradiological evidence that this is not due to cerebral atrophy. Under such circumstances, consideration should be given to a ventricular shunting procedure.

ASSOCIATED CONGENITAL ANOMALIES

The various anomalies of the posterior fossa include Arachnoid and Neuroepithelial cysts, Dandy-Walker malformation, Isolated fourth ventricle, Pulsion diverticulum and Mega cisterna magna and ex-vacuo states.

Arachnoid Cysts

These arise by a splitting of the arachnoid membrane and are lined by fibro-connective tissue. About 30-40% of arachnoid cysts arise in the posterior fossa and present with signs and symptoms of increased intracranial pressure secondary to hydrocephalus or direct mass effect. Neuroepithelial cysts resemble arachnoid cysts but are lined by cuboidal to columnar epithelium. Surgery is recommended only if the child is symptomatic or the cyst shows evidence of expansion. A cysto-peritoneal shunt using a low pressure valve is an accepted initial procedure. Cyst excision or decompression into the subarachnoid space is recommended by some neuro surgeons in view of the high rate of proximal shunt dysfunction and non obliteration of many cysts despite providing a drainage.

Dandy-Walker Malformation

This is characterized by the presence of a dilated fourth ventricle and enlarged posterior fossa and complete or partial agenesis of the vermis. Dandy-Walker malformation comprises of a triad of hydrocephalus, posterior fossa cyst and absence of cerebellar vermis. There is atresia of foramen of Magendie and Luschka. It is associated with hydrocephalus in 65% of cases.

MRI is the best diagnostic investigation which classically shows a large posterior fossa with an elevated torcule and complete or partial absence of the vermis. This syndrome is associated with hydrocephalus and agenesis of the corpus callorum. About 20% of the patients are asymptomatic. Most present with signs and symptoms related to the associated hydrocephalus and only a few have symptoms related to the cyst itself. Till last decade excision of the cyst membrane along with shunt was the treatment of choice. From the last decade, only a shunt is the treatment preferred. The lateral ventricle or the cyst has been drained by a ventriculo or cysto peritoneal shunt. It is now recommended that the shunt should be placed in the cyst and not in the lateral ventricles. Upto 40% of such patients require the other CSF space to be subsequently drained. With the advent of third ventriculostomy various authors now advocate an initial cystoperitoneal shunt followed by a third ventriculostomy if needed. With a recognized need for a second decompression surgery, some surgeons advocate an initial combined cysto-ventricular drainage using a Y connector, placed proximal to the shunt valve.

The outcome depends on the associated anomalies and over 50% of children with the Dandy-Walker complex perform satisfactorily at school provided the hydrocephalus is well controlled.

Isolated Fourth Ventricle

Patients of hydrocephalus adequately decompressed by a shunt can develop secondary aqueductal stenosis as a result of chronically diminished flow through the aqueduct. Some of these patients may develop an enlarged 4th ventricle and present with a mass lesion in the posterior fossa, nystagmus, lower cranial nerve palsy or bradycardia. Patients with posthemorrhagic or a post inflammatory hydrocephalus and Chiari II malformation are predisposed to developing an
isolated fourth ventricle. In the absence of a Chiari II malformation, ventriculostomy is a viable alternative. Patients with a Chiari II malformation require cannulation of the 4th ventricle preferably under CT guidance to avoid injury to vital structures.

**Chiari Malformations**

The various types of Chiari Malformation described are:

- **Type – I** Caudal displacement of cerebellar tonsils below the plane of the foramen magnum
- **Type – II** Caudal displacement of the cerebellar vermis fourth ventricle, and lower brain stem below the plane of the foramen magnum. Commonly associated with myelodysplasia
- **Type – III** Caudal displacement of the cerebellum and brain stem into a high cervical meningocele
- **Type – IV** Cerebellar hypoplasia (not a type of cerebellar hernia)

Only patients with type-II Arnold-Chiari malformations have associated hydrocephalus and require shunts (Fig. 100.15).

**Meningomyelocele (MMC) and Hydrocephalus**

About 80% of all infants with myelomeningocele either concomitant hydrocephalus or develop the same within the first few weeks after MMC surgery. More distal the lesion, more the chance of developing the hydrocephalus. Clinical features of hydrocephalus become apparent within 1 to 2 weeks of MMC repair. A regular monitoring of the head size in the postoperative period is mandatory to note the progress of hydrocephalus. A medical therapy is first instituted with acetazolamide and Glycerol. If the hydrocephalus remained uncontrolled on ultrasonography, surgical intervention is recommended.

There is much controversy about the timing of the MMC repair and the shunt in a patient who has both the MMC and the hydrocephalus at the time of presentation. In patients with hydrocephalus having a tense fontenella and raised ICP, it is better to drain the hydrocephalus before resorting to MMC repair. However, simultaneous surgery can also be performed for both the MMC and the hydrocephalus with some added risks of infection. Similarly, a shunt inserted before the MMC repair may allow the infection to ascend up from the surgery site to the ventricles due to suctioning effect of the VP shunt. Similarly, in the similar case if the excision of the sac is done first, to be followed by the shunt surgery, then there is a risk of persistent leak at the MMC repaired site.

**PROGNOSIS**

**Natural History**

Approximately 50% of untreated patients die. The remaining 50% survive with so-called arrested hydrocephalus. Of these, 11-18% have normal cognitive and neurologic findings.

![Fig. 100.15: A sagittal depiction through the craniocervical junction. The rhombic roof bulges towards cisterna magna during fetal age. The choroid plexus has migrated intraventrically and caudally displaced cerebellar vermis](mebooksfree.com)
Course of the Disease

The course of the hydrocephalus is quite variable and depends on a complex interplay of factors such as patient age at the time of presentation, severity of symptoms, degree of dilatation, presence or absence of infection and associated abnormalities.

The etiology of the hydrocephalus affects the morbidity. Hydrocephalus following brain injuries affect the cognitive functions more than those by obstructive pathologies. Prenatal hydrocephalus is considered to have a poor prognosis with only 1/3 having an intelligent quotient (IQ) of above 80. The rate of progression also has an impact on development. Slowly progressive hydrocephalus may be asymptomatic with a normal IQ inspite of papery thin cortical mantle. About 1/3 of these patients with gradually progressing hydrocephalus will go into a state of arrested hydrocephalus in their life time. Mortality of patients with hydrocephalus associated with other congenital abnormalities is 80% within the first 5 years of life. The average life time of a shunt varies in different case series though it has even been reported to be as high as 73 months.

The rate of cardiac malformations has been reported to be higher in the group without neural tube defects (p = 0.015). The morbidity has been reported to be higher in the group with neural tube defects, possibly due to the higher number of surgical interventions in the central nervous system. However, the mortality was higher in the group without neural tube defects, possibly due to the presence of other associated malformations, especially congenital heart disease.

In a nationwide Japanese survey, surgical treatment was performed in 341 of 380 patients who survived the early neonatal period. This is a relatively high incidence of performing shunt surgery. 91.9% of these underwent ventriculoperitoneal shunt and 2.8% ventriculoatrial shunt. The incidence of complications after the first shunt was 55.4% in the programmable and 61.6% in the non-programmable valve groups. The types of shunt complication differed significantly between these groups (p < 0.001), as the incidence of shunt infection and malfunction was lower in the programmable valve group. Clinical outcome was generally better with later delivery stage during gestation (p < 0.02). The clinical outcome was statistically significantly better in term patients who underwent early shunt placement than in those who underwent late shunt placement (p < 0.05).

A mathematically model of survival to study the prognosis of a newly inserted shunt in pediatric or adult patients with hydrocephalus has been reported. Shunt survival rates calculated with this model in children and adults were calculated for 1 year (64.2 and 80.1%, respectively), 5 years (49.4 and 60.2%, respectively), and the median (4.9 and 7.3 years, respectively).

LONG-TERM FOLLOW-UP RESULTS

Mortality in hydrocephalus patients is usually related to the etiology and associated conditions. Most published series report long-term survival (50-90%) in surgically treated patients. Patients with myelomeningocele associated hydrocephalus have a higher mortality rate as compared to isolated congenital hydrocephalus. Patients with vascular shunts have a significantly higher morbidity and the mortality than those with peritoneal shunts (19% vs 11%). The natural history of untreated hydrocephalus is dismal and only 20% of patients survive till adulthood. IQ has been correlated cortical mantle thickness as:

- Patients with cortical mantle thickness with < 2 cm remain uneducable.
- Patients with the cortical mantle thickness between 2-3 cm develop an IQ < 100.
- Patients with cortical mantle thickness more than 3 cm have normal IQ.

The best functional results after shunt surgery are obtained in infants below 5 months of age. Patients with myelomeningocele associated hydrocephalus have a better intellectual outcome as compared to other children with hydrocephalus. This is probably related to the myelomeningocele sac acting as a reservoir and preventing ventricular dilatation before birth. Only 38% of patients with congenital hydrocephalus have normal cognitive development. The factors affecting nonverbal IQ in hydrocephalus are associated brain malformation, age at shunt surgery, antiepileptic drugs, side of shunt (right better than left) and associated perinatal insults.

The care of children with hydrocephalus requires a multimodality approach. Early treatment and regular follow-up can ensure a favourable outcome in these children. A follow-up CT scan for at least
3 years or so with no increase in the ventricle size and the shunt lying blocked, would suggest that the hydrocephalus has achieved a state of arrest and the shunt is no more needed. However, in normal circumstances the shunt is not removed unless the surgeon feels that the shunt has really been unnecessary. Some patients manage with their shunts well, however, others would require many revisions, as many as 20 revisions in their life time. Each revision may be associated with deranged brain function. Many children have been achievers in their personal and family life including sports but it has been observed that number of children leading such quality of life decreases with age, especially after the age of 20-25 years. It is estimated that about 1,50,000 shunt units are marketed in USA alone with billions of dollar expenditure each year. In developing countries like India, an inexpensive shunt developed by Prof P Upadhyaya has been used regularly in the author’s institution since 1970, costing now about USD 25 only. It has been used in over 2000 children with hydrocephalus of different etiologies, including the postmeningitic and tubercular hydrocephalus with gratifying results. Patients with shunt hydrocephalus need to be kept under constant supervision of the experts so that the timely help could be provided in case the patient develops shunt related complications, which are in any case not infrequent.

**RECENT ADVANCES**

- To detect possible ultrastructural alterations of the lateral ventricles, choroid plexus (responsible for the CSF production) have been studied in rats that were submitted to an intracisternal injection of 20% kaolim (hydrated aluminum silicate) for hydrocephalus induction.
- Newer shunt devices (Saply SV8): In this system the pressure valve is situated externally over the skin and patient manipulates the pressure valve as per his symptoms.
- Endoscopic laser ablation of choroid plexus: Recently the endoscopic laser ablation of choroid plexus has been done in cases of idiopathic hydrocephalus and the choroids plexus hyperplasia.
- Gentian Violet impregnated shunts to reduce the incidence of shunt infection and the shunt colonization with *Staph. albus*.
- Barium impregnated shunts for visualization of the shunt assembly by imaging. This is especially useful to demonstrate if the shunt assembly has either fractured or one of its ends has migrated and lost in the peritoneal cavity or the heart chambers.

**IDIOPATHIC CHILDHOOD HYDROCEPHALUS**

Magnetic resonance imaging with flow quantification has been done in idiopathic childhood hydrocephalus. It was found that in children with hydrocephalus, the cerebral blood inflow was normal, but the superior sagittal sinus (SSS) and straight sinus outflows were reduced by 27% and 38%, respectively, when compared with the measurements in control group (p = 0.03 and 0.002). These findings suggest that approximately 150 ml of blood per minute was returning via collateral channels from that portion of the brain drained by the SSS, and 60 ml/minute was returning from collaterals in the deep venous territory. This has been correlated with idiopathic intracranial hypertension seen in adults and it has been elucidated that the same venous pathophysiological process may be operating in both conditions. Whether or not the ventricles would dilate, may depend on the differences in brain compliance between adults and children.

Encephaloceles

DEFINITION AND HISTORICAL ASPECTS ON ENCEPHALOCELES

Encephaloceles are congenital disorders characterized by protrusion of brain or meninges out of the cranial cavity through defect in the skull. Depending on the content or herniation, it may be cranial meningoceles or meningoencephaloceles. When herniated brain contains a part of the ventricle, the condition is called hydroencephaly. Thus, encephalocele is a generic term used to describe above mentioned congenital cranial abnormalities.

According to Emery and Kalhan, the first medical report on encephalocele dates back to 16th Century, however, deformity like encephalocele was first illustrated in medieval art and archaic sculpture. It was Ritcher et al, who first described a case of nasal encephalocele in 1813 (Fenger).1,2 Heinecke in 1882 classified encephalocele (Fenger) depending on herniation tract.2 In 1903, Stadfeldt first coined the term frontoethmoid encephalocele (Bumenfeld and Skolink).2 Brower and de Veer in 1934 termed nasal encephaloceles as Rhinoencephaloceles.4 Suwanwela and Suwanwela in 1972 proposed a morphological classification of sincipital encephaloceles.5 Tessier in 1976 described different facial clefts and correlated them with the congenital deformities.6

The incidence of encephaloceles is less common than spinal dysraphism, being 1 per 3000 to 10,000 live birth.7,10 Overall occipital encephaloceles are more prevalent than anterior encephaloceles. In western countries occipital encephaloceles constitute 80 to 90 percent of all encephaloceles.10,11 However, higher incidence of anterior encephaloceles is reported from Thailand, Indonesia, India, Papua New Guinea and Africa.5,11-15 The incidence of anterior encephalocele reported from the West is 1 per 35000 to 40,000 live birth.15-17 Basal encephaloceles are rare,18-21 Authors have encountered 5 cases of intranasal encephaloceles in their series of 65 cases.21

CLASSIFICATION OF ENCEPHALOCELES (TABLE 101.1)

Encephaloceles have large number of classifications based on several aspects of the encephalocele i.e. site of cranial defect, visibility of encephalocele from outside and the size of the encephalocele.22-26 Encephaloceles are classification as occipital, parietal, frontal, nasal and nasopharyngeal type. Suwanwela and Suwanwela put forward the morphological classification of sincipital encephaloceles.5 Anterior encephaloceles (Table 101.2) again have many classifications. Heinecke, in 1882, classified the encephaloceles (a) sphenopharyngeal, (b) Spheno-orbital and sphenomaxillary types (quoted by Fenger) depending on hernial tract.2 Mesterton in 1885, classified anterior encephaloceles into (a) Nasofrontal, (b) Nasoethmoidal and (c) Nasoorbital types. In 1965 Bumemfeld et al classified encephaloceles as (a) transethmoidal, (b) trans-sphenoidal, (c) spheno-ethmoidal and (d) Sphenomaxillary.3 Suwanwela et al proposed the morphological basis classification of sincipital encephalocele.5 The bony defects involving inner and outer tables of the skull are enumerated in Table 101.3.

EMBRYOLOGY

Anterior neuropore closes around 24th day of gestation. Developmental neural tube defects have
been attributed either to the primary failure of closure of neural tube, or neural tube rupture after its closure. Severe forms like an encephalus, and cranioschisis may point to an earlier effect, may be in early neurulation stage. The unfused cephalic end of the neural fold, or defective closure of anterior neuropore may communicate to amniotic cavity, when skin, cranium and dura fail to cover neural tissue. However, the above hypothesis does not explain the occipital or sincipital encephaloceles with healthy skin cover and the absence of cranial dysraphism. Gardner’s hydrodynamic theory does not explain the well formed skin cover and lack of cranial dysraphism, as it is usually the case with encephaloceles. Neuroschisis theory proposes bleb formation over the neural tube, which on healing gets adherent to cutaneous ectoderm, this can explain the formation of encephalocele.

Various etiological factors have been incriminated in the formation of encephalocele. Willamson et al. postulated viral antigen following maternal infection in the early phase of pregnancy. Hyper-vitaminosis, irradiation, hypoxia, hyperthermia and salicylates have also been reported to cause encephalocele in experimental animals. Moerman et al. postulated a band of amniotic adhesion resulting in formation of encephaloceles. Leong et al postulated the displacement theory for occipital encephalocele, which also corresponds to the area of anterior neuropore.

</table>
Anterior encephaloceles result due to failure of anterior neuropore, which is located in front of the foramen caecum of anterior cranial fossa floor, just ahead of crista galli, which is the junction of the ethmoid bone and frontal bone. In the early embryonic life, failure of closure of anterior neuropore results in herniation of neuroectodermal tissue, interposed between the mesodermal elements, which later develops into ethmoid frontal bones. Various theories have been put forward for the development of anterior encephaloceles. Geoffrey et al proposed the adhesive theory, while Wiese et al suggested the primary mesodermal failure theory leading to defective bone formation resulting in formation of anterior encephalocele.

ASSOCIATED PATHOLOGY

A number of systemic abnormalities (Table 101.4) may be associated with encephaloceles. Musculoskeletal defects, the “morning glory syndrome (progressive hormonal and visual disturbance progressive), and the Knobloch syndrome (skin defect and visual problems).

CLINICAL PRESENTATION

Swelling at Birth

Patients with encephaloceles are born with a swelling on the scalp at birth, the location depends upon type, which may or not be visible. The shape, size and contents of the encephaloceles are variable. In occipital encephalocele, a globular swelling is noticed over the occipital bone in midline, which may be sessile or pedunculated. The size of encephalocele is independent of the amount of herniated neural tissue. Although most encephaloceles transilluminate brilliantly as they contain clear CSF, a large amount of gliosed brain within them may reduce the degree of transillumination.
Size of Encephalocele and Relation with Size of Head

Size of the head is usually small\(^{11,12}\) and depends on the amount of herniated brain tissue. Occasionally the size of the encephaloceles may be very large. Encephaloceles with diameters larger than the diameter of head of the patient\(^{3,4,43-45}\) are called giant encephaloceles. Typically the head looks smaller than the size of the encephalocele causing difficulty in nursing. Over the years the authors have encountered 4 patients with giant encephaloceles, 3 in occipital and one in frontal area. Giant encephaloceles contain a large amount of brain tissue and can cause considerable problems during closure.

Location of Encephalocele

Site of encephaloceles (Fig. 101.1) is frequently occipital or suboccipital.\(^{20,26,29,46}\) Ten percent of the encephaloceles are located anteriorly (Fig. 101.2).\(^{5,11,41}\) Rarely encephaloceles could be in frontal, temporal, parietal, transethmoid, intranasal, or orbital region (Fig. 101.3) (Table 101.5).\(^{9,11,14,18,42,44,47-51}\)

Visibility of Encephalocele

Patients with frontoethmoid encephalocele present with swelling over the root or the bridge of nose since birth.\(^{5,14,15,24,52}\) Those with nasopharyngeal, transsphenoidal, and sphenethmoidal encephaloceles do not have an obvious external swelling and may present with nasal obstruction causing difficulty in breathing, CSF rhinorrhea, or recurring attacks of meningitis.\(^{8,14,20,24,32,43,50,53-55}\) Often a suspicion of encephalocele becomes evident when a patient with intranasal encephalocele presents to an Otolaryngologist as a nasal polyp and it is inadvertently biopsied or operated leading to development of CSF rhinorrhea.\(^{13,14,24,43,54}\) Rarely, encephaloceles may present in mouth through a cleft palate.\(^9\)

absence of wing of the sphenoid bone. The proptosis is positional, and disappears on assuming a supine position.

**Anterior Encephalocele**

It can be subdivided into following sub-groups (Fig. 101.4)

a. **Nasoethmoid type:** Also called *Long nose encephalocele* is the commonest type of sincipital encephalocele constituting 85% of anterior encephalocele. The inner cranial defect lies in front of crista galli in the floor of anterior cranial fossa. The facial defect lies at the junction of the nasal bone and nasal cartilage (Fig. 101.5). The frontal process of maxilla and nasal bone form the anterosuperior part of the sac, and the postero-inferior wall is formed the nasal cartilage and nasal septum. The lateral part of the sac extends into the orbit and presents at the inner canthi causing bilateral displacement orbit and the eye ball laterally, downward and produces severe degree of hypertelorism. The neck of the encephalocele is also very long. The swelling causes widening of the nasal bridge and pushes the tip of the nose typically downward, thus producing a markedly elongated the nose.

b. **Nasofrontal type:** Also called glabellar or frontonasal encephalocele and is relatively rare (Fig. 101.6). The internal bone defect is
Encephaloceles

present in front of the crista galli with is round or oval shaped. Usually crista galli project into the defect and forms the posterior margin of bone defect. Anterior cranial fossa is deep. The fascial bone defect lies at the junction of nasal bone and frontal bone. Patient may or may not have hypertelorism. However, maxilla, nasal bone and nasal process of maxilla are normal.

c. **Naso-orbital type:** A rare form of frontoethmoidal Encephalocele. Among the reported 75 cases of anterior encephaloceles, the authors have noted 7 of them (Table 101.5). The inner skull defect is located in front of crista galli and the outer fascial defect is present between the frontal process of maxilla and lacrimal bone. Frontal process of maxilla forms the anteromedial whereas lacrimal bone forms the posterior lateral boundaries of the sac. Outer swelling appears at the inner canthus of the eye. It may either project unilateral or bilaterally. The eyeball and the inner canthi are pushed downward and laterally (Fig. 101.7). Thus, all these patients invariably have some degree of hypertelorism, which will require correction. Nose and nasal bones are normal.

d. **Trans-sphenoidal encephaloceles:** This is the rarest from of encephalocele. Pollack et al reviewed 8 case of trans-sphenoidal and transethmoid encephaloceles. The Bony defect is present over the roof of the sphenoid sinus. Thus, the encephalocele may come through the sella or through planum sphenoidale and enters into the sphenoid sinus and nasopharynx. Patients may present with history of CSF rhinorrhea, endocrine disturbances and rarely visual disturbances.

**Rare Clinical features (Table 101.6)**

**Hypertelorism**

Hypertelorism is a common finding in anterior encephalocele. This type of encephalo-
Rarely, maxillary and zygomatic bone abnormalities, neurofibromatosis and 13-15 triosmy have been reported.

**Mental Retardation and Other Neurological Deficits**

1. **Mental retardation:** Severity of mental retardation depends upon the degree brain damage in encephalocele. Suwanwela et al reported a higher incidence of mental retardation in patients with anterior encephalocele. However, in the authors' series there was a low incidence. Children with occipital encephaloceles may present with poor cry and suckling due to herniation of cerebellum and brainstem into the sac. Increased tone in limbs and defective temperature regulation indicate a poor prognosis.

2. **Smell and visual abnormalities:** Defects of smell and vision are rarely discussed. It is logical to have smell abnormalities in patients with frontoethmoidal or sphenoidoethmoidal encephaloceles. In cases of unilateral nasoorbital encephaloceles with paramedian anterior fossa defect, smell is likely to get preserved in one side. Visual abnormalities may be due to herniation of occipital lobe into occipital encephalocele, chiasmal abnormality in transsphenoidal encephalocele, compression of optic nerve by an orbital encephalocele, associated hydrocephalus, or rarely vitreoretinal degeneration.

3. **Associated Syndromes:** Few rare syndromes are associated with encephaloceles. “Knobloch syndrome” was deserved by Knobloch and Layer in 1971. The syndrome is transmitted by autosomal recessive inheritance and characterized by vitreoretinal degeneration with retinal detachment, high myopia and encephalocele. “Morning glory syndrome” is a condition, characterized by nasal encephaloceles associated with progressive hormonal and visual problems. The basal encephaloceles are in the form of transsphenoidal or sphenoidoethmoidal type. Because of pituitary involvement, deficiency of growth hormone and ADH patients present with polyuria, polydipsia and dwarfism. “Von Vos-Chestrovoy syndrome” is another clinical entity described by Von Voss et al in 1979. The syndrome is characterized occipital encephalocele, phocomelia, along with cerebellar anomalies transmitted by autosomal recessive gene. The upper limb abnormality more often due to defect in radius. The other associated anomalies involve face, heart, lungs, urogenital system, gastrointestinal system and include thrombocytopenia. Lubinski et al in 1994 reported 4 cases and a review the literature on this subject. Walker–Warburg Syndrome (WWS) is a lethal, complex syndrome involving of the CNS and the eyes, and is genetically transmitted by autosomal recessive gene. Martinez et al reported 9 children with WWS, 8 children of them had occipital encephaloceles.

**INVESTIGATIONS**

Diagnosis of encephalocele is usually made clinically, except in rare cases where encephaloceles is not visible externally. A large number of factor influence the treatment and ultimate prognosis. These includes hydrocephalus, associated CNS anomalies, facial deformity and associated systemic abnormalities. Assessment of all the above factors needs proper radiological, genetic and hormonal assessment.

**Plain X-ray**

Shows a soft tissue mass and a circular smooth bone defect depending on the site of the encephalocele. It may show nasopharyngeal soft tissue mass or displacement of nasopharyngeal region in sphenoidal or nasopharyngeal encephalocele. In sincipital encephaloceles, X-ray skull shows deformity of orbits and hypertelorism and enlargement of orbit in intraorbital encephaloceles. There may be hypoplasia of anterior or middle fossa.

**Carotid Angiograms and Pneumoencephalograms**

Have been used as investigations in the past. Suwanwela et al reported the value of ventriculography in patients with anterior encephaloceles in assessment of communication between CSF pathway with encephalocele sac. Similarly cerebral angiography delineates the intracranial vasculature including sagittal and transverse sinus. In a large number of cases there may be abnormalities of dural venous sinuses.
Computerized Tomography and Magnetic Resonance Imaging

CT and MRI scans are the commonly used modalities to evaluate craniocerebral anomalies including encephalocele.\textsuperscript{8,32,37,61,63,74} (Fig. 101.8). There are only few reports dealing with MRI.\textsuperscript{32,73,74} CT scan helps in evaluation of dilation of ventricular system and CSF pathway. The bone window can delineate the contents of encephalocele and the bony defect in the skull base.\textsuperscript{8,25,55,73-75} Hydrocephalus is commonly associated with posterior encephaloceles. However, in anterior encephaloceles association of hydrocephalus is reported in 10-15\% cases.\textsuperscript{8,16,32,33,37,41} CT scan is also helpful in detection of associated CNS anomalies like agenesis of the corpus callosum (Fig. 101.9) and porencephalic cysts.\textsuperscript{21,37,40,62} In cases of transethmoidal

\textbf{Figs 101.8A and B:} CT scan axial slicer show frontothemidal encephalocele

mebooksfree.com
or transsphenoidal encephaloceles, a soft tissue density mass in the sinuses and bone defect in skull base are well visualized.\textsuperscript{8,9,15,50,55} In orbital encephaloceles the relation to the eyeball and optic nerve can be established (Fig. 101.10). The bone window may show a sphenoid wing defect. Recently, metrizamide CT cisternography has been used in cases of occult encephalocele.\textsuperscript{76} Three-dimensional CT scans are used for evaluation of basal defect (Fig. 101.11A).\textsuperscript{32,74} MRI helps in soft tissue delineation (Fig. 101.11B), diagnosis of Chiari malformation and syringomyelia.\textsuperscript{21,32,73,74}

### Isotope Studies

Are sometime useful in diagnosis of encephalocele.\textsuperscript{43,55,72} Yoshimoto et al reported trans-ethmoid encephalocele in a 2 year old child, who had bacterial meningitis.\textsuperscript{55} Isotope cisternography confirmed the CSF rhinorrhea. Anand et al suggested Isotope studies for preoperative surgical approach planning.\textsuperscript{1}

### Electroencephalography and Visual Evoked Potential

May show electrical activity from the content of the sac. However, little attention is usually paid in assessing encephalocele electrophysiological. Recently, visual evoked potentials have been used to assess occipital lobe and anterior visual pathway function.\textsuperscript{77} Surprisingly, not much literature is available on visual evoked potentials. The ability to obtain VEP from the sac indicate presence of occipital cortex within the sac, absence of visual evoked potentials may suggest defect in visual cortex or dysplasia of optic pathway.\textsuperscript{7,29}

### TREATMENT

The aim of surgical therapy of encephalocele is to excise the hernial sac, repair the dural defect after putting back the herniated brain into cranial cavity. Sometime it may not be possible to push the brain into the cranial cavity. Then the choice is to either excise
part of the brain or to give support to the brain in an extracranial space. Sometimes, in a patient with leaking encephalocele associated with hydrocephalus, shunt surgery may stop CSF leak and allows skin to heal. A large number of children with occipital and anterior encephalocele require CSF shunt diversion. Except for the situation with CSF leak, fortunately most of the encephaloceles are with good skin cover, and an immediate or emergency surgery is not required. Surgery can be delayed for weeks and months depending on the condition of the neonate. Surgical procedure becomes simple, when an encephalocele sac has a small cranial defect, narrow neck, small sized and with very little or no herniated brain tissue inside the sac.

**SURGERY OF OCCIPITAL ENCEPHALOCELE**

Occipital encephalocele without brain herniation can be operated easily, however, when the sac contains cerebrum, cerebellum, and brainstem, surgery may be harmful and it is better to avoid an operation. Large number of authors have reported a poor outcome in patients with microcephaly with large volume of neural tissue within the sac. Some authors have treated the occipital encephalocele in special way. Gallo described a technique for the management of a giant occipital encephalocele where an extracranial compartment is created by utilizing a fine tantalum mesh to enclose the herniated brain for the protection.

Patients with occipital encephalocele are operated in a prone position, with controlled ventilation and closed temperature monitoring. In patients with large encephalocele aspiration of CSF prior to incision in, helps in dissecting out the sac. For a circular encephalocele with small occipital bone defect, a transverse incision is ideal. Patients in whom the encephaloceles extend above and below the posterior fossa need a vertical incision. The sac is separated out from the skin flap. Care must be taken to identify the contents of the sac. Sometimes brainstem and occipital lobe are present in the sac (Fig. 101.12). Rarely, sagittal sinus, torcula and transverse sinus are in the vicinity of the sac. It is always preferable to preserve the neural tissue. The dural defect can be repaired by using pericranium as graft. In neonates and infants no attempt should be made to cover the bone defect by graft. In older children with large cranial defect, the autogenous bone graft or acrylic plate may be used for the closure (Figs 101.13A and B).
Postoperatively patients may develop CSF leak, acute hydrocephalus and meningitis. Patients where shunt is not performed prior to encephalocele repair may need CSF diversion procedure subsequently. External ventricular drainage is the only alternative in patients with meningitis. Once the meningitis is adequately controlled, a ventriculoperitoneal shunt is advisable.

**PROGNOSIS IN PATIENTS WITH OCCIPITAL ENCEPHALOCELES**

Large number of factors can influence the outcome, including, site, size of the encephalocele, amount of the brain herniated into the sac, presence of brainstem, occipital lobe, cerebellum, with or without dural sinuses and presence of hydrocephalus. One of the most important prognostic factor is the associated brain and systemic anomalies. Overall, the long-term outcome in occipital encephalocele is not encouraging.

**ENCEPHALOCELES THROUGH THE CRANIAL VAULT**

Encephaloceles through the cranial vault are rare. They may be through frontal, parietal or temporal bones. Encephaloceles can occur through anterior or posterior fontanel. Parietal or interparietal encephaloceles are probably the most common encephaloceles of the cranial vault. Interparietal encephaloceles are difficult to treat and have poor prognosis. Only 15% of these patients have normal mental development, while the rest have mental and physical abnormalities. Treatment in patients with small parietal encephaloceles is not difficult. Patients with large skull defect need cranioplasty. In several occasions, when there is a large cranial defect. To cover the large cranial defect the authors have used split autogenous outer table grafts (Fig. 101.13), using Aesculap or Midas Rex drill. Temporal encephaloceles are less common. They constitute 1% of all encephaloceles. Rarely, temporal encephalocele may develop following radiation. Clyde and Stechison reported a temporal encephalocele presenting with CSF rhinorrhoea. They repair the temporosphenoidal encephalocele with vasculised split calvarial graft.

**TREATMENT OF ANTERIOR ENCEPHALOCELES**

The main aim of the management of the anterior encephalocele is to repair the dural defect and to correct the bony deformities. Unfortunately a vast majority of patients have facial abnormality and associated hypertelorism. Sometimes the malformation may be complex. The associated facial deformity plays an important role in final corrective surgery. The cosmetic outcome depends upon the experience of the surgeon.

One stage repair of encephalocele along with the correction of facio-orbital deformity is a long procedure and requires on an average 6-8 hours of surgery. Hence, the age of patient at the time of surgery must be such that the child should be able to stand a long surgical procedure. In our centre, we prefer the surgery when the child is over 8-10 months old. Early surgical repair is ideal, as the bones being thin can be easily moulded. Early surgery also prevents CSF leak and risk of meningitis.

A Ventriculoperitoneal shunt procedure prior to definitive corrective surgery prevents postoperative CSF leak in patients having hydrocephalus. One stage correction of craniofacial deformity is ideal. The factors that influence the surgery are, type of encephalocele, degree of hypertelorism, degree of nasal deformity, and associated CSF leak or meningitis. Tesier, popularized the concept of one stage repair. Sometime, in a small child with CSF leak, two stage procedure may have to be carried out. Large numbers of authors have reported good results with one stage craniofacial correction. Recently Mahapatra et al and Mahapatra have reported craniofacial surgery in newborn with good results.

**One Stage Surgical Correction Involves Following Steps**

1. Bifrontal craniotomy, frontoorbital osteotomies.
2. Medial advancement of orbit, after excising the extra bone is the midline, to correct the hypertelorism.
3. Initial part of surgery deals with delineation of neck of encephalocele, followed by excision of herniated gliosed brain.
4. The dural defect is closed by dural graft, either by suturing or by using biological glue.
5. The type of correction of hypertelorism depends upon degree of the hypertelorism. In case of mild hypertelorism, excision of soft tissue in medial canthus and fixing the medial canthi to nasal bone may suffice.\textsuperscript{24,61} Sometimes, nibbling of bone at the medial canthi followed by reconstitution of medial canthus by canthal stitch corrects the hypertelorism.\textsuperscript{12,51}

6. Over correction of hypertelorism is important, as a significant amount of soft tissue may still be left in the medial canthus at the end of the operation. The aim is to achieve an inner canthal distance of 25 mm. Sometimes, a classical Tessiers operation may not be necessary. Recently, Mahapatra\textsuperscript{21,25,32} reported advancement of medial half of the orbit medially and placing a supraorbital bone graft on either sides. By above procedure the operating time can be reduced by an average of 90-100 minutes.

7. Reconstruction of the nose is also a very important step in correction of anterior encephaloceles.\textsuperscript{6,12,16,32,79} Nose deformity is maximum in patients with nasoethmoid type of anterior encephalocele. Extra skin over the encephalocele has to be excised.

8. The bridge of the nose is reconstructed either by using rib or split calvarial graft.\textsuperscript{6,12,24,79} Overall cosmetic correction is satisfactory in our experience (Figs101.14A and B).

Sometimes, to achieve a cosmetically excellent result, several small plastic surgical procedure may be necessary depending on the need of an individual patient, to correct nasal deformity or to excise extra skin or soft tissue at the medial canthi. This is basically because of cosmetic acceptance depends upon socioeconomic status and age of the patient. In girls the need for a better cosmetic result is more. An important postoperative problem following anterior encephalocele repair is, CSF leak leading to meningitis (Table 101.7). Large number of children develop transient CSF rhinorrhea, which stops within few days. Small number of patients require a thecoperitoneal shunt. In our series of 65 patients there was one postoperative mortality.\textsuperscript{21}

**PROGNOSIS IN PATIENTS WITH ANTERIOR ENCEPHALOCELES**

Anterior encephalocele has a better overall prognosis than occipital encephalocele.\textsuperscript{11,21,32,68,75,79} Presence of hydrocephalus in occipital encephalocele makes the prognosis poorer.\textsuperscript{29,46} In absence of hydrocephalus or

meningitis, a large number of children are at a have normal intellectual development. Cosmetic deformities can be corrected with appropriate craniofacial surgery. Thus, overall outcome in children with anterior encephaloceles are more favourable as compared to occipital encephaloceles.

REFERENCES

Microcephaly is a common situation in pediatric practice. The clinician has to first confirm presence of microcephaly, distinguish primary and secondary microcephaly, identify microcephaly as distinct from craniosynostosis, evaluate family for a possible familial microcephaly and lastly probe into etiology of pathologic microcephaly. The clinician must clearly identify all neurological and systemic associations to determine the cause and appropriately counsel the family. A thorough evaluation of influence on development, neurological deficits and intelligence is warranted. The variations of norms of head size in the population should also be addressed to in drawing clinical conclusions.

**DEFINITION**

Microcephaly denotes an occipitofrontal circumference (OFC measured around forehead and occipital protuberance) as two or more standard deviations below the mean for the individuals age gestation gender and race (below the 2nd percentile).

The definition of microcephaly inadvertently includes 1.9% of normal children who have a head circumference below 2 SD of mean. At term the average neonate has an average head circumference of 33.5-35 cm and the brain averages about 12% of the body weight. At one year age the OFC is 45 cm and is almost 950 grams. In clinical practice serial measurement of head circumference and comparing the serial head circumference profile to norms is a very useful clinical parameter because a deviant OFC warns of an abnormal brain. It may be important to remember that patients may have normal neurological function and intellectual abilities even with a small sized brain. In general however the brain size - OFC-IQ have a good correlation in normal subjects. Only 14% of subjects with an OFC below 2 standard deviations below the means had IQ above 100, while in 70% the IQ ranged between 71-80, only 10.5% had an IQ below 70. If growth was concurrently affected 13.3% had IQ below 70.

The OFC correlates strongly with the intracranial volume. Factors that determine the OFC are thickness of the scalp, the thickness of the calvarial bones, the ability of the cranial sutures to expand, and most importantly the volume of the intracranial contents. The intracranial contents are comprised by brain volume, CSF in ventricles and subarachnoid spaces, blood volume in the intracranial vessels and any space-occupying lesions.

**ETIOLOGY**

Microcephaly may be caused by a teratogen, a chromosomal abnormality, or a genetic defect (Table 102.1).

A small brain volume is the most common cause of microcephaly except in cases of premature sutural fusion. Extremely preterm birth is associated with adverse neurodevelopmental sequelae. Head circumference has been used as a measure of brain growth (Figs 102.1A and B). In a study on 227 preterm infants, a strong correlation was noted between head circumference and brain volume at term. There was no significant relationship between head circumference and white or gray matter abnormalities on MRI. The microcephaly increased from 7.5% at term to 29.7% at 2 years. Brain volume is a determinant of head size at term. Microcephaly is associated with a

An abnormally small brain results from anomalous development in the first 7 gestational months (primary microcephaly) or from an insult after 7 months of gestation, perinatal period or in infancy when it is termed secondary microcephaly. The earlier the insult the greater the potential of microcephaly. Primary microcephaly results from anomalies of neurogenesis and migration due to genetic or early detrimental influences.

In vivo studies suggest that many forms of microcephaly result from defects in the control of cell fate: precocious formation of neurons during early developmental stages produces deficiencies in progenitor cells at later stages of neurogenesis, resulting in an overall small cerebral cortex.\(^3\)

Malformations of cortical development caused by disruptions at various stages are increasingly recognized as an important cause of developmental delay especially with the emergence of high resolution imaging.\(^4\) Disorders of neurogenesis give rise to microcephaly (small brain) or macrocephaly (large brain). Disorders of early neuroblast migration give rise to periventricular heterotopia (neurons located along the ventricles), whereas abnormalities later in migration lead to lissencephaly (smooth brain) or subcortical band heterotopia (smooth brain with a band of heterotopic neurons under the cortex). Abnormal neuronal migration arrest give rise to over...
migration of neurons in cobblestone lissencephaly. Lastly, disorders of neuronal organization cause polymicrogyria (abnormally small gyri and sulci). Identification of various gene mutations has not only given us greater insight but also an understanding of the processes involved in normal cortical development.

Genetic factors determine much of the normal variation in brain size and hence OFC, and thus usually result in primary microcephaly. Many errors of chromosomal morphology and aneuploidies translocations, trisomies, nondisjunctions, and duplications — cause a small, defective brain. In genetic microcephalies the migration anomalies include lissencephaly, pachygyria, polymicrogyria and corpus callosum defects. Heterotropias are commonly recorded. Primary microcephaly can be transmitted as autosomal dominant, autosomal recessive or even in X linked manner. Various genetic loci have been identified of which a common one is on 8 p chromosome. In some families migration defects, visuo-retinal abnormalities or spasticity in varying combinations may be observed. Associated dysmorphisms lead to identification of the various syndromes. Other genetic disorders, such as neurofibromatosis I and achondroplasia generally cause large brains.

Microcephalic osteodysplastic primordial dwarfism type II is a specific disorder characterized by severe intrauterine and postnatal growth retardation, acquired microcephaly, cerebrovascular abnormalities, progressive bone dysplasia, and a characteristic face. Genetic malformations of the cerebral cortex are an important cause of neurological disability in children. The genes implicated in these disorders are essential for normal cerebral cortical development. Therefore, identifying these genes and studying their functions will help us further the understanding of the normal biological mechanisms of brain development. Lissencephaly and microcephaly are two groups of disorders that have been intensely studied and several causative genes within each group have been identified. Type I (classical) lissencephaly is characterized by a smooth-appearing brain with a lack or severe reduction of normal gyri. Three of its identified causative genes (LIS1, DCX and TUBA1A) are related to microtubules, which are essential for neuronal migration in the developing cerebral cortex. Microcephaly vera is a form of microcephaly with four responsible genes reported to date. Three of them (ASPM, CENPJ and CDK5RAP2) localize to the mitotic centrosome, and one (MCPH1) is implicated in cell cycle checkpoint regulation and DNA damage response. This suggests that abnormalities of neural progenitor cell division are fundamental to the pathogenesis of microcephaly vera. These genes for microcephaly vera are also suggested to have played a role in evolutionary volume expansion of the human cerebral cortex. Genetic studies of lissencephaly and microcephaly have been very fruitful in providing novel insights into various aspects of human cerebral cortical development.

A network of DNA damage response mechanisms functions co-ordinately to maintain genomic stability and ensure cellular survival in the face of exogenous and endogenous DNA damage. Microcephaly, representing reduced brain size, is a feature common to a diverse range of DNA damage response-defective disorders. Microcephaly is most likely caused by loss (increased cell death) or failure of the developing neuronal stem cells or their progenitors to divide suggesting a fundamental role for the DNA damage response in maintaining proliferative potential in the developing nervous system.

Microcephaly may be associated with a normal contour of the skull or an abnormal shaped head. In the latter situation focal anatomical lesions of the brain, e.g. porencephaly, hemimegalencephaly or abnormalities of the overlying bones like craniosynostosis may need to be excluded. Craniosynostosis may be simple, i.e. single suture fusion or compound. It may be an isolated phenomenon or part of a dysmorphology, genetic or chromosomal syndrome.

Intrauterine infections with the TORCH-S complex, varicella, HIV can all result in microcephaly. The associated perinatal events and associated clinical features IgM Ab against specific agents in the perinatal period and identification of HIV infection can all provide diagnostic pointers.

Irradiation during the first two trimesters of pregnancy can result in microcephaly. Irradiation of less than 10 Gy is safe. The risk is proportional to the amount of radiation. Hypoxia is one of the important and commonly encountered insults, severe hypoxia can result in permanent sequelae.
Chronic maternal exposure to alcohol, cocaine smoking have been recognized as incriminative. Additionally drugs such as antiepileptic drugs, corticosteroids, antineoplastic agents may result in microcephaly besides other teratogenic consequences. Maternal phenylketonuria, if untreated may also result in a microcephalic neonate.

ANTENATAL DIAGNOSIS

There are cases of antenatal diagnosis of microcephaly but the diagnosis is usually based on ultrasound examination. The diagnosis may not be correct in some cases especially in twins. It is not always possible to differentiate between the normal and the abnormal by ultrasound. In borderline cases ultrasound has the advantage that it can point out the need for extra careful post-natal examination of the infant. Thus complementary examination should be performed and the results obtained should be studied critically, confirmed by repeated examinations and integrated into the whole clinical picture.

Modern ultrasound equipments allow a detailed investigation of the fetal brain from a very early stage of development. Congenital anomalies involving the central nervous system can be accurately predicted. These include hydrocephalus, holoprosencephaly, cephaloceles, porencephaly, hydranencephaly, and microcephaly.

The antenatal diagnosis of microcephaly is most commonly made in the third trimester or rarely in the second trimester. Biometric measurements of the head of three or four standard deviations below the mean are suggestive of microcephaly. Antenatal ultrasound diagnosis of isolated microcephaly is difficult. Other malformations must be safely excluded. The presence of associated intracerebral calcification suggests antenatal congenital infectious encephalopathy and may warrant medical termination of pregnancy.

Prenatal detection of lissencephaly by high-resolution ultrasound has also been reported. To confirm the diagnosis, a fetal blood sample may be obtained to look for any chromosomal abnormality.

The sibling recurrence risk was 19% in a series of 29 isolated cases of microcephaly and 9 families with recurrent microcephaly, which reflects the high incidence of autosomal recessive microcephaly in this series. The most frequent, affecting 5 sib pairs, was associated with spastic quadriplegia, seizures, and profound mental handicap. Infants with congenital microcephaly are mentally and motorially severely retarded and thus if the diagnosis can be confirmed antenatally, termination may be advised. It is estimated that 20-35% of idiopathic microcephaly is hereditary. Thus after the birth of such a case, subsequent pregnancies should be monitored ultrasonographically in order to facilitate early antenatal diagnosis and genetic counseling.
The approach to nonfamilial microcephaly is dependent upon consideration of common causes (Table 101.2).

Hereditary microcephalies may be observed as an isolated familial occurrence or as part of various syndromes. If the infant is dysmorphic a karyotyping is useful to distinguish chromosomal, e.g. Down’s from non chromosomal syndromic microcephalies.

Repeated and severe hypoglycemia may also predispose to permanent brain damage and microcephaly. Associated endocrinopathies may need exclusion specially if there are associated thyroid, pituitary or adrenal dysfunction pointers.

Chronic malnutrition may also contribute, calorie deficits, early trace element deficiency, e.g. zinc may have microcephaly besides growth failure.

OUTCOME

In general, life expectancy for individuals with microcephaly is low and the prognosis for normal brain function is poor. The prognosis varies depending on the presence of associated abnormalities. The prognostic significance for intellectual impairment is more likely to be accurate when the head circumference is 3 SD or more below the mean for dates. Microcephaly was associated with delayed development but did not influence final seizure outcome in a series of 94 infantile epileptic encephalopathies.17

Spina Bifida

The history of spina bifida stretches back to ancient times, though the plight of an infant born with an open neural tube defect has improved significantly only recently that too only in developing countries that can provide an insurance cover for rehabilitation.

The intellectual evolution of neurological spine surgery had originated in the golden age of Greece with the founding of the Alexandrian School way back in 300 BC. In the 1950s, John Holter, an engineer, developed the first effective differential pressure valve to control hydrocephalus for his son who was born with spina bifida. This was at that time perceived as the ultimate answer to the problems of a child with spina bifida. In the 1960s, worldwide, the birth of an infant with spina bifida was treated as an emergency. Open neural tissue was surgically covered regardless of the time of day or night. Ventricular atrial shunts were installed to control hydrocephalus. The early mortality rate decreased rapidly, almost reversing the previous 90% mortality to a survival rate of 80%. The shunt brought with itself further problems not anticipated. In the 1970s, the main problems were incontinence, paraplegia, and scoliosis coupled with the new problems of shunt malfunction, infection, and mental retardation. John Lorber, a neurologist in England, led the drive to control the problem. Selection criteria were developed based on the perceived quality of life expected for the infant. Children selected for nontreatment were not allowed to survive. The mortality rate climbed to 70%, and this method of caring for the newborn with spina bifida was adopted worldwide.

However, a prospective study performed between 1975 and 1979 on the outcome of 100 children with spina bifida treated aggressively from birth clearly demonstrated that the selection criteria were not valid predictors of the functional outcome for the child. Lorber’s selected population was not more functional than the unselected aggressively treated group. The only difference was the number of survivors in the selected group was much fewer. Thus the controversy remains till date and the management policies adopted differ from place to place.

The term spina bifida was mentioned way back in 1645 by Dr Nicolaes Tulp to define certain congenital malformation of the spine associated with overt cystic protrusion and some of the content of vertebral canal.

DEFINITION
Spina bifida is a neural tube defect where the vertebral and/or spinal cord of the fetus fails to develop properly and results in varying degrees of permanent damage of the spinal cord and nervous system, usually accompanied by hydrocephalus. The damage usually occurs within the first 4 weeks or pregnancy. The various synonyms are spina bifida cystica, spina bifida occulta, myelomeningocele, spinal dysraphia.

INCIDENCE
The incidence of spina bifida has been estimated at 1-2 persons per 1000 population, with certain populations having a significantly greater incidence based on genetic predisposition.

A decrease in incidence has been noted as a result of improved maternal nutrition and antenatal diagnosis with elective termination. Wider availability of maternal alpha-fetoprotein and more refined high resolution ultrasonography have given the parents an option to terminate the pregnancies. The incidence is...
Spina Bifida

0.7 to 1 in 1000 live births in US, 1 in 750 live births in Canada and 0.2 in 1000 in Japan. Spina bifida aperta is at least 7 times greater than the occult. The risk factor in a mother with previously affected children is 40-50 in 1000 that rises to 100 in 1000 with two such children. The recurrence rate usually after the birth of one affected sibling is 5%.

The chance of producing dysraphic child after the birth of two affected children increases two fold to 10%. The improved outcome with better medical care, and possible prevention of myelomeningocele with the use of folic acid has a direct impact on the recurrence risks. Originally myelomeningocele was considered to be a polygenic disorder, but later studies have shown that a recurrence risk in affected parents is only 1%. Despite this, a sufficiently high recurrence risk for parents, one of whom is affected with myelomeningocele, or a mother with one affected child warrants a therapy of 5 mg of folic acid 3 months prior to planned pregnancy.

EMBRYOLOGY

The primitive streak that appears at the caudal end of the embryo in stage 6 between day 13-15 of gestation elongates cranially. The Hensen’s node is at the cranial end of the primitive streak. The epiblast cells migrate through the primitive groove and form the endoderm and mesoderm (gastrulation) during stage 6. As the primitive streak regresses the notocord is formed which has a central canal (Fig. 103.1). The notocord induces the overlying ectoderm to form the neural plate as a slipper shaped plated of thickened ectoderm in the middorsal region in front of the primitive gut. The lateral ends of the neural plate form neural folds that fuse in the midline to form the neural tube (neurulation – stage 8-12, 18-27 days). The formation of the neural tube starts from the cervical region and proceeds cranially and caudally. At both ends fusion is delayed and cranial and caudal neuropores temporarily form open connection between lumen of the neural tube and amniotic cavity. The final closure of the cranial pore occur on 23rd-25th day, caudal neuropore closes on 25th-27th day.

The superficial ectoderm fuses in the midline and mesenchymal cells migrate between the neural tube and skin to form the meninges, neural arches and muscles.

By day 27, the caudal end of the neural tube blends into the caudal cell mass. Small vacuoles form in the caudal cell mass, which coalesce and eventually connect with the central canal of the cord by a process called canalization. The distal spinal cord then involutes (retrogressive differentiation) to form the filum terminale and the differential growth causes the conus medullaris to ascend. The conus lies at the L 2-3 interspace at birth and reaches the adult position (L1-2) by 3 months of age.
Theories on Embryogenesis of Neural Tube Defects

a. Simple nonclosure: This theory postulates that the normal process of neural fold formation and closure is interrupted in a localized area leading to a NTD.

b. Overgrowth and nonclosure: The overgrowth of the neural epithelial cells interfere with the normal folding and neural tube formation.

c. Reopening: This theory states that the neural tube reopens after closure as a result of degenerative changes at the junction of the ectoderm and neural tissue.

d. Overgrowth and reopening: The overgrown dorsal caudal neural plate is exposed after normal closure has taken place.

e. Primary mesodermal insufficiency: The mesodermal defect is the primary event that leads to the neural tube defect.

f. A unifying hypothesis for hydrocephalus, Chiari malformation, syringomyelia, anencephaly and spina bifida has been proposed recently. It proposes that hydrocephalus is caused by inadequate central nervous system venous drainage. Any volume increase in the central nervous system can increase venous pressure. This occurs because veins are compressible and a CNS volume increase may result in reduced venous blood flow that has the potential to cause progressive increase in cerebrospinal fluid volume. Obstruction to CSF flow causes localised pressure increases, which have an adverse effect on venous drainage. The Chiari malformation is associated with hindbrain herniation, which may be caused by low spinal pressure relative to cranial pressure. When spinal injury occurs as a result of a Chiari malformation, the primary pathology is posterior fossa hypoplasia, resulting in raised spinal pressure. It is proposed that hydrocephalus may occur as a result of posterior fossa hypoplasia, where raised pressure occurs as a result of obstruction to flow of CSF from the head to the spine, and cerebral injury with raised pressure occurs in anencephaly by this mechanism. It is proposed that the mesodermal growth insufficiency influences both neural tube closure and central nervous system pressure, leading to dysraphism.

ETIOLOGY

I. Unknown

II. Multifactorial: These include a combination of various causes.

III. Genetic: The genetic and familial risk of first born being affected is 1 in 250 but increases to about 1 in 20 or 1 in 25 in next pregnancy.

Polymorphism in UCP2 (uncoupling protein-2) gene
- Deranged myo-inositol, glucose and zinc metabolism in fetus.
- Polymorphism of the 5, 10-methylenetetrahydrofolate and methionine synthase reductase gene. The risk of recurrence is around 3-5%.

IV. Viral infection: Influenza infection in the childhood

V. Birth order: Higher in 1st and 2nd born

VI. Geographical variation.

VII. Vitamin deficiency: Folic acids association seen with vitamin A deficiency in the experimental animals.

VIII. Chemicals: Trypan blue

Solamine present on the skin of potatoes (in experimental animal).

Smoking during peri conceptional period and pregnancy

IX. Environmental: Alcohol, drugs like Carbamazepine and Valproate.

X. Malnutrition.

XI. Others: Relation with maternal age and seasonal variation have all been implicated as etiologic factors.

ROLE OF FOLIC ACID

Folic acid supplementation has been demonstrated to reduce the prevalence of myelomeningocele. Studies of serum RBC cell levels of folic acid and its absorption in women who have borne children with myelomeningocele suggests that there is an increased need for folic acid by these women. An alternative explanation to the deficiency theory may be the action of Pterin aldehyde, a known contaminant of commercially produced folic acid. Pterin aldehyde inhibits xanthine oxidase that in turn produces free radicals. Free radicals are known to injure tissues. By reducing the free radical load at the high energy site, folic acid may impart and protective effect. It has been suggested that changes in prevalence of anencephaly and spina bifida surrounding folic acid fortification
Spina Bifida

6 The UK Food Standards Agency Board conducted a research on options to increase folate intake in women of reproductive age in order to reduce the risk of neural tube defect (NTD) affected pregnancies. Only a minority of participants knew about a link between spina bifida and folic acid, and these tended to be women with young families. In this research, mandatory fortification was the preferred option.7 The risk of recurrence is around 1-3% and it is mandatory that mothers with one affected child are started on 5 mg tablet of folic acid daily at least three months prior to a planned pregnancy to prevent recurrence in the next pregnancy. It may be stressed that the amount of folic acid incorporated in the iron tablets/capsules (available in the market, and usually prescribed during pregnancy) is not sufficient enough to prevent spina bifida.

CLASSIFICATION

Spina Bifida Occulta
- Radiological
- Clinical
  - Extradural,
  - Intradural with or without surface stigma,
  - Intramedullary.

Spina Bifida Aperta
- Meningocele
- Meningomyelocele or myelomeningocele
- Myelocele – (Myeloschisis/Rachischisis)
- Neuroenteric canal.

Spina Bifida Occulta
Spinal bifida occulta is a mild form of dysraphism that is not accompanied by extrusion of the contents of vertebral canal. It is usually a radiological diagnosis. The defect is in the spinous process and/or associated posterior neural arch and is usually in the lumbar spine at one level only. Manifestations are less severe and diagnosis are missed until a definite and often irreversible orthopaedic or urologic syndrome develop. The cutaneous manifestations are present in half of the cases that act as sentinel for malformations of bone and nervous tissue deep beneath the skin surface. In order of decreasing frequency, these include lipoma, hypertrichosis (hairy patch) dermal dimple or sinus. Pigmented macules, vascular nevus and tail like cutaneous appendage. A pilonidal sinus usually terminates extradurally, but those occurring cephalad to the lumbosacral region should be reviewed with high index of suspicion and should be evaluated to exclude intraspinal pathology. These patients may be completely asymptomatic for years and operative interventions are usually not needed for asymptomatic cases. However, some of them may present in infancy and childhood with progressive neurological deficit (bladder dysfunction, clawing of toes, pees caves, spasticity, shortening of a limb and trophic ulcers).

Spina Bifida Aperta

Meningocele: Is a cystic lesion occurring due to herniation of the covering of the cord through a bifid neural arch that may be skin covered. The contents are only cerebrospinal fluid covered with meninges and skin. The dura is some times very thinned out and fluid contents are visible. The neural tube is fully developed There is usually no associated neurological deficits and poses no emergency unless it is thin walled with impending rupture.

Occasionally, there are double menigoceles in the same child, usually one in the cervical or the occipital region and the other in the lumbar area.

Myelomeningocele: A myelomeningocele or meningo-myelocele is a parchment membrane covered lesion that in addition to CSF and meninges also contains the neural plaque which is usually an abnormal conus medullaris (Figs 103.2A and B). The duramater and skin are deficient over the posterior aspect of the defect but the cord is still protected by the pia arachnoid. The visible abnormal tissue is usually covered by a reactive response that consists of gliosis and dysplastic axons and cell bodies. At rostral end of the sac, the spinal cord can be traced as it exits from the spinal canal: caudally may end within the meninges, extend out as a thickened filum or penetrate the spinal canal to continue. Multiple healthy nerve roots may be present on the ventral surface of placode.

In addition, there are nerve roots present that end blindly to the lateral and dorsal dural encasement. The interior of the sac is frequently honeycomb by arachnoid strands and at least one or two anomalous vessels, usually veins are present. There is usually
evidence of myelodysplasia and diastematomyelia. The neurologic deficit depends upon the level of the defect that is usually lumbar or lumbosacral.

Associated hydrocephalus is noted in 75-90% patients and neurological deficits are common. Myelomeningocele is the commonest lesion.

Rachischisis refers to a large filleted neural placode with open central canal without any encasing meninges (Fig. 103.3). The dura is deficient and stops at the margin of the defect. The lesion is usually oblong with open central canal constituting a median furrow and crossing the thoracolumbar junction. Early hydrocephalus and severe neurological deficit are present. Myelodysplasia and diastematomyelia are common. There is evidence of intrauterine muscles paralysis leading to CDR talipes arthrogryposis. If left untreated, it is usually not compatible with life.

Neuroenteric canal: During embryogenesis, the neuroenteric canal connects the neurotube with the yolk sac, the structure that later develops into the midgut. The neuroenteric canal should close during development. Neuroenteric canal is a rare malformation that results from persistence of the embryonic neuroenteric canal that allows the content of the gut to flow into the spinal central canal and causes infection (Fig. 103.4).
PRENATAL DIAGNOSIS

Screening for spina bifida may be done by assessing maternal serum AFP levels at 16-18 weeks gestation. A raised value suggests a neural tube defect with a sensitivity of 75% only and is not expected in skin covered lesions. Elevated amniotic fluid AFP and acetylcholinesterase measurement also suggests NTD but false positive results can be expected. Fetal ultrasonography may visualize the spinal placode or splaying of the posterior elements or vertebral anomalies.

Positive test needs to be reconfirmed after about a week. A single high value is not be relied. Ultrasound is making rapid technical advancements. Minor variations in the frontal bones of the fetuses and compression of the malformed and caudally displaced cerebellum can be interpreted as the lemon and the banana sign. There are direct and indirect signs of neural tube defects on ultrasound. Fetal spine is ossified by the 16-17 week of gestation. In the coronal plane the normal posterior ossification centers are seen as two parallel lines of discrete echoes that normally widen in the cervical region and converge in the lumbosacral region. Disruption of smooth alignment of the spinal segments may be seen. There may be failure to see the normal, gradual craniocaudal narrowing of the spinal canal and disruption of the intact integument overlying the spine. The most reliable feature of spina bifida is the splaying of the posterior elements of the spine in the axial plane.

In 1986, Nicolades and associates described two signs, the so called Lemon and the Banana sign. Lemon Sign refers to the concave contours of the frontal bones, the cause of which is unknown. One fact of the lemon sign is that, it is known to disappear in many fetuses as the gestational age progressed. The Banana Sign refers to the anterior curving of the cerebellar hemispheres (like a banana), with simultaneous obliteration of the cisterna magna and has proved to be a specific sign for spina bifida. It is also a sonographic manifestation of Chiari malformation.

Indirect signs of myelomeningocele are more easily detected and include the banana sign (elongated appearance of the cerebellum secondary to the Chiari malformation) and the lemon sign (inward appearance of the frontal bones). The lemon signs detects 80% of NTD as compared to 93% with the banana sign.

The earliest antenatal diagnosis of a case of spina bifida in the upper thoracic spine with an accompanying meningocele was suspected at 8 weeks’ gestation via transvaginal sonography as a subtle angulation or “step” in the posterior contour of the embryo; this may be attributed to kyphosis, which often accompanies this condition. This was confirmed at 13 weeks’ gestation via 3-dimensional sonography.

Ventriculomegaly is assessed by measuring the transverse diameter of the lateral ventricular atrium. Vventriculomegaly (> 10 mm lateral ventricular atrium diameter) is usually more common after 24 weeks of gestation. Vventriculomegaly is reported to occur in 70-80% of myelomeningocele, however literature reports that the ventriculomegaly varies with gestational age, with a prevalence of only 44% before 24 weeks of age, compared with 94% after 24 weeks of age. USG helps to establish the precise duration of pregnancy and direct demonstration or exclusion of the neural tube defect. Together with amniocentesis, USG detects 96-100% of defects.

Fetoscopy is direct visualization of the fetus for birth anomalies. The main source of alphafetoprotein in the amniotic fluid is fetal urine. Alphaetoprotein is synthesized from normal embryonal liver cells, yolk sac and intestinal tract. The normal value is 25 microgm/ml between 14-16 wks or gestation and increases upto 10 times in dysraphic fetus. The causes of false negative reports are skin covered lesions and amniotic fluid samples taken late in pregnancy. The increase in alphafetoprotein in neural tube defects is due to direct communication between CSF and amniotic fluid in open defects. Though not specific marker, it is recommended for woman at high risk of having a child with neural tube defects. High Field MRI can document anatomy of a fetus thus helps in intrauterine surgical repair. These screening programs have allegedly decreased the frequency of spina bifida cystica if the affected parents agree for medical termination of pregnancy.

Upto 14% of fetuses with NTD detected in the 2nd trimester have associated trisomy 13 or 18 and therefore, it is mandatory to do a chromosomal analysis prior to taking a decision regarding further management. Cesarean section or continuation of pregnancy is contraindicated in presence of chromosomal abnormality, associated anomaly, advanced
hydrocephalus, flat lesion at or below plane of the back and absent knee and ankle movements.

**CLINICAL FEATURES**

The lesion is covered with a sterile dressing immediately after birth. The child is placed in a prone or a lateral recumbent position (Fig. 103.5). Evaluation of the degree of neurological deficit, child’s functional level and the associated hydrocephalus, orthopedic, genitourinary problems, head circumference, shape are all noted at repeated intervals by different observers to avoid any bias.

The sensory examination requires that the child be relaxed and quiet or even sleeping. The cutaneous dermatomes are stimulated sharply from distal to proximal until one identifies the dermatome that produces facial or upper extremity response characteristic of pain.

The motor examination begins with sharp or painful stimulation of the torso or the upper extremity with observation for voluntary motion below the level of the lesion. Hip flexion and knee extension requires innervation of L1-L3, and adduction requires the innervation of L2-L4. Hip abduction, extension, and knee flexion requires the presence of L5-S2. The sensory level is usually one or two segment higher than the anticipated motor level.

More than 90% of myelomeningocele have a neurogenic bladder. A history of constant leakage of meconium and of urine implies a state of future incontinence. Not all cases require surgery. The anomaly is associated with serious postoperative morbidity, a strict selection criteria is followed.

**CLINICAL EXAMINATION**

**General Assessment**

General assessment is done to rule out associated anomalies or chromosomal anomalies (club feet, congenital heart disease, cleft palate, hernias, congenital dislocation of the hips, genitourinary abnormalities).

**Local Examination**

The meningomyelocele is examined as a swelling (Fig. 103.6). The size, extent, location, underlying defect, consistency, fluctuation and transillumination to assess the amount of neural tissue in sac is elicited. A cervical meningomyelocele has a better prognosis than a lumbosacral meningomyelocele (Fig. 103.7). The presence of scoliosis or kyphosis and laxity of surrounding skin to plan surgery is examined. Evidence of rupture / impending rupture , CSF leak or infection are noted. The extent of marginal epithelialized dura is noted. The level of the defect, size of neural plate and size of membrane covering are noted. A sacral meningomyelocele needs to differentiated from a sacrococcygeal teratoma (Fig. 103.8).
Evaluation of Other Regions

Lower limb power, tone and reflexes: There is usually flaccid paralysis with lumbosacral meningomyeloceles. In cervical and some of the thoracic lesions there may be features of spasticity. Deformities of the foot and evidence of flexion contractures. Note grade of muscle power by stimulating upper abdomen or chest. The lower lesion, the more restricted is the neurologic deficit. In less than 10% cases, the lesion is present in sacral region. The nerve involved at the various joints for the associated movements is given in Table 103.1. Lesion at or above the thoracolumbar junction may have flaccid paraplegia without hip dislocation or deformity. The involvement of lower lumbar segments may have preserved hip flexors and abductor but weak/absent extensors and abductor with no useful function at knee or ankle as well as dislocation at this joint is common because opposed muscular activity at the hip. Cases of low myelomeningocele may present with deficits below the knee or involvement of only the ankle or movements of distal foot. The movements can be observed by the response to pulling or extension of extremities.

Spine: Widened pedicles may be felt in the region of spina bifida. Visible and palpable prominent laminae are usually scattered at the lateral margin of the defect. Associated kyphosis, lumbar lordosis, telescoping and scoliosis may be looked for. Congenital dislocation of hip (Paralytic type) may be associated. The feet may have Talipes equinovarus or Calcaneo valgus. Knee joint deformities in the form of arthrogyrosis may be present.

Hydrocephalus: The initial head circumference is measured. The size and tension of the anterior fontanelle are noted. The amount of separation of the skull sutures especially squamo-parietal sutural diastasis and prominent scalp veins are looked for. The eyes are examined for sunsetting of the eyes and VI cranial nerve palsy. The nature of the cry is observed.

Lower cranial nerves and brainstem function: Look for regurgitation, difficulty in feeding, stridor, apnea, hypotonia which suggests a significant chiari malformation (poor prognostic factor).

Bladder and bowel: The anocutaneous reflex and bulbocavernous reflex are elicited. The bladder and kidneys are palpated. A patulous anus is suggestive of fecal incontinence (Fig. 103.9). The expressibility of the bladder is noted and the urinary stream is observed. The excoriation in the peritoneal area is

Fig. 103.8: A six months old girl with large sacral meningocoele filled with CSF with no neurological deficits. The lesion needs to be differentiated from sacro-coccygeal teratoma
suggestive of urinary incontinence (Fig. 103.10). It is important to note that if one leg is normal, bladder function can be expected to be normal. The bladder and bowel involvement is due to autonomic system involvement. If there is flacid involvement, there is urinary and fecal incontinence, rectal prolapse and a palpable bladder. In the presence of a palpable bladder, there is dribbling of urine which increases on crying or movement. If there is spastic involvement, there is neurogenic bladder, megacolon and urinary incontinence.

ASSOCIATED ANOMALIES

These are given in detail in Table 103.2. Hydrocephalus is the most common associated anomaly. It is secondary to sylvian aqueduct stenosis, as well as Chiari Malformation. In the skull, cranialacunia, small post fossa with enlarged foramen magnum and low attachment of tentorium may be seen. The vertebral defect may extend beyond the obvious region of myelomeningocele. In telescoped spinal axis, the head seems to impacted on the trunk and lumbar spine seem almost non coexistent.

**Pathogenesis of Cerebral Malformations in Human Fetuses with Meningomyelocele**

In fetal SBA, neuroepithelial/ependymal denudation in the telencephalon and the aqueduct can occur before Chiari II malformation and/or hydrocephalus. Since denuded areas cannot re-establish cell function, neurodevelopmental consequences could induce permanent cerebral pathology.9

**INVESTIGATIONS**

1. Swab culture: of the surface and its content for prophylaxis against meningitis and ventriculitis
2. X-ray spine
   - Multisegment canal widening
   - Anterior or posterior fusion defects
   - Hemivertebrae
   - Block vertebrae
   - But features are not essential for early treatment decision
3. X-ray skull:
   - Craniolacunia
4. CT Skull:
   - Features of hydrocephalus
   - Expansion of lateral ventricle with minimal dilatation of hook shaped frontal and expanded occipital horns.
   - Mild to moderate dilatation of 3rd ventricle
   - Scalloping of petrous bone
   - Prominent cerebellar vermis.
5. USG skull
   - Coronal views–teardrop appearance of the ventricle.
   - Apparent ablation of interhemispheric fissure.

**MANAGEMENT**

**Fetal Surgery**

Fetal repair of myelomeningocele in utero has been attempted to decrease the risk of neurological deficits as a result of trauma or amniotic fluid exposure. This is currently done in very few centers who believe that it can reverse some effects of spinal birth defects and ultimately decrease paralysis and brain damage and improve the quality of life. The disadvantages include bleeding, infection and sometimes even the life threatening side effects caused from drugs used during fetal surgery to control premature labor. However, the authors have treated a baby who had got the fetal surgery done for spina bifida, with quite a bad scar, residual meningocele sac, neurological deficit and tethered cord.

Cesarean section becomes necessary for further deliveries. Virtually all fetuses are born prematurely, increasing the chances of complications. Although surgical closure of this anomaly is usually performed in the early postnatal period, an estimated 330 cases of intrauterine repair have been performed in a few specialized centers worldwide.10 It was hoped prenatal intervention would improve the prognosis of affected patients, and preliminary findings suggest a reduced incidence of shunt-dependent hydrocephalus, as well as an improvement in hindbrain herniation. However, the expectations for improved neurological outcome have not been fulfilled and not all patients benefit from fetal surgery in the same way.10

In future, refined, risk-reduced surgical techniques and new treatment options for preterm labor and preterm rupture of the membranes are likely to reduce associated maternal and fetal risks and improve outcome, but further research will be needed.10

Collagen biomatrices can be used for intrauterine coverage of an experimental spina bifida and can preserve the architecture of the spinal cord.11 Neurological outcome is not different between fetuses with their spinal cord covered and fetuses with uncovered cords.11

**Initial Assessment**

A detailed family history is taken for previous history of CNS anomalies, number of pregnancies and abortions and age of parents including chances of future normal pregnancies. A history of drugs or viral infections during pregnancy especially in the 1st month is also elicited. The management depends upon the age and general condition at presentation, level and magnitude of defect, presence of infection or CSF leak, status of lower limbs and sphincters, presence of hydrocephalus and socio-economic status of parents and family history. The prognosis in terms of ambulation, mental development and continence is explained to the parents. The need for shunt surgery in up to 75-80% cases with its associated complications and revisions need for urological and bowel treatment with repeated follow up and surgical intervention, chances of secondary tethered cord are explained.
The parents should ultimately decide regarding the management, but it is the duty of the surgeon to give the correct picture in detail. Also, it must be remembered that not all untreated children die and may present later with a far worse neurological status. A few of them may require surgery of the large sac for better nursing care. Active treatment is withheld if the patient already has gross hydrocephalus and significant neurologic impairment who after closure of defect develop meningitis and ventriculitis. Active treatment is also withheld in presence of Kyphosis/Scoliosis clinically evident at birth, severe cerebral birth injury/intracranial hemorrhage and other congenital defects, e.g. cyanotic heart disease, Mongolism and or serious GU malformation.

Elective early treatment is widely accepted with improvement in the quality of survival. The results of early operation without selection have been disheartening. A large number of survivors are mentally retarded and physical handicaps. The social life of the involved family is adversely affected. If the child survives by the age of 6 months and if it appears likely that will continue to live, a decision could then be made afterwards.

**Timing of Operation**

If a decision is made for surgery, then under favorable conditions, it should be done as soon as possible to decrease the risk of meningitis and to prevent possible drying of the sac and damage to neural structure. Immediate surgery is warranted in presence of rupture/imminence of rupture of the sac. Progressive hydrocephalus is not a contraindication for surgery provided a shunting procedure is done early to prevent irreversible brain damage with subsequent mental retardation.

The operation should be delayed in the presence of an already infected/ulcerated lesion, until the infection is controlled and the ulcer is healed. This should include to (cover the sac with sterile gauze soaked in saline, daily baths with soap and water and antibiotics. If meningitis has already set in, intravenous antibiotics should be given before operating upon the lesion. Unless the hydrocephalus is rapidly progressive, it may be better to defer the shunt surgery until 4-6 weeks of age as there is high incidence of complications (obstruction of ventricular end of shunt and shunt dependence) if shunt is done before 1 month of age. Also there is no significant increase in proportion of retarded children by such judicious delay.

If the hydrocephalus is rapidly progressive, primary treatment of hydrocephalus is indicated to decrease the size of sac, promote healing of the infection and prevent post repair CSF leak.

**PREOPERATIVE CARE**

Besides maintaining normothermia and the standard neonatal care, these children have to be nursed prone. The lesion is covered with sterile and saline soaked dressings. A deep head ring may be helpful for nursing. Preoperative antibiotics are used routinely in anti-meningitic doses.

**Operative Treatment**

The goals of an early operative treatment in a neonate with an open myelomeningocele are:
1. Preserving all viable neural tissue.
2. Water tight closure of the dura.
3. Reconstituting the normal anatomic environment.
4. Minimizing the chance of infection or preventing ascending infection of the neural axis.

The threat of superficial infection of the placode increases after the 72 hours of birth, thus a surgery at that time increases the risk of meningitis, ventriculitis, and an increase in the deficit. It is important to identify the neural placode, intermediate epithelial layer, skin, and the pia-arachnoid and the dura to achieve a complete skin closure, and to prevent any leakage of CSF.

**Principles of Operation**

The patient is positioned in the prone position with a roll under the pelvis and a folded towel under the chest to keep the abdomen free for respiration. An elliptical incision is given after planning the adequacy of the skin to cover the defect. The sac is mobilized from the skin and subcutaneous tissues and neck delineated. The use of bipolar coagulation and optical loupes are advisable. The central membrane and placode are separated by sharp dissection from the sac. The cord is detethered by dividing arachnoid adhesions and epithelial elements trimmed from the placode. The neural placode retubularized by 7-0 sutures on the pia-arachnoid tissues. The dura is dissected from the sac and areolar tissue and closed with continuous
5-0 prolene or Vicryl. Fascial flaps are used to cover the dura. Wide mobilization of the skin and subcutaneous tissues is done in all directions till closure is possible without tension. Closure of subcutaneous tissue and skin is done and a pressure barrier dressing is applied.

**POSTOPERATIVE CARE**

Routine antibiotics are given. The baby is nursed prone or in a lateral recumbent position. Hydrocephalus associated with myelomeningocele is attributed to aqueduct stenosis. About 15% of patients with myelomeningocele are born with clinical signs of hydrocephalus, but 80% develop hydrocephalus in late infancy with myelomeningocele.

Mannitol is given for 3 doses followed by oral diamox (50-100 mg/kg/day) the next day. The head circumference is monitored and serial ultrasound is done for hydrocephalus. The diagnosis is confirmed by a CT scan or an ultrasound scan and a shunt (preferably a VP shunt) is inserted. A watch is kept for Chiari malformation complications. The postoperative neurological status is monitored. The CSF leak is managed by increasing the dose of acetazolamide, repeated aspirations from the subcutaneous plane, pressure dressings and CSF shunting (lumbotheco-peritoneal). Barrier dressing is done at all times to prevent any source of infection from the perineum.

**Postoperative Complications**

1. **Worsening neurological deficit**: Occasionally worsening of the neurological function may be seen after the closure that may be preventable with a little caution. One should not splash betadine on to the neural placode, which is best rinsed with warm jets of plain saline and not subjected to any mechanical scrubbing. One should not cut the membrane too medially into the neural tissues causing bleeding and loss of function. One should cauterise the bleeding edges with a bipolar cautery, set at its lowest current. The lower part of the placode should be inspected for the presence of a neurulated cord, caudal to it, to rule out a segmental neural placode.

   Mild fever is not unusual. This is usually due to the presence of blood in the CSF in the post-operative period. This does not result in neurological deficits. However, the presence of intradural hematoma or an ongoing bleeding should be suspected if the neurological deficit has appeared a few hours later after the surgery. An urgent MRI scan may be indicated and an urgent re-exploration is helpful.

2. **Wound Dehiscence**: It is common to have erythema along the either side of the wound. Sometimes the flaps may look deep red to purple as a result of venous stasis. The predisposing factors include a state of cortisol mediated catabolic stress and poor feeding due to associated hydrocephalus, postoperative ileus, Chiari malformation, and prematurity. There may be tension at the suture line in cases with a large sac. An untreated kyphosis may add a vertical vector to the stretching of the wound.

3. **Wound infection**: The infection rate is about 1-5%. The prolonged catabolic phase after surgery certainly interferes with the newborn’s white cell function and immunity. Also because IgA does not cross the placenta, infections with enteric bacteria are common. Local factors predisposing to infection are, a large sac with a redundant multiply folded membrane surrounding the placode.

   Intradural infection is usually primary. Because most of the organisms are gram negative enteric bacteria, systemic signs of sepsis are usually present within the first 24 hours of surgery. In the neonates these signs are non specific. The infant shows poor feeding, lethargy, ashen complexion, and mottled blotches (livido reticularis) over the trunk. Hypothermia, low TLC often less than 4000 cells / mm, and a very high band count are suggestive of sepsis. A ventricular tap to obtain CSF for bacteriological examination may be done, and treatment started according to the sensitivity pattern.

   If the infection is confined to the extradural space, the wound becomes red, hot, and fluctuant on day 5-7. The surrounding skin may be edematous. The untreated subcutaneous infection passes on to the dura. A red fluctuant wound should be aspirated for purulent material that may be sent for culture.

4. **CSF Leak**: CSF leaks are more common in large myelomeningocele. Also since more than 80% of
myelomeningocele are associated with hydrocephaalus, increased CSF pressure poses a risk of leak. CSF leaks occur most commonly during the 4th postoperative day. A slight fluctuation under the skin flaps during the first few postoperative days is likely due to collection of blood and CSF, and if the closure is strong this transdural seepage is self limiting. A large transdural leak presents as a rapid accumulation of a bulging fluctuancy in the wound, usually at 5-6 days after closure. Spontaneous closure of such a leak is not hopeful.

The best preventive measure is a meticulous watertight closure of the dura. It is preferable to use a 7-0 prolene on an atraumatic needle. Immediate integrity of the closure is tested by two Valsalva manoeuvres held at a peak pressure of 40 cm H$_2$O for 2 seconds. If the lateral dura is too tenuous the lumbosacral fascia and the periosteum overlying the incomplete neural arches is mobilised. Fascia Lata is the most suitable graft material. Lastly even the best closure cannot withstand a high CSF pressure when hydrocephalus develops. Good judgement dictates that progressive hydrocephalus in the first 2 weeks of life should be promptly treated with an external ventricular drainage.

**MULTIDISCIPLINARY CARE**

Counseling of the family should begin immediate with explanation of the problem and potential difficulties to be encountered. A social worker may be helpful for guiding the family for education requirements and vocational trainings.

A paediatric urologist determines the degree of sphincter impairment, bladder dysfunction, arterial reflux, infection and begins clean intermittent catheterisation. Bowel management programs are easily achieved by supplementing proper nutrition, by using laxatives. The pediatric orthopedist evaluates the spine for scoliosis, neurogenic clubfoot, and neurogenic hip dislocation.

Most children born with spina bifida have normal renal function. If left untreated, more than half of these children will have serious renal deterioration by age 5 secondary to neurogenic changes of the bladder. Renal development should follow a normal course when close evaluation and intervention are undertaken during the newborn period and toddler years. As children age, attention is directed to quality-of-life issues, such as the establishment of urinary and bowel continence. Teenagers face the responsibility of understanding their medical condition and should begin to assume responsibility for their own care with eventual transition to the adult health care system.

In children with spinal dysraphism such as myelomeningocele the relation between muscle mass and body composition varies considerably. Therefore, it is difficult to evaluate the relevance of renal function assessments done with serum creatinine. Since serum cystatin C has been suggested to be independent of body size and composition, this evaluation was compared to chromium(51) edetic acid clearance. Cystatin C values were within the normal range in all patients, while chromium(51) edetic acid clearance was reduced in 10. Using chromium(51) edetic acid clearance as a gold standard, children with spinal dysraphism and slightly to moderately reduced renal function may remain undiagnosed if cystatin C is used for evaluation. Robotic-assisted laparoscopic surgery has been applied to creating both an appendicovesicostomy and an antegrade continent enema colon tube in a 9-year-old female with a neurogenic bladder and bowel secondary to myelomeningocele.

The majority of patients can be dry for urine by the time they go to primary school if they have been treated from birth onward for detrusor overactivity. As the upper urinary tract changes predominantly start in the first months of life, they should be treated right from birth by clean intermittent catheterization and pharmacological suppression of detrusor overactivity with imipramine. Urinary tract infections, when present, need aggressive treatment, and in many patients, permanent prophylaxis is indicated. Later in life, therapy can be tailored to urodynamic findings. Children with paralyzed pelvic floor and hence urinary incontinence are routinely offered surgery around the age of 5 years to become dry. Rectus abdominis sling suspension of the bladder neck is the first-choice procedure, with good to excellent results in both male and female patients. In children with detrusor hyperactivity, detrusorectomy can be performed as an alternative for ileocystoplasty provided there is adequate bladder capacity. Bladder augmentation, artificial sphincter and perineal urethrostomy are other options that may be required depending on the case. Wheelchair-bound patients can
manage their bladder more easily with a continent catheterizable stoma on top of the bladder. This stoma provides them extra privacy and diminishes parental burden. Bowel management is done by retrograde or antegrade enema therapy. Concerning sexuality, special attention is needed to address expectations of adolescent patients. Sensibility of the glans penis has been reported to be restored by connecting the ilioinguinal nerve with the dorsal nerve of the penis in the majority of patients.15

Management of bowel continence has been given in the chapter on bowel management.

**Orthopedic Management**

Orthopedic management is required for correction of the deformity and maintenance of the correct position as well as for obtaining the greatest possible degree of mobility and self sufficiency. Early correction enables prevention of the further disuse deformities and contracture. Conservative measures like casting and brace are usually contraindicated because of risk of causing skin breakdown in the presence of sensory deficit or existing deformity. Recurrence is likely if muscle imbalance is present. Muscle balance may be achieved by tendon transfer or lengthening, denervation or excision of overactive muscle and correction of the deformity by osteotomies. The ideal time is between 6 months to 2 years. For lumbar lordosis and scoliosis, a multiple wedge osteotomy and fusion is done.

For hip flexion contracture, anterior hip release or iliopsoas transfer with or without osteotomy are done. For hyper extension deformity of the knee joint, serial plaster casting in the position of flexion to prevent elongation of the quadriceps may be done. Flexion deformity of the knee is treated by Hamstring tendon transfer. Orthopedic devices are given for CTEV.

**LONG-TERM OUTCOME**

Patients with spina bifida exhibited more problems than both published norms and a local comparison group of healthy children in metacognition but not behavior regulation.16 More shunt-related surgeries and history of seizures predicted poorer metacognitive abilities. Adolescents and young adults with spina bifida who smoked were 10 times more likely to report being sexually active and women were 2.3 times more likely to be sexually active than men.17 Participants with urinary incontinence were less likely to be sexually active. Women without hydrocephalus were significantly more satisfied with life than women with hydrocephalus.17 Adolescents and young adults with spina bifida were only slightly satisfied with life and sexual activity was only associated with life satisfaction among women.17 Survival to adulthood for people with Spina Bifida now exceeds 85% due to improvements in medical and surgical management. Rates remain lower than expected for community participation, healthy lifestyle choices, employment and independent living. The importance of transition programming to help adolescents with disabilities prepare for adult life roles is now understood.18 Both the transition to adulthood and the transfer of care to adult care clinics are important and distinct components of spina bifida lifespan care.18

With multidisciplinary approach, the survival rates are approaching 95% in the first 2 years of life. The most common cause of death is related to hindbrain dysfunction (73%). Around 10% have mild dysfunction, with inspiratory stridor, 9% have moderate dysfunction with inspiratory stridor and periodic apnea, and 13% have severe dysfunction with periodic apnea and GER. The natural history of this hind brain dysfunction appears to be that of gradual improvement. An Arnold Chiari malformation can cause severe symptoms, such as choking, stridor, becoming clinically significant in only 10–32% of these conditions. Leakage of the CSF after closure of an myelomeningocele is reported as high as 17%. Most of these leaks close down spontaneously.

Children with myelomeningocele and no evidence of ventriculitis develop normal intelligence. Children with hydrocephalus who are treated aggressively have near normal IQ. Success with walking is subject to many factors. To stand erect requires a level of motor function at L3, motor function at L4-L5 is necessary for walking. As children age, their body weight may exceed the increase in their motor strength, creating difficulties in walking. However with better care about 80% of patients are able to walk. Sexual development and function requires motor ability at the level of S2-S4. Patients have a variable level of sexual development. Psychosocial problem is one of the greatest obstacles in children with myelomeningocele. Therefore, a co-ordinated and a comprehensive treatment plan should be charted out.
SPINA BIFIDA OCCULTA

Spina bifida occulta is present with an incidence of about 2-3% in the general population as a bony defect in the L-S region without any neurological symptoms. However, only a few of them are likely to develop symptoms and gait changes much later in life. Over 60% patients with hypertrichosis would have an associated diastematomyelia, a fibrous cartilaginous, or more commonly a bony spicule separating the spinal cord into hemicords can occur as an isolated defect or in association with either myelomeningocele or lipomyelomeningocele.

TETHERED CORD SYNDROME (TCS)

The entity “Tethered cord syndrome” is a result of interference with normal cephalad migration of spinal cord during the disproportionate growth of the vertebral column. The fixation is due to abnormally thickened filum terminale tethered to the inner surface of dorsal dura mater. TCS refers to a group of lesions in which the spinal cord is fixed to a structure like a lipoma, vertebra, dura or skin and abnormal stretching of the cord results in progressive neurological damage.

In 1981, Yamada and associates adopted the term tethered cord syndrome to designate two groups of patients (i) Patients with tethered cord and (ii) Patients who harbour any structures that may cause viscoelasticity of the filum terminale to be ineffective in protecting the cord which could be a tumor, occult myelomeningocele, arachnoiditis or a bony spur.

Primary TCS or occult spinal dysraphism includes lesions that are not associated with an open neural tube defect or trauma (Table 103.3). Secondary TCS includes lesions that occur due to prior arachnoiditis, surgery or trauma.

Functional and Metabolic Impairment in TCS

The interlacing fibres of neurones, glia, pia, blood vessels in the spinal cord provide some resistance against traction in the longitudinal direction of the cord. If the viscoelasticity is sufficient to stretch the spinal cord the viscoelasticity of each structure protects neurones and glia from disruption and helps to maintain normal function to a certain degree. If the spinal cord is stretched to a level beyond this inherent viscoelastic resistance neuronal function may be disrupted. In brief, experimental studies of cord tethering and laminectomy and dural opening, various correlations between experimental results and clinical observations have been made:

1. Cord tethering produces excessive tension within the spinal cord and can result in metabolic derangement and histologic changes.
2. Oxidative metabolism is impaired in the spinal cord under tension. The severity of neuronal dysfunction parallels the degree of impairment in the oxidative metabolism.
3. Blood flow decrease and glucose metabolic impairment also contribute to cytochrome reduction. Blood flow increases are reported with post surgical improvement in neurological status.
4. Irreversible damage can occur with sudden stretching of the already chronically stretched TCS.

Primary TCS

Cutaneous markers like midline dimples, dermal sinuses, nevi, hemangiomas, hairy patch (Fawn’s tail), lipoma, gluteal asymmetry or split-buttock crease and small areas of thinned out epidermis are pointers towards an occult spinal lesion (Figs 103.11 to 103.13B). However, 20-40% patients may not have any cutaneous marker.

Clinical Features Associated with TCS

a. Cutaneous markers
b. Symptoms
   • Pain -Back, legs
   • Lower limb fatigue, weakness
   • Scoliosis, Lordosis, Kyphosis

Abnormal gait
- Delayed toilet training
- Recurrent UTI
- Recurrent meningitis
- Progressive foot deformity
- Sudden neurologic deficit due to trauma or postural change.

The symptoms may be broadly divided into two, orthopedic symptoms or urologic symptoms. The orthopedic symptoms include asymmetry of legs due to predominant unilateral diminished muscle bulk, short foot, often inverted with high arch and clawed toes, variable sensory loss and trophic ulcer present on sole. The deep tendon reflexes in the involved extremity may be absent in the presence of extensor plantar response.

Kyphosis and scoliosis may be present. The urologic symptoms include frequent bed wetting or incontinence present or UTI.

In a study to evaluate presence of spinal cord abnormalities in 176 patients with functional urinary and bowel problems out of which 88 children had radiographic evidence of spina bifida occulta and 88 were age- and sex-matched controls. Magnetic resonance images were obtained in all patients and evaluated for spinal cord abnormalities. Sacral ratios were calculated on the basis of plain radiographs.19

Among children with functional bowel and urinary problems, there was no statistically significant difference in the prevalence of abnormal spinal MR imaging findings in those with radiographic spina bifida occulta and an age- and sex-matched control group. Spina bifida occulta was thus not shown to be a reliable indicator of spinal cord structural abnormalities.19

Fig. 103.11: Spina bifida occulta with a tuft of hair on the back. The child had diastematomyelia on investigating with an MRI.

Figs 103.12A and B: A. Spina bifida occulta–atretic meningomyelocele

Investigation

All children with suggestive symptoms and those with cutaneous markers should be evaluated completely. Current recommendations also include children with the VACTERL association, cloacal extrophy and imperforate anus. The basic investigation to assess the spinal anomaly is MRI. During follow up and in presence of symptoms, Urodynamic study may be helpful to study the urological status. Somatosensory evoked potentials have also been studied.

Treatment

The treatment of TCS involves surgical release and excision of the tethering lesion. It is presently the consensus that detethering should be carried out at diagnosis even in the absence of symptoms. Since a number of studies have reported neurological damage in infancy, the current recommendation is for prophylactic repair at 3-6 months of age. It is believed that up to 90% of patients with TCS will develop deficits which are irreversible if left untreated. The surgical risk of a new deficit is around 2%.

The principles of surgical treatment include removal of the abnormal tissue to reconstruct the dural sac. Vigorous toilet is needed to remove any debris or blood that can cause secondary TCS. Lipomyelomeningoceles do not need to be totally resected but should be debulked. In SCM, all tethering bands need to be resected and a single dural tube is reconstructed. The filum terminale should be identified in all cases and sectioned if it appears to contribute to the pathology. Intraoperative motor evoked potential and EMG monitoring is vital to prevent operative trauma to viable nerve roots.

DIASTEMATOMYELIA

Diastematomyelia (or split cord malformation) is a condition in which the spinal cord is split in a sagittal plane forming two hemicords that may be separated by a spur (Figs 103.13A and B). This lesion is seen more frequently in girls and is most commonly associated with a hairy patch (Fawn’s tail) on the overlying skin. Over 60% of patients with hypertrichosis have an underlying Diastematomyelia. Pang has classified these lesions into two types. Type I is the classical Diastematomyelia with two hemicords lying in separate dural sheaths and separated by a bony spur. Type II consists of two hemicords in a single dural sheath separated by a thin sagittal fibrous spur. This lesion was earlier termed as diplomyelia.

Embryologically, it is believed that these lesions result due to a defect in gastrulation where there is either a localized duplication of the notochord or persistence of the neuroenteric canal causing a split notochord. Mesenchymal elements interpose between
the split notochord and lead to the development of the lesion. Surgical treatment consists of laminectomy, complete dethatching of the cord with excision of the bony spur and division of the tight filum-terminale if warranted.

LIPOMYELOMENINGOCELE

Lipomyelomeningocele usually present as a swelling in the lower back that is well covered with a healthy skin. It has to be differentiated from extramedullary lipoma and from the fat in the filum terminale. The subcutaneous component of the lipoma extends through the dural defect due to a premature dysjunction of the cutaneous and neuroectoderm. The spinal cord is low lying and tethered by the lipoma and closely resembles the neural plate seen in myelomeningocele. The dural attachment, which has surgical significance, is attached to the edges of the neural plate just dorsal to the entry of the dorsal nerve roots. The intra medullary component of the lipoma grows with the child and causes spinal cord compression as well. The term lipomyelomeningocele is actually a misnomer in that it suggests herniation of neural elements through a spina bifida defect into a meningeal sac. Chapman has classified lipomyelomeningocele into dorsal and caudal variant. A third transition form has also been described.

Spinal lipomas have thus been classified into:

a. Dorsal variant were the fatty tissue lies dorsal to the neural plate and nerve roots. These often present as subcutaneous masses which may be asymmetric. The pia and dura are fused along the lateral interface with sensory roots emerging just anterior to this line of fusion, as a result neither the sensory nor the motor roots lie within the lipoma.

b. Caudal variant which is located at the transition of the cones and filum terminale. Here the fatty tumour may replace the filum. The normal roots lie ventrally but may lie within the lipoma also.

c. Transitional form which is an admixture of the dorsal and caudal variants.

Pathogenesis

Abnormal function of the spinal cord and roots during embryogenesis may result in permanent damage manifesting at birth, as seen in myelomeningocele. Local mass effect from the fatty tissue may be cause several dysfunction. Finally symptoms may be produced by the traction on the cord. Early in the embryonic period there is progressive ascent of the conus within the spinal canal owing to the faster growth of the vertebral bodies compared to the spinal cord. If the cord is tethered to the spinal canal there is loss of mobility of the conus during spinal flexion and extension and decreased cord pulsations as demonstrated by MR imaging.

Manifestations

Manifestations are those of tethered cord syndrome and patients present with one or more of the syndromes.

1. Cutaneous Syndromes: The cutaneous abnormalities, which are indicative of an underlying lipoma, are situated on or near the midline in the lumbosacral region. The most common finding is a skin covered fatty mass which is usually indicative of an underlying intradural lipoma (Figs 103.14 and 103.15). A hemangoma in the lumbosacral region is highly suggestive of underlying spina bifida. Another striking feature is a hairy patch (hypertrichosis) also known as the Fawn’s Tail. This always occurs in the midline, occurring as a diamond shaped patch. Dimples, sinus tracts, skin tags, or even appendages are associated with lipomyelomeningocele. A current are of controversy is the radiological investigation of the infant with a dimple overlying the coccyx. Such abnor-
malformations are extremely common and rarely associated with symptoms. Imaging should be done only if the dimple is rostral to the level of the coccyx or if there are associated problems such as orthopedic or the urological abnormalities.

2. **Neurological manifestations:** Motor dysfunction becomes apparent only after the child begins to walk.

3. **Orthopedic manifestations:** Most frequent finding is the unilateral/bilateral cavovarus deformity of the foot with or without limb leg length discrepancy. There may be claw toe, or scoliosis.

4. **Urologic manifestations:** Abnormal voiding pattern with new onset of urinary/fecal incontinence. The other abnormalities seen may include flaccid, spastic or dysynergic bladder abnormalities.

### Investigations

The investigation of choice of a suspected lipomyelomeningocele is the MRI in both sagittal and coronal planes. Fatty tumors are readily visualised on T1 images as areas of increased signal intensity. The conus is often low. The primary consideration from the surgical perspective is inferring the presence of tethering from an abnormally low conus and the mechanism of tethering. In typical cases MRI suggests either a dorsal or an caudal insertion of the fatty mass. Additionally presence or absence of Syriax or a terminal hydromyelia is readily apparent.

### Surgery

All children with radiographically demonstrated lipomyelomeningocele should be operated upon preferably in the first 6 months of life. The goals are to:

1. Untether the cord from the lipoma, filum terminale, or both
2. Remove the lipoma, or a dermoid cyst causing compression of the spinal cord.
3. Excise the dermal sinus completely.
4. Avoid damage to the nerve roots.
5. Reconstruct the dural canal, to prevent the CSF leakage, often requiring a dural patch graft.
6. Reduce the bulk of the subcutaneous lipoma, excise an area of hypertrichosis, and achieve a tension free anastomosis.
7. Approximate the skin and the subcutaneous surfaces liberally to avoid formation of the dead space allowing postoperative collection.

### Complications

Major postoperative complications have been CSF leaks (14%). A persistent subcutaneous collection/frank leak requires re-exploration. A external spinal drainage catheter carefully inserted above the laminectomy defect is useful in protecting the closure following re-exploration. The incidence of a permanent neurological defect after the initial surgery is around 3-6%.

### Retethering

Although the neurological and urologic status of a patient with a lipomyelomeningocele should remain stable after a successful surgery, any significant deterioration in a patients status (e.g. new onset incontinence, pain, or progressive weakness), should provoke a search for a cause. Possible ones being hydromyelia, re-tethering, infection, or an unrecognised diastematomyelia superior to the operated lipomyelomeningocele.

Hydromyelia if noted on a preoperative scan should be addressed at the same time of surgery by a terminal ventriculostomy. If a symptomatic hydromyelia if noted on a preoperative scan should be addressed at the same time of surgery by a terminal ventriculostomy.
myelia recurs, treatment is by a syringopleural/syringoperitoneal shunt. An association between terminal syringomyelia and tethered cord syndrome has been recognized. However, it has been suggested that tethered cord release alone may be sufficient to improve preoperative symptoms and the terminal syringomyelia may be an associated phenomenon that does not mandate separate treatment.20

The incidence of retethering is 10%. It is possible that virtually all patients retethering within a few weeks of surgery, but the dorsal reattachment is at a higher level and thus the symptoms are relieved. The onset of new pain/neurological deficit/urological signs prompt a repeat MRI of lumbosacral spine. Immediate postoperative MR imaging scans in successfully untethered patients continue to show a low lying conus and a dorsally displaced spinal cord and therefore these findings neither confirm/rule out retethering in postoperative period. It has been suggested that ultrasound evaluation through the laminectomy defect is helpful in this situation. The finding of prominent pulsations of the spinal cord is reassuring that retethering has not taken place. Another technique helpful is the prone supine metrizimide CT myelography. It has been a policy to recommend re-exploration in any patient in whom significant radicular pain develops regardless of the radiological studies. The techniques include;

1. Use of dural graft.
2. Use of stay sutures.

Successful reuntethering can be done in 90% of patients.

DERMOIDS AND DERMAL SINUS TRACTS OF THE SPINE

A midline cutaneous pit or dimple above the intergluteal crease is present in all children with a dermal sinus. There may be associated cutaneous manifestations as discussed above. The most common location is the lumbosacral region. Family history is unusual and there is a small male preponderance. Although all midline skin pits above the intergluteal fold must be assumed to communicate intraspinally, those below the top of the intergluteal crease are blind sacrococcygeal dimples. They are seen in nearly 5% of newborns. Dermal sinuses provide a portal for infection. Meningitis or intraspinal abscess occurs in nearly half of all cases. The most common organisms are the *Staph aureus* and *E coli*. Nearly all patients with dermal sinuses have intact neurological function at birth. Rapid neurological deterioration suggests infection within dermoid tumors adjacent to the conus or adherent within the cauda equina. An unusual presentation of dermoid tumors is recurrent episodes of sterile meningitis caused by contact of the spinal fluid with irritative dermoid or epidermoid elements.

**Dermal Sinus Tract**

These lesions are seen mainly in the lumbosacral region (usually above S2 level) and extend from a caudal skin level to a rostral intra-spinal level (Fig. 103.16A). Besides tethering, a dermal sinus tract is suggestive of intraspinal dermoids and epidermoids. There is also a significant risk of epidural abscess or meningitis. The lesion can be differentiated from benign sacral dimples by their location and by applying caudal traction on the skin below the lesion which causes the skin lesion to elongate.

**Radiological Diagnosis**

Dimples below top of the intergluteal crease require no investigation other physical examination probe insertion is not justified traction tests of skin movement may suggest the cephalad or caudal path of a sinus tract. The usefulness of plain radiographs may be limited because of immature calcification in children less than 18 months of age (Fig. 103.16B). Ultrasound readily demonstrates the subcutaneous tract, intraspinal inclusion tumors and diminished cord pulsations. Fine section axial CT images with sagittal reconstruction following intrathecal contrast defines bony landmarks and tract attachment to distal neural elements invasive contrast studies have largely been replaced by MRI which visualises in three dimensions the extraspinal tract path, inclusion tumors and other malformations associated with spinal cord tethering.

**Surgery**

An elliptical skin incision excising the sinus opening, is dissected circumferentially to the fascial defect. Laminectomy is performed over the intact arch and the tract is followed in epidermal space up to the point of entry through dura. The dura is opened
circumferentially around it, the tract is followed further down and divided flush with the neural elements. Any associated dermoid cyst or the tumor is also excised. The filum is divided if thickened. The dura is then repaired watertight.

TIGHT FILUM TERMINALE

The tight filum terminale refers to patients with features of tethered cord syndrome associated with a short and thickened (> 2 mm) filum terminale. The filum often contain fat and fibrous tissue and the conus is below L2 level in 80-90% cases.

REFERENCES

Section 8

Head and Neck Surgery
Craniosynostosis is a congenital defect that causes one or more sutures on an infant’s skull to close earlier than normal. The premature closing of a suture leads to an abnormally shaped head. During the first year, the brain more than doubles its size and attains 60% of its adult weight. Except for the uniqueness of the cranial vault sutures, the brain growth could be pathologically restricted with irreversible damage caused to it by mounting intracranial pressure. In the past, the sutures were thought to be sites of active growth that push the cranial plates apart, but further investigation has shown their role to be passive. In response to the rapidly enlarging brain, bone is deposited along the edges of the sutures and the epicranium while resorption occurs along the dural surface.

Normally the cranial sutures are patent at birth and progress in early infancy to a yielding fibrous union that allows continuation of appositional bony growth. By 6 years of age, the cranium has attained 90% of its adult size, but complete solid sutural bony union does not occur until at least the 5th decade. Should a suture close prematurely, however, growth is arrested in a direction perpendicular to the fused suture, whereas compensatory expansion occurs in a parallel plane to the affected suture (Virchow’s law). The resulting distortion of the skull depends on the suture or sutures that are closed.

The two subdivisions of craniosynostosis have important genetic and long-term growth implications. In general, the malformations of the non-syndromic subset occur sporadically, whereas the syndromic ones have a hereditary component. Furthermore, after surgical correction, normal craniofacial development is the rule for the non-syndromic patients, whereas those with syndromal attributes do not fare so well.

**NONSYNDROMIC CRANIOSYNOSTOSIS**

The overall incidence of nonsyndromic premature stenosis of cranial sutures has been stated to be 1 in 1000 live births. These figures include all forms of single suture fusion with the sagittal being most commonly affected and unilateral coronal, metopic, and lambdoidal areas following in frequency. Bilateral fusion of the coronal as well as multiple suture involvement also occurs.

Based upon the suture involved, the following deformities present clinically:

**Scaphocephaly (Boat shaped)**
The sagittal suture is partially or wholly fused; when fusion is complete, there is often external bony overgrowth extending in the midline from lambda to bregma. Sometimes there is overgrowth on the internal surface (Fig. 104.1). X-ray of the skull in an anteroposterior (AP) view shows sagittal suture fusion (Fig. 104.2).

**Plagiocephaly (Unilateral coronal suture fusion)**
The affected coronal suture shows synostosis in its lateral segment. In young infants, the medial end of the suture is usually patent. In cases older than 6 months the synostosis is usually total and extends up to the anterior fontanelle, which may be small or even absent. There may then be no external trace of the suture, or it may be seen as a shallow groove like a
constriction ring in the bone (Fig. 104.3). Sutural fusion can be seen on a plain X-ray or a 3-D CAT scan of the skull (Fig. 104.4).

**Brachycephaly**
*(Short–bilateral coronal suture fusion)*

When both coronal sutures are involved the forehead becomes fore-shortened antero-posteriorly (Fig. 104.5).

The diagnosis can be confirmed by X-ray skull (Fig. 104.6) and 3-D CAT scan.

**Trigonocephaly**
*(Triangular-metopic sutural fusion)*

Premature fusion of the metopic suture is usually most evident above the glabella, and may be incomplete or absent in the region of the anterior fontanelle. There
is often a marked bony overgrowth on the inner surface of the frontal bone at the lower end of the synostosis (Fig. 104.7). X-ray of the skull (Fig. 104.8) or 3-D CAT scan is unmistakable.

**SYNDROMAL CRANIOSYNOSTOSIS**

In contrast to nonsyndromic fusions, syndromal craniosynostoses behave differently and have genetic implications and pattern of inheritance have been established for these malformations. Crouzon’s syndrome is the most commonly seen syndromal craniosynostosis anomaly, and its incidence has been estimated as being as high as 1 in 10,000 births. The inheritance pattern is autosomal dominant with almost complete penetrance.¹

**Crouzon’s Syndrome**

Mid-face hypoplasia, parrot beak nose, lateral canthal dystopia, hypertelorism (Broad set orbits) and relative mandibular prognathism characterize the defect (Fig. 104.9). High arched palate is also an associated finding. The typical skull deformity is brachycephalic, though other head shapes are seen. Exorbitism is a cardinal sign. It is often very marked, and may endanger sight.
Apert's Syndrome

Also termed as acrocephalosyndactyly, the incidence of this anomaly has been estimated to be 1 in 1,60,000 live births. Exorbitism, midfacial retrusion with maxillary constriction, and pseudomandibular prognathism, as in Crouzon's syndrome, are present. The exorbitism is more moderate and asymmetric. The face also is transversely flattened. The distance between the orbits is greater. The cranial deformity is almost always associated with premature fusion of the coronal sutures, though the skull base is also involved. The Apert's syndrome is distinguished from other acrocephalosyndactylies by the severity of the syndactyly, which involves bony fusion of the phalanges of at least the index, middle, and ring fingers (Fig. 104.10). The inheritance mode is autosomal dominant, although occurrence tends to be sporadic. As with Crouzon's syndrome, a genetic defect has been identified.2

Others

More than 50 syndromes associated with craniosynostosis have been described in addition to the most common Crouzon's and Apert's syndromes. Because they are few in number, their frequency is not well established. Pfeiffer's, Carpenter's and Saethre-Chotzen syndromes belong to this group and are distinguished by broad toes and thumbs (Pfeiffer’s), preaxial polysyndactyly with soft tissue syndactyly of shortened fingers (Carpenter’s), and soft tissue webs between the second and third digits (Saethre-Chotzen) are seen. These malformations are also transmitted in an autosomal dominant manner except Carpenter's syndrome, which is autosomal recessive. The rare Kleeblattsschadel (cloverleaf skull) anomaly is not easily forgotten. The skull cap assumes a trilobular configuration with a protruding vertex and bulging temporal regions (see Fig. 104.12).

MULTIPLE SUTURE INVOLVEMENT

Oxycephaly or Turricephaly (Figs 104.11 and 104.12)

Oxycephaly—has been defined as a deformity in which the head is abnormally high and conical. The vertex appears pointed whether viewed from the side or from the front in a case of typical oxycephaly. Depending on the part of the cerebral capsule first involved, the deformity process can also involve the coronal suture.

Cloverleaf Skull

This deformity (triphylocephaly) appears to be a nonspecific consequence of multiple sutural fusion: a
constriction ring develops in the lambdoid-squamosal zone and allows disproportionate bulging in the frontal and temporal bones. Seen from in front, the head looks trilobular (Fig. 104.12). There is almost always associated hydrocephalus. Less severe forms of this condition may exhibit a pointed oxycephalic appearance.

**DIAGNOSIS**

Diagnosis of craniosynostosis can be established in most instances on clinical examination alone because of the characteristic deformation of the skull cap and evidence on palpation of a ridge formed by the fused suture. Plain X-rays of the skull in different views should be taken to help confirm the clinical impression. A radiographic linear opacity replaces the wormian lucency of a patent suture. For unilateral coronal synostosis, a classic 'Harlequin' eye sign formed by the elevated ipsilateral lesser wing of the sphenoid can be seen on a postero-anterior skull film. Computed tomography (CT) scans are usually not diagnostically helpful unless reformatted in three-dimensionally (Figs 104.13 and 104.14). Detailed psychological assessment, ophthalmic evaluation for evidence of raised ICT and dental examination should be carried out.

**DIFFERENTIAL DIAGNOSIS (TABLE 104.1)**

Muscular torticollis, cervical spinal abnormalities and favored sleeping positions can produce positional distortions. The sutures are patent in these conditions. Treatment should be focused primarily on the cause of positional deformities.
Positional posterior plagiocephaly, when viewed from the vertex, has an oblique orientation of the skull cap, and the ear on the affected side is pushed anteriorly and away from the flattened posterior side. In contrast, true unilateral lambdoidal synostosis produces a trapezoid deformity with the ipsilateral ear being drawn toward the defective suture. It is critically important to distinguish positional deformations from those caused by true craniosynostosis.

Investigative workup for these patients has been summarized in Table 104.2.

**Surgical Management**

Non-syndromic craniosynostosis should be corrected because of the severe distortion reflected onto the face. Other reasons address possible functional problems that the condition might cause, all of which are related to increased intracranial pressure. Thirteen percent of infants with single suture synostosis have elevated pressures and 42% of those with multiple sutural involvement. Visual impairment can occur but is rare when only one suture is prematurely fused.

Before the era of craniofacial surgery, the classically accepted method of treatment was a linear strip craniectomy of the pathologic suture. The incidence of refusion and continued deformation, however, was disappointingly high. To take advantage of the rapidly expanding infant brain, early intervention is advised. Most centers favor the period of 3 to 6 months of age; others wait until after the sixth postnatal month. Early correction produces superior results than late intervention, in the long-term.

Because of disappointment with the strip craniectomy techniques, the principles of treatment have constantly evolved. Regardless of the type of craniosynostosis, emphasis has been directed toward releasing the affected suture and immediately restoring normal architecture by repositioning and contouring the deformed bones.

Initial enthusiasm to the benefits offered by rigid fixation provided by using biocompatible plates and screws, has not sustained. Subsequently, their use on a growing skull cap found the devices being translocated from the epicranium onto the dura.

**Partial Calvariectomy and Onlay Periosteoplasty**

Partial calvariectomy and harvesting the periosteum is an alternative technique. In this procedure, not only the involved sutures are removed but the adjacent deformed bones are also excised after separating and preserving the periosteum. Towards the end of the procedure this harvested periosteum is laid down as an onlay over the exposed dura (Figs 104.15 and 104.16). Subsequently, neocalvarium is formed by the periosteum according to the contour of growing brain. (Figs 104.17 to 104.20).
The surgical management of all the syndromic craniosynostosis malformations generally falls into three chronologic stages. In contrast to the non-syndromic variety, in this group normalization of facial growth is not realized after surgical intervention. Treatment is directed at the immediate problem. Thus, a phased approach is used. Elements that must be addressed are release of elevated intracranial pressure caused by the premature suture closure, compromise of the airway by severe midfacial retrusion, and protection of the corneas because of the exorbitism. During the first year of life, the synostotic suture is released as well as a fronto-orbital advancement (Figs 104.15 and 104.16). This frees the rapidly expanding brain, more normal calvarial contours are achieved, and the corneas are offered more protection.

Treatment plans and timing may vary according to experience and preference. A second operation is performed around the sixth year of life when the orbits and skull cap have attained 90% of their adult size. If the forehead is of normal shape, the classic LeFort III midfacial advancement is used to bring the entire midface forward. The maxilla is deliberately placed in an overcorrected anterior position as future
midfacial growth is be limited. This positioning opens the crowded nasopharynx and corrects the exorbitism.

If the forehead is found to be recessed, as is often the case, two alternative paths can be followed. As a preliminary operation, a fronto-orbital advancement is performed. Approximately 6 months later, a LeFort III is added. This approach is safer because sterility is maintained by separating a clean intracranial procedure from the contamination introduced by the subsequent extracranial midfacial advancement.

The other approach is the monobloc frontofacial advancement. The advantage of this technique is that only one operation is required to reposition the forehead.

When orbital hypertelorism is present, a facial bipartition procedure can be added to either the LeFort III or frontofacial monobloc advancement. This procedure is particularly indicated in correcting the flattened forehead and midface that is typical of patients with Apert's syndrome.

The final stage must await the completion of facial growth. After presurgical orthodontic alignment of the teeth, the pseudomandibular prognathism is corrected with a LeFort I (maxillary) advancement. A simultaneous advancement osseous genioplasty is frequently required to correct the retruded chin.

REFERENCES

Facial clefts have been recognized and recorded in medical writings from the earliest times. Their occurrence has been attributed to many weird and wonderful causes, but stigmatization and victimization of sufferers was commonplace until relatively recently. The first attempt at repair by surgery was noted in a Chinese text from 390 BC. Concepts of the lip cleft as simply a split or dehiscence led to early attempts at direct edge to edge closure by cautery, pinning and stitching.

The gradual elucidation of cleft anatomy, and recognition of the importance of failed fusion processes, allowed a more refined definition of the requirements for corrective surgery. The advent of anesthesia made possible more comprehensive efforts at the re-alignment of distorted and displaced cleft structures and brought about the introduction of many novel and clever developments and variations on the theme of tissue mobilization and flap design by eminent surgeons of the day. Follow-up of patients from infancy to adulthood emphasized the important role of growth in outcome of cleft repair and identified those repairs which facilitated normal growth and those which impeded it. Some initially promising designs were therefore discarded so that current surgical approaches both observe closely the anatomical defect and also respect the potential for interference with growth potential.

EMBRYOLOGY

The development of facial anatomy takes place from about the 5th week of gestation as frontonasal and maxillary processes become apparent. Growth downwards of the median and two lateral processes of the frontonasal process defines the central lip and palate and the future nares—the prolabium and premaxilla. Growth forwards and inwards of the lateral maxillary process defines the maxilla. Fusion of these processes (Fig. 105.1) and in growth of mesoderm unite the upper jaw by about the 8th week of fetal life forming the primary palate. Failure of this fusion process leads to the common form of clefting (i.e. in the line of the philtral ridge and between lateral incisor and canine teeth) and failure of ingrowth of mesoderm into the central part of the frontonasal process leads to the rare form of midline cleft. The range of highly unusual facial clefts categorized by Tessier (1976) are explained by variations and aberrations of this relatively simple fusion model.

From 8 weeks onwards, the formation of the secondary palate continues by growth of palatine
processes inwards from each maxillary process. These plates or shelves move from a more vertical to a transverse orientation where they come into contact, adhere and fuse from anterior (incisive foramen) to posterior to form the hard and soft palates. In front of the incisive foramen, fusion between palatine processes and premaxilla forms part of the primary palate behind the alveolus. The fusion processes are complete by 12 weeks of intrauterine life (Figs 105.2 and 105.3).

**GENETICS AND ETIOLOGY**

Much research has been conducted into the etiology of clefts and the over-riding conclusion is that causation is largely multifactorial and due to gene-environment interactions, though monogenic patterns are recognized. Various investigations using linkage analysis, association studies and gene probes into the large number of candidate genes and loci generally lead to identification of genetic predisposition rather than to a major locus. A familial pattern of inheritance is seen and is more pronounced for cleft lip with or without cleft palate than for cleft palate alone. In bilateral cleft lip and palate, an incidence of up to 18.5% is found in first degree relatives. The risk of recurrence for further siblings following presentation of an index case is approximately 4%, rising to 10% if two siblings are affected and up to 15% if both sibling and parent are affected. There is no sex-linked genetic influence. Though most genetic patterns are autosomal recessive, occasional autosomal dominant inheritance emerges as in the van der Woude (1954) syndrome consisting of lower lip pits in association with cleft lip (Fig. 105.4). A relatively recent and common association of cleft with 22q11 chromosome deletion is described as part of the Di George spectrum and presents as the velo-cardio-facial syndrome. The syndrome has a wide phenotypic spectrum (Fig. 105.5).
that has been described in detail but early diagnosis
of the syndrome can be reached by fluorescence in situ
hybridization (FISH) test. An association has been
described between CL (P) and the transforming
growth factor alpha locus, which may offer further
clues to etiology.

The geneticist requires taking a full and detailed
family history in order to assess risks accurately and
to establish the counseling process. Throughout the
patient’s care pathway, teamwork is essential and all
members need an appreciation of the origins and
etiology of clefts. The pediatric nurse, who plays a
major role in the care of child and family and in
education of parents, must base advice on a sound
understanding of underlying genetic and etiological
factors. The high incidence of associated anomalies
has major implication for genetic counseling.

Environmental and exogenous factors are also
implicated in cleft pathogenesis although interactions
and multifactorial effects make unequivocal
identification difficult. Inferences drawn from clinical
studies and observations and from experimental
animal work point to some of the following as terato-
genic agents:

- Drugs such as thalidomide, phenytoin, amino-
  pterin, paracetamol, retinoids and folate anta-
gonists;
- Dietary factors such as vitamin deficiency;
- Alcohol intake during pregnancy which may not
  necessarily be dose related;
- In utero infection
- Excess fetal flexion in utero associated with
  oligohydramnios
- Irradiation in utero

The common link between genetic and environ-
mental influences on cleft formation and a key to the
pathogenesis of clefting is thought to lie in the process
of epithelial breakdown and fusion which depends on
changes in enzymes in the extracellular matrix.

**EPIDEMIOLOGY AND INCIDENCE**

Studies on epidemiology of cleft lip and palate have
continuing importance partly because of the lack of
full understanding of the etiology. The very detailed
studies from Denmark starting with the work of Paul
Fogh-Andersen which included twin studies, have
been fundamental to this. Various registers such as
EUROCAT (European Register of Congenital
Anomalies and Twins) collect and assess information
about prevalence, incidence and associations of clefts
and gradually increase the knowledge base.

The incidence of cleft lip and palate ranges from
1:1000 to about 2.2:1000. Scandinavian data are
possibly most reliable and give an incidence of about
1.7:1000. There is usually a greater incidence of cleft
lip and/or cleft palate (CL/P) than cleft palate alone
(isolated cleft palate, CP).

CP is commoner in girls and CL (P) is commoner
in boys: there is a slight male preponderance (60%) for all clefts. The left side is affected significantly
more commonly than the right and there are
geographical and racial variations with a lower
incidence in black than white races. More clefts are
reported in still than in live births. CP is associated
with socioeconomic deprivation and an important
increased risk (1.5) is noted with maternal cigarette
smoking during pregnancy. Annual frequency
variations may suggest environmental influences.

**ASSOCIATED ANOMALIES**

The incidence of associated anomalies with facial clefts
is as high as 50% and well over 300 syndromes in
which orofacial clefting is a part have been defined.
It is essential that each newborn is examined carefully.
and extensively particular for skeletal, central nervous system and cardiac defects. Low birth weight, preterm newborns and newborns with bilateral clefts have a higher risk of associated anomalies and should be especially carefully screened. Both minor (e.g. external ear deformity) and major, life-threatening (cardiac, esophageal atresia) anomalies demand recognition before prognosis and treatment planning.

The associated anomalies and syndromes include:
- Chromosomal anomalies: Trisomy 13, 18 and 21
- Pierre Robin syndrome (or sequence) in which the cleft palate is associated with a small mandible (micrognathia) (Fig. 105.6). This leads to respiratory and feeding problems.
- Treacher Collins syndrome (facial dysostosis) shows a typical facial appearance of down-slanting palpebral fissures, coloboma and ectropion of the lower eyelids due to maxillary hypoplasia associated with cleft palate and mandibular hypoplasia. Inner ear anomalies lead to deafness.
- Stickler syndrome has a phenotype of flat nasal bridge and midface in association with cleft palate and myopia, which carries a risk of retinal detachment and consequent blindness. The syndrome is autosomal dominant.
- Goldenhar syndrome is better known as the oculo-auriculo-vertebral syndrome and is a spectrum of malformations including cervical spinal fusion, external ear anomalies, epibulbar dermoid, mandibular hypoplasia and cleft (Fig. 105.7). The hemifacial syndrome, in which facial asymmetry is pronounced, is variant of this.
- Van der Woude syndrome is important in alerting to an autosomal dominant pattern of cleft inheritance. Lower lip pits present in association with the cleft.
- The velo-cardio-facial syndrome is now recognized as part of the Di George syndrome related to a 22q11 chromosomal deletion.

**TERMINOLOGY, CLASSIFICATION AND RECORDING**

The terms used in description of orofacial clefts are various and, although some are self-explanatory, others are less clearly defined. They include:
- Primary and secondary palate
- Pre-alveolar, alveolar and post-alveolar
- Complete and incomplete
- Unilateral and bilateral
- Hard palate, soft palate and submucous clefts.

Some terms, such as “isolated cleft palate”, are confusing: either a cleft of the palate only, as opposed to lip and palate, or a cleft of the palate without any other anomaly could be implied. The terms “syndromic” and “non-syndromic” better describe cleft palate with or without other anomalies.
Four groups of cleft type were defined by Veau (1928) in his classification:

- Cleft of soft palate only
- Cleft of hard and soft palate to incisive foramen (the secondary palate)
- Complete cleft of soft palate. Hard palate, alveolus and lip on one side
- Complete cleft on both sides.

However, this does not include clefts of the lip and alveolus only (the primary palate).

Kernahan and Stark (1958) developed a more detailed, descriptive classification based on the use of the embryological concepts of primary and secondary palate:

- Clefts of the primary palate only;
  - Unilateral, complete/incomplete
  - Median, complete/incomplete
  - Bilateral, complete/incomplete
- Clefts of the secondary palate only;
  - Complete/incomplete/submucous
- Clefts of both primary and secondary palate;
  - Unilateral, complete/incomplete
  - Median, complete/incomplete
  - Bilateral, complete/incomplete

A diagrammatical form of cleft recording (Fig. 105.8) was introduced by Kernahan and developed by Millard (1976) to allow greater definition of detail and has been further enhanced and modified to allow recording of minor morphological differences and variations of the lip deformity. This has the additional advantage of suitability for computer storage and potential for subsequent analysis.

Photography affords an objective method of recording the cleft appearance and is used from birth and throughout the child’s clinical course. Reproduction of a standard image presents difficulties and relies as much on the experience and expertise of the photographer as it depends on technical aspects such as use of a grid. Capture of a satisfactory image may be achieved best when the child is anaesthetized for surgery. Recently, work has been done on 3D photographic recording linked to computerized data storage, which holds out the promise of accurate analysis of facial growth in clefts and the effects of surgery on growth.

ANATOMICAL AND CLINICAL FEATURES OF CLEFTS

Lip and Alveolar Cleft

In the lip the cleft line follows the philtral ridge on the lateral margin of the philtrum (Fig. 105.9) from the middle of the nostril sill to the peak of the cupid’s bow of the vermillion border. The abnormal muscle insertions of the broken ring of the circumoral muscles causes marked displacement and distortion of the anatomical features but, although some degree of hypoplasia of tissues occurs, there is no significant loss or absence of tissues (Fig. 105.10). Some of the factors leading to aberration of both soft tissues and bone/cartilage structures are therefore:

- Inherent abnormality of growth centers in the orofacial complex;
- Asymmetry and imbalance of muscle forces in the cleft area;
- Absence of the restraining forces of normal lip structures;
- Misplaced pressure of the tongue in the cleft area.

In the dynamic situation of facial movements of smiling, blowing or whistling, the insertion of interrupted circumoral muscle sphincter into the cleft margins at the base of the ala and the columella leads to a prominent bulge or bunching of muscle fibers. The cleft edges show progressive thinning of the
The normal regular arch of the maxilla is replaced in the cleft case by greater and lesser maxillary segments, which are misaligned. The line of the cleft at the alveolar margin is between the lateral incisor and canine teeth. The greater maxillary segment is more prominent and the premaxilla is rotated into an anterior position with the midline displace towards the non-cleft side. The lesser segment tends to collapse into the cleft. The absence of symmetrical soft tissue and muscular restraining forces fails to mold a normal arch. In addition to asymmetry, there is relative hypoplasia of the lesser segment with decreased height or vertical shortening of the maxilla.

Bilateral cleft lip may present a symmetrical appearance but also may display disproportion of the two sides and a displaced midline (Fig. 105.11). The premaxilla and prolabium can rotate around a vertical axis and also tilt markedly upwards with the effect of foreshortening the columella. While growth of the premaxilla may be excessive, the prolabium may be relatively deficient and is devoid of muscle tissue. There is no buccal sulcus between premaxilla and prolabium. In complete bilateral clefts the nasal tip may be central and the alae and nostrils symmetrical and equal although wide and flattened. However, when there is a difference in degree of cleft between the sides - one complete and one incomplete - marked asymmetry and deviation of structures from the midline arises. The presence of even a minimal skin bridge - Simonartz bar - limits extent of deviation and asymmetry (Fig. 105.12).

The vermilion border of the lip as they run towards the deficient and cleft nasal sill. The columella is misaligned due to the offset position of the nasal spine and comes to lie in a plane canted away from the vertical toward the horizontal. In turn the nasal septum is deviated from the midline and the lower lateral alar cartilage of the cleft side is splayed out and looses its “C” shape. The medial and lateral crurae of the cartilage are attached on either side of the cleft respectively to the base of the septum and the alar base in the region of the nasal vestibule.
Palate Cleft

The line of a unilateral cleft of lip and palate is through the alveolus and primary palate to the position of the incisive foramen and then in the midline of the bony hard palate and soft palate ending with a bifid uvula. The cleft extends into the nasal cavity on the cleft side of the nasal septum but on the non-cleft side there is fusion of the palatine process of the maxilla to the nasal septum. The palatine process on the cleft side is usually deficient and is displaced cephalad into the nasal cavity. The lower and middle turbinate bones intrude into the cleft and may be more prominent because of marked mucosal edema and hypertrophy. The principle blood supply to the palate tissues is the greater palatine artery, which emerges through the palatine foramen in the bone just medial to the position of the posterior molar teeth. At the posterior edge of the hard palate the muscles of the soft palate, levator palati and tensor palati — are inserted into the bone instead of uniting and fusing in the midline raphe. This abnormal muscle orientation is evident as a ridge in the soft palate tissue running obliquely forwards and medially into the hard palate margin. The hemi-uvula is drawn into a lateral position on each side. The absence of a complete sphincter encompassing the palate (velum) and the posterior pharynx causes failure of velopharyngeal closure (incompetence) and is responsible for typical cleft palate or nasal speech tone.

In a complete bilateral cleft of primary and secondary palate, the premaxilla has no maxillary attachments and shows unrestrained forward growth. The free lower border of the vomer and nasal septum is prominent in the midline of the cleft and the lateral palate processes are often displaced into the nasal cavity alongside the vomer. The cleft soft palate tissues are drawn into a lateral position and the muscle may be deficient.

An isolated secondary palate cleft may involve only the soft palate or both hard and soft (Figs 105.13 and 105.14). A complete secondary cleft extends posteriorly from the incisive foramen and the relative positions of the palatine processes and the vomer are better preserved than in a complete primary/secondary cleft. Incomplete clefts include lesser degrees of hard palate cleft, simply a notch at the posterior margin of the hard palate, or soft palate cleft only. The shape of the defect may conform more to a “U” than a “V” especially in conjunction with a small mandible (micrognathia) in the Pierre Robin sequence. The sequence possible starts with hypomandibulism, which causes the developing tongue to intrude into the space of conjunction of palatine process and vomer and interfere with the normal fusion. Soft palate cleft may be muscular only with intact mucous membrane on oral and nasal surfaces—so-called submucous cleft palate (SMCP) (Fig. 105.15). The anatomical/clinical features consist of a notch in the posterior edge of hard palate, a midline grey, translucent zone, oblique muscle prominence and a bifid uvula but may be difficult to define and lead to delayed diagnosis.
PRENATAL DIAGNOSIS

Prenatal diagnosis of the presence of a facial cleft is becoming increasingly likely. Anomaly scanning may detect clefts but an indication such as previous family history, risk factors or hydramnios may be the stimulus to careful inspection of fetal craniofacial anatomy. Other anomalies also increase the index of suspicion and detection rate for craniofacial abnormalities and will also lead to fetal karyotyping.

Whilst in utero detection does not necessarily confer specific benefit on the fetus or neonate, the parents have the advantage of up to 80% detection rate though there is also a significant false positive rate. Detailed counseling in the event of a prenatal diagnosis is extremely important and there is good evidence of the major benefit of psychological preparation for the birth of an infant with a cleft anomaly - 85% felt that prenatal counseling was much more helpful than postnatal counseling. Full evaluation and counseling may be especially important in Pierre Robin sequence where concurrent cardiac anomalies (20%) and abnormal karyotype (10%) are more common. Careful ultrasound evaluation is needed to give an accurate prognosis based on where the fetus/neonate fits in the spectrum of the Pierre Robin sequence. The potential for much greater clarity of definition of fetal craniofacial anatomy from in utero magnetic resonance imaging (MRI) is now gradually becoming evident.

Informed parental choice regarding continuation or termination of the pregnancy and consideration of the option of early neonatal surgery follow directly from in utero diagnosis. However, prenatal diagnosis raises difficult practical, moral and ethical issues at a sensitive time for prospective parents and complex medicolegal questions such as “wrongful life” potentially follow from decisions made prenatally. Fortunately, normal pregnancy and term delivery of a healthy baby are the usual sequelae.

It is well known that in utero surgery may produce virtually scarless healing and recent experiments have confirmed that both scar formation and growth are better following in utero than neonatal cleft surgery in an ovine model. A large body of research continues into the potential for fetal surgery for clefts though the work is complicated by the natural history of a significant association of other anomalies and high consequent fetal loss in animal models.

PRESENTATION

The cleft usually comes to notice first at birth or at the time of routine newborn examination. To this end it is important that those performing routine examinations are familiar with the need to visualize the palate on intraoral examination. It is also important that attending staff are trained to cope with the inevitable anxiety and concern which recognition of a congenital anomaly raises, and can provide initial answers and appropriate reassurance based on a basic knowledge.
of facial clefts. This should include the immediate risks and an outline of the plan of management. Early and definitive consultation with a member of a cleft team—specialist nurse, surgeon, orthodontist, speech therapist — follows and affords an opportunity for detailed discussion of residual concerns and of the planned treatment program. The parents should be helped towards an understanding of the nature of clefts and to a realistic expectation of outcome. Unreasonable doubts and anxieties can be allayed but false reassurance must be avoided. Further counseling to deal with genuine concerns may be arranged. The course of cleft management stretches throughout childhood and adolescence into early adult life and cannot be guaranteed to be smooth. The full cooperation and patience of the parents is needed to achieve the best outcome for the patient.

**Respiratory Problems**

Airway obstruction due to relative micrognathia, abnormal tongue position and retained oropharyngeal secretions is a potential immediate postnatal risk for all babies with a cleft. Routine measures to clear the newborn’s airway by suction will be sufficient to avert problems in most cases but readiness to take further steps is required. These include drawing the tongue forward with an instrument if necessary, placing the baby in the more favorable ventral suspension position, or airway intubation. More major problems are associated with Pierre Robin sequence. effects. Blood gas analysis, electrocardiography and echocardiography will show warning signs of hypoxia and hypercapnia and cardiac enlargement and failure due to pulmonary hypertension and cor pulmonale. Failure to control these consequences may precipitate hypoxic damage with psychomotor impairment and potential fatal outcome. With growth of the infant the respiratory problem lessens which appears to be due to catch-up in jaw size in some cases but this does not always occur and the mandible/maxilla relationship may remain unchanged. It is clearly essential that adequate, or even enhanced, nutritional intake is assured throughout this period.

**Feeding and Growth**

Feeding normally from the breast may present no problem at all to a baby with CL+/-P and, unless breathing problems preclude it, a trial of breast-feeding should certainly be allowed if the mother wishes. Similarly, feeding from a normal bottle and teat may well be possible despite the cleft. However, normal sucking may be prevented by inability to seal the lips around the nipple or teat and by inability of the tongue to compress either against the palate. Negative suction in the hypopharynx may not be possible because of velopharyngeal incompetence and attempted feeding may cause respiratory distress due to incoordination and entry of milk into the nasopharynx. About 25% of babies have significant feeding problems reflected in poor weight gain and those with Pierre Robin sequence are especially disadvantaged. The lag in weight gain may continue beyond the first months despite a relatively normal birth weight and a deficiency of growth hormone in some cases has been postulated. Growth delay (both weight and height) is more evident in infants with syndromic than non-syndromic clefts and in cleft palate than cleft lip, but catch up usually occurs following cleft palate repair by 2 years of age. Short stature, however, tends to be a persisting feature of syndromic cleft patients.

At the first sign of feeding difficulty help and advice and suggestions for feeding strategies should be offered to the mother. A variety of modified teats is available ranging from a specific cleft palate teat (Nuk Medical Services) to lamb’s teats, flanged teats and double teats (Fig. 105.17). The Haberman feeder (Fig. 105.18) allows delivery of milk at a variable rate without requiring the baby to suck. Prosthetic plates and obturators can be developed to occlude the cleft and aid sucking and may be incorporated into an extra-oral appliance to realign the maxillary segments.

If feeding difficulty is complicated by respiratory problems and the baby shows signs of failing to thrive, tube feeding is indicated. A nasogastric tube is a short-term solution but may increase pharyngeal secretions and pulmonary aspiration. Persisting trouble is best helped by a percutaneous endoscopic gastrostomy tube insertion but the possibility of associated gastroesophageal reflux should be considered. Thickened feeds using Carobel (Cow and Gate) or Gaviscon (R and C) less readily reflux but fundoplication and gastrostomy is needed in a few cases. A calorie intake of at least 100 cals/kg/24 hr is required and should be exceeded if energy demands are increased by respiratory effort, pulmonary disease, cardiac disease or pyrexia.
Submucous cleft palate (SMCP) is frequently missed at birth despite an incidence of about 1:1,200. As a large proportion are asymptomatic, this is not a great problem. However, some do not come to light until the child presents with hypernasality, relative unintelligibility of speech and possibly Eustachian tube dysfunction at nursery or early primary school age. Initial referral may be to an otolaryngologist on suspicion of obstruction due to enlarged adenoids or tonsils, but examination reveals the features of an SMCP. There is, of course, a strong contraindication to adenoidectomy in this circumstance. Confirmation of the SMCP may be sought in detailed speech assessment and demonstration of velopharyngeal inadequacy and can be documented in the cooperative patient using lateral videofluoroscopy of palate movement or nasoendoscopy. The latter investigation shows a characteristic abnormality of the dorsal convexity on palate movement and a coronal, as opposed to circular, pattern of velopharyngeal closure.

PRESURGICAL ORTHODONTICS

The disruption of continuity of the maxillary arch in complete unilateral and bilateral clefts allows the maxillary segments to assume markedly misaligned and asymmetrical positions. The consequences for primary surgery and later jaw development are considerable and have led to various strategies to realign segments. Simple techniques using gentle sustained pressure from elastic strapping to more comprehensive attempts to mold both alveolus and nasal structures have been devised; however, alveolar realignment must not occur at the expense of excessive maxillary collapse inwards and an intraoral plate may be needed to prevent this. A further benefit may be seen in improved sucking and feeding and assumption of a more normal tongue position, which is helpful in later speech development. In addition, some parents may derive psychological benefit from the recognition that active steps are being taken to help their child’s problems.

Whilst evidence for long-term improvement in arch formation is sparse, there is no doubt that surgery for lip repair and primary rhinoplasty is facilitated. The best outcomes are achieved when orthodontic management is continued through to the time of eruption of the permanent dentition. Although many technical and surgical advances have been made in orthodontic management of the cleft patient, objective evidence of improved outcomes from controlled, randomized studies is generally lacking. In practice, close cooperation between orthodontist and cleft surgeon is needed to decide on precise timing of lip closure once optimal molding has been achieved. Recording of cleft shape using plaster models before, during and after surgery allows assessment of progress in individual cases.

PREOPERATIVE PREPARATION

Preparation for the surgical procedure of lip and palate repair includes the full preoperative assessment and consent procedures necessary for all surgery in infants and children. Points of specific relevance in for satisfactory cleft surgery are:
- Adequate weight gain
- Hemoglobin above 10 gm/100ml
- Bacteriological swab of oral cavity to exclude pathogens (e.g. hemolytic streptococcus)
- Consideration of blood grouping/cross-matching (e.g. for severe cleft palate).

Close cooperation and understanding between anesthetist and surgeon are necessary as the airway is shared and the potential for ventilatory/respiratory problems is thereby greater. The anesthetist will normally wish to use a reinforced preformed endotracheal tube to minimize risks of tube compression and to give the surgeon the maximum degree of access. The surgeon is responsible for ensuring that peroperative bleeding does not track into the lower airway by adequate hemostasis and packing; a non-cuffed endotracheal tube is normally used for young infants and affords less protection to the lower airway against ingress of secretions. Laryngeal spasm, related to immediate postoperative irritation from blood, is potentially fatal. In experienced hands, anaesthesia in less sophisticated surroundings using basic techniques without access to advanced equipment and monitoring can be made very safe with a carefully derived protocol and close attention to detail.

CLEFT LIP REPAIR

The timing of cleft lip repair has been a matter for debate. Protagonists have argued the case either for
an immediate neonatal repair or for repair at about 3 months of age.\textsuperscript{83,84} It is agreed that repair in the first month or two is inadvisable for reasons including the neonate’s natural drop in hemoglobin and lowered immune defenses at this stage. Factors to balance in considering the optimum age for repair are:

- Wound healing and subsequent scarring
- Technical ease or difficulty of repair
- Psychological effect on the mother and baby
- The effects of surgery on subsequent growth
- The presence or absence of other anomalies.

Whilst wound healing is undoubtedly better after operation in the early newborn period, the advantage of preoperative surgical orthodontics is lost and technical difficulty may be greater. Careful selection is necessary for early newborn repair to screen out significant associated anomalies and the maternal/newborn bonding process is interrupted. The parents’ coping strategies may be enhanced by the psychological lift of immediate repair of the defect or, conversely, by the necessity of coming to terms with the unrepaird defect for a longer period prior to repair.

The success of the policy of a particular cleft unit with respect to age of repair may depend more on implementation and explanation of that policy than on the chosen age of repair. The most common age for repair of the lip, which is the best compromise between the various considerations, is approximately 3 months.

The repair of the lip attempts to achieve a series of objectives embracing:

- A scar which is inconspicuous and orientated to reproduce the missing philtral line
- A vermilion line with peaks of equal height and a balanced cupid’s bow
- A central vermilion tubercle of the lip
- A nasal sill equal in width to that of the non-cleft side
- Repositioning of the lateral alar cartilage to correct the tip, dome and ala of the nose
- Restoration of the columella to a central, vertical position
- Reorientation of the orbicularis oris muscle to restore muscle function
- A buccal sulcus to allow lip movement.

In summary, a symmetrical, balanced, scarless normally functioning nostril and lip is the acme of the cleft surgery.

The earliest and simplest lip repairs involved straight line closure with little respect for the displacement and distortion of anatomical features. Subsequent efforts to realign and balance these features were typified by techniques such as rectangular flap and triangular flap but unsatisfactory scars ensued (Fig. 105.19).\textsuperscript{85,86} A major leap forward was made by Millard (1960) who devised the rotation/advancement flap technique upon which most subsequent refinements have been based.\textsuperscript{87,88}

Many technical points play a part in achieving satisfactory, reproducible primary lip repairs. Detailed assessment and precise planning of each repair includes silastic models, measurements and marking of all skin incisions - usually with methylene blue dye. Infiltration of tissues with 1:200,000 adrenaline with 0.5% Marcaine (Astra) both reduces bleeding, which helps to keep a clear operating field, and also minimizes the need for general anesthesia, which speeds postoperative recovery. Bipolar diathermy aids in maintaining clear vision and ensuring meticulous repair. Fine instruments and sutures (6/0, 7/0) and magnification are needed to achieve precise apposition of mucosa, muscle and skin (Figs 105.20 and 105.21).

Attention has been drawn to the need to avoid any interference with important growth sites in the mid-face in the repair of cleft lip. Scarring in the area of the vomer and premaxillary suture, in particular, might subsequently impede the development of the dentoalveolar structures.\textsuperscript{89} Emphasis is also placed on the careful definition and reconstruction of the circumoral muscle complex so as to achieve restoration of function and hence optimal growth.\textsuperscript{90} Some of the best outcomes of the primary lip repair have resulted from the recognition that the cleft nose correction can be performed as an integral part of the repair rather than as a second stage. Repositioning and elevation of the lower lateral alar cartilages can achieve a correction of the nasal tip and realignment of the nostril rim thereby avoiding the drooping appearance which is an obvious stigma of cleft repair, whilst preserving the potential for nasal growth into adolescence.\textsuperscript{91-93}

Bilateral cleft lip repair introduces the additional difficulty of the excessive forward displacement of the premaxilla. Presurgical orthodontics may reduce the position to one where lip repair can be achieved without significant tension but this is not always the case. In extreme situations a unilateral repair may be
performed initially with a simple lip adhesion on the contralateral side to attempt to maintain a central position of the premaxilla. However, simultaneous is bilateral repair is the gold standard and preferred option. Before the significance of growth centers was fully understood, a set-back of the premaxilla by vomerine osteotomy and resection was used to achieve a satisfactory lip appearance initially, but gross mid-face hypoplasia and reverse dental bite developed subsequently. The lessons from unilateral lip repair may be imported with modifications into the bilateral operation.94,95 A good functional result depends on realigning and establishing continuity of the orbicularis oris muscle and on creating a buccal sulcus between premaxilla and prolabium. In addition, a good cosmetic outcome follows from some narrowing of the often wide prolabium (Fig. 105.22), alar correction and development of the columella.96

Recovery from operation is usually rapid. Blood transfusion is rarely needed and feeding can be started from breast or bottle within a few hours and certainly by the following day — this may well be a better way of settling the baby and relieving strain on the repair than the use of sedation. Discharge from hospital will be on the second or third postoperative day and the non-absorbable monofilament sutures will be removed on about the fifth day.
CLEFT PALATE REPAIR

The principle objectives of cleft palate repair are to produce a palate:97

- Of adequate length
- Mobile enough to close the velopharyngeal space
- Whose dorsal surface will conform to the curvature of the posterior pharyngeal wall.

However, the goals for the outcome of repair of the hard and soft palate differ: hard palate repair should facilitate normal facial growth whilst soft palate repair aims to allow velopharyngeal competence.98 An essential step in achieving the latter aim is the repositioning and reconstruction of the levator veli palatini sling by detaching the muscle insertions from their aberrant attachment to the posterior hard palate.99 Lengthening of the soft palate and improved function of levator and tensor muscles may then permit adequate soft palate movement and velopharyngeal closure.

The timing of cleft palate repair is governed by various factors identified as:

- The size of the child and of the child’s jaw, influencing access for the surgeon
- The effect of the age at palate repair on speech development
- The effect of age at palate repair on subsequent palate growth100
- The effect of repair on the nasal airway
- The effect of repair on Eustachian tube function and middle ear development.

- Changes in the width of the unrepaired cleft palate with time alone.

It is generally accepted that attempts at very early palate repair are vitiated by the difficulty of access, though some surgeons have performed early repair of the soft palate in order to encourage narrowing of the hard palate cleft and thereby limit the need for mobilization at subsequent hard palate repair.101 However, there is some tendency for the unrepaired cleft to narrow spontaneously. Any interference with the mucoperiosteum and soft tissue attachments of the facial skeleton is liable to have a deleterious effect on bone growth and this consideration logically leads to delay in palate operations; unrepaired clefts in adults show excellent maxillary growth.102 Speech, on the other hand, will develop best if the young infant is making noises and reproducible sounds in a consistent way by using an intact, repaired palate. The effects of palate repair on nasal airway and Eustachian tube function are less definable but in both cases better function is likely to occur with more normal anatomy.

These considerations are dominated by the advantage of improved speech development and, with this in mind, palate repair at about 6-9 months of age is widely advocated.84,103 A direct relationship exists between delayed palate repair and increased nasality of speech.104,105

A great variety of techniques and operations have been described for hard palate repair and these differ principally in the extent of soft tissue mobilization advocated to perform repair without excessive tension. Simple lateral peri-alveolar releasing incisions and mucoperiosteal bipedicle flap elevation allows midline cleft closure (Fig. 105.23). More mobility and easier closure can be achieved using a flap based only on a greater palatine artery posterior pedicle but maxillary growth may be affected to a slightly greater degree. The two techniques show very similar results with an overall need for repeat velopharyngeal surgery in about 15% which rises to 23% for severe clefts.104 The soft palate muscle is normally repaired synchronously using an intravelar veloplasty technique or a double reversing Z-plasty to reconstitute the levator/tensor muscle sling.106

The Furlow operation for soft palate repair is based on retroposition of the levator/tensor complex and lengthening of the palate by Z-plasty in two layers which are not superimposed (double reversing) and

Fig. 105.22: Repaired bilateral cleft lip with excessively wide prolabium
is therefore a secure and reliable closure (Fig. 105.24). In comparison with intravelar veloplasty there is a reduced need for subsequent pharyngoplasty.\textsuperscript{107}

Submucous cleft of the palate requires muscle repositioning and repair despite the intact mucosal layers and apparent palate continuity.\textsuperscript{108} The Furlow repair gives a high level of successful outcome unless the initial velopharyngeal gap is large — greater than 8 mm.\textsuperscript{109}

In cleft palate surgery, the postoperative appearances are not helpful in predicting the functional outcome. Velopharyngeal functional outcome relates to severity of cleft but it has also been shown that there is a learning curve for each surgeon and a correlation between higher volume operators and a reduced need for secondary procedures.\textsuperscript{110} The overall assessment of outcome after cleft palate surgery requires long-term follow-up including review of speech, hearing, dental development and maxillary/mandibular arch relationship. The need for secondary surgery depends on these parameters.

**ASSESSMENT AND OUTCOME**

The whole area of assessment of outcome from the management of cleft lip and palate is complicated by the wide range of treatment strategies, the complexity of the issues relating to outcome and the relatively long duration required for an assessment of final outcome. The perennial debate goes on about whether early repair aimed at producing the best speech results or later repair aimed at allowing optimal maxillary growth ultimately give the better functional and aesthetic outcome. Resolution requires randomized controlled trials to determine the issue from scientific study.\textsuperscript{111} The need for detailed audit has been advocated not only to resolve matters of treatment protocols but to look at the important question of whether centralized services with relatively high volume operators lead to better outcomes.\textsuperscript{112} Such an extensive study was established to look at all aspects of cleft management in the UK and has reported in detail.\textsuperscript{113}
Speech

Following cleft palate surgery an initial residual speech problem related to inadequate velopharyngeal function is to be expected. Many factors are involved in this and understanding of both normal and cleft speech is essential in analyzing and measuring the individual components. A trained speech therapist is able to distinguish between articulatory, dysphonic and velopharyngeal problems and concentrate on the predominant issue. Velopharyngeal inadequacy itself has various aspects, which may each contribute to the overall speech problem:

- Insufficiency — as seen in the unrepaired cleft
- Incompetence — a functional or neurogenic problem
- Mishearing — nasal loss with specific sounds sometimes related to deafness.

The extent of the speech problem is generally more severe for more major, bilateral clefts and, although the technique of repair has some bearing on the outcome, the timing is probably of greater significance-earlier repair producing better results. The principle in speech therapy management, however, is to start early in all cases with assessment and therapy with the goal of establishing normal speech by school age. In addition to standard listening and recording methods, the therapist may use:

- Lateral videofluoroscopy of palate movements
- Nasoendoscopy to observe directly palate movement during speech
- Anemometry to assess airflow through the nose during speech.

Up to 20% of cleft palate patients will not achieve satisfactory articulation and nasal tone even with extended speech therapy and will go on to consideration for secondary surgery.

Hearing

A degree of otitis media is common in children with cleft palate — unrepaired or repaired and the risk of conductive deafness should be borne in mind by teachers and specialists. Formal audiometric evaluation should be performed regularly by a trained specialist and it must be recognized that a hearing loss of more than 15 decibels will compound the speech problems for cleft palate patients. The management of the middle ear problem includes simple measures such as use of decongestants and antibiotics and also myringotomy and tympanostomy tube insertion for adequate ventilation.

The acquisition of language is a complex process depending not only on hearing but also on cognition and communication and it is notable that there is a significant delay in the early years for cleft palate patients.

Dental Development and Jaw Growth

The care of the dentition starts at an early stage for the cleft patient with attention to adequate fluoride intake and good dental hygiene. The primary dentition may show abnormalities of dental development in addition to the problem of missing teeth at the cleft site. Hypoplastic, bigeminal (double) and supernumerary teeth are seen but generally do not warrant attention other than hygiene. As the permanent (second) dentition appears from age 7/8, attention is paid to alignment and assessment is made of the need for bone grafting to the alveolus. Orthopantomograms are needed to identify the position of unerupted teeth and plan management fully. The restorative dentist has an important role in dealing with residual dental problems in an effort to achieve a symmetrical arch of well-aligned teeth which protects not only dental hygiene but also jaw function.

Detailed assessment of the outcome of dental management and jaw growth uses an index (the Goslon index) for defining the dental relationships at the stage of early permanent dentition. The need for later orthognathic surgery to establish satisfactory cosmetic appearance, jaw relationship and dental bite may be as high as 25% and is not entirely dependent on the nature of the cleft.

SECONDARY SURGERY

Following initial repair of the cleft lip and palate, consideration of further (secondary) surgery is indicated in a number of situations including:

- Unsatisfactory cosmetic appearance of lip or nose
- Inadequate velopharyngeal function
- Residual cleft of alveolus and primary palate.

Lip and nose

Current techniques of primary repair aim at as complete a correction as possible and avoidance of
revision surgery. However, nasal asymmetry and persistent displacement of alar cartilages may warrant repositioning. The deleterious effects on subsequent growth are always borne in mind. More minor scar revisions to improve the vermilion line can be performed at any stage without detriment.

**Velopharyngeal Function**

If adequate function is not achieved after initial palate repair and speech therapy, it is not likely that a further intravelar repair will be successful. In this circumstance a pharyngoplasty, incorporating both the velum and posterior pharyngeal wall tissue, is preferable. The principal techniques use either:

- A posterior pharyngeal flap which swings forward to anchor into the velum or
- A sphincter formed by reorientation of palato-pharyngeus muscles, which offers a more dynamic solution.

Both techniques produce excellent results in reducing velopharyngeal incompetence and there is no clear consensus for preference.

A residual fistula in the line of palate repair is not necessarily symptomatic, but if nasality of speech or fluid loss through the nose is noted, fistula repair will be indicated. Direct closure using local flaps is simplest but, if deficiency or scarring is significant, tissue may be imported from buccal mucosa or tongue.

**Alveolar Cleft**

The cleft of alveolus is often not closed with primary surgery but remains open to allow maxillary growth to proceed. Following maxillary realignment just prior to eruption of secondary dentition, bone grafts (usually from iliac crest) are placed in order to provide a matrix for dental eruption and alignment and to retain maxillary position.

**PSYCHOLOGICAL ISSUES**

It is obvious that a congenital abnormality as central to an individual’s image and perception as a craniofacial anomaly is liable to have a significant effect on a young person’s development. There is indeed wide awareness of the many psychological issues that confront not only patients with craniofacial anomalies but also their parents, and much research has been undertaken. Up to 40% of children are known to have major problems such as learning disorders and difficulties with social competence. It is important to recognize that patients and parents often have different perceptions about outcome, both in clinical and psychological terms and therefore to consider the opinions of both in reaching conclusions about management. There is a need for early assessment of the psychological component of disability related to craniofacial clefts and for introduction of appropriate guidance, advice and counseling. Training in social skills at a young age may help the individual to circumvent later difficulties. Continuing multicenter research aims to define the psychological and social problems associated with craniofacial anomalies and to devise strategies for minimizing risks to patients.

**ORGANIZATION OF CLEFT SERVICES**

There is no doubt that management of the patient with a cleft requires teamwork of a high order. Many different disciplines are involved in delivering the total “package of care” and this must be presented to the patient and parents in an integrated, logical and timely manner. This is best achieved in the context of a multidisciplinary clinic and this would generally include:

- Cleft surgeon
- Orthodontist
- Speech therapist
- Otolaryngologist
- Geneticist
- Specialist nurse
- Audiometrician
- Dentist
- Pediatrician
- Psychologist.

Some team members require dedicated and highly specialized training while others bring the more general skills of their specialty. It is increasingly recognized that, in order to draw together and capitalise on the expertise of a team, a support network embracing skills in the following fields is helpful:

- Clerical/administrative
- Audit
- Medical illustration
- Information technology
- Research.
A recent national survey has emphasized all these aspects of cleft care and has also highlighted the fact that concentration of experience in fewer centers performing a higher volume of work is more likely to fulfil the above objectives.\(^{138}\)

Clarens E, Anderson B, Wolf LS. Feeding infants with cleft lip, cleft palate or cleft lip and palate. Cleft Palate J 1987;24:244-49.

Neck masses, sinuses and fistulae are a frequent occurrence in pediatric surgical practice. By recording detailed history, careful clinical examination, by understanding the embryology of branchial arches and anatomy of its derivatives, the surgeon may arrive at a proper diagnosis on clinical grounds in most of the cases.

CONGENITAL LESIONS

The pharyngeal region, because of its complexity and its phylogenetic significance, has received more attention from embryologists than have most other regions of the body. Von Bear first described the clefts of the human embryo.1,2 Von Acherson related cervical cysts to anomalous closure of the clefts.1,2 Phylogenetically, the branchial apparatus is related to gill slits. In fish and amphibians, these structures are responsible for the development of the gills (Branchia is Greek for gills). The word pharyngeal is often substituted for branchial, because humans do not develop gills.

At the fourth week of embryonic life, the development of 4 branchial (or pharyngeal) clefts results in 5 ridges known as the branchial or pharyngeal arches (Fig. 106.1). They contribute to the formation of various structures of the head, neck and thorax. The fifth and the sixth arches are believed to be rudimentary (Fig. 106.2).3 The second arch grows...
Neck Anomalies

caudally and ultimately covers the third and the fourth arches. The buried clefts become ectoderm lined cavities which normally involute around 7th week of development. If a portion of the cleft fails to disappear completely, the entrapped remnant forms an epithelium lined cyst with or without a sinus tract to the overlying skin.

Cystic and Fistular Remnants of the Branchial Apparatus

Different types of cysts, sinuses and fistulae can arise from the incomplete obliteration of embryonic spaces of transitory branchial apparatus of the embryo.

First Cleft Defects

The earliest classification of first branchial cleft defects was published by Arnot in 1971 and was primarily based on the anatomical location of the defect. In a simpler classification proposed by Olsen et al, a first branchial cleft anomaly need only be labeled as a cyst, a sinus or a fistula. This classification was designed to facilitate preoperative decisions about surgical approach. Anomalies of the first branchial cleft have been reported to be around 8 to 10%. It has been reported that cystic lesions are more common in adults and fistulas and sinuses are more commonly seen in children. The patient may present as a preauricular swelling or sinus, as a mass in the external auditory canal or as a discharge from the ear (Fig. 106.3). The internal openings for both the sinuses or fistulae are found to terminate along any portion of the external auditory canal with antero inferior bony - cartilaginous junction being the most common site. When a patient requires repeated incisions and drainage procedures in the preauricular region or parotid region, one should suspect the possibility of a first branchial cleft anomaly. The investigations like sonogram, CT scan or MR imaging are of limited value. Various conditions like inflammatory lymphadenitis, dermoid cysts, cystic hygroma, hemangioma, lymphoma are to be differentiated from first branchial cleft anomaly. Operation can be done only after the infection has been controlled. During surgery the anomalous tract may run lateral to, medial to or even directly through the main trunk of the facial nerve. The surgeon must be aware also that the tract may involve the middle ear. Recurrence is uncommon after complete excision. Higher incidence of recurrence have been reported in patients with pre-existing fibrosis from prior infections and surgery.

Congenital Auricular Pits

They represent ectodermal folds sequestrated during the fusion of the six tubercles. These pits or sinuses are lined by skin and are usually only few millimeters deep but they may be longer, tortuous and branched. They appear to be bilateral in 33% of patients and when unilateral, more common on the left side. These sinuses may be familial. They are said be associated with congenital nasal fistulae and with deafness and branchial cleft anomalies in the same pedigree. Preauricular pits and sinuses are present from birth and most of the time there is history of recurrent infection. Prior infection increases the difficulty of complete surgical excision and increases the risk of recurrence. Complete surgical excision of the sinus tract up to temporalis fascia should be done. During excision, one should search for branches from the main tract. Recurrence rate as high as 42% has been reported particularly in the presence of multiple branches.

Cervicoaural Fistulae, Sinuses and Cysts

Cervicoaural fistula represents the persistence of the ventral end of the first branchial cleft (the external auditory canal represents the dorsal end). It is lined with skin and extends from the neck below the ear to
the styloid process and carotid sheath and open into the external auditory canal. In some cases the tract reaches the canal but does not actually open into it. The tract usually passes over the facial nerve (a component of the second arch) but may also pass under the nerve. The anomaly usually presents as a swelling below the ear or as an infected sinus. Treatment consists of complete excision of the sinus tract or cyst. It is important to note that the facial nerve may be displaced upward or downward by the anomalous tract and must be identified to prevent injury to the facial nerve.\(^{19,20}\)

**Second Cleft and Pouch Defects**

Sixty seven to ninety percent of all branchial anomalies are due to defects of the second branchial cleft and pouch.\(^{21}\) Most complete branchial fistulae derive from the ventral portion of the second branchial cleft and pharyngeal pouch. Typically the external opening is in the lower third of the neck on the line of the anterior border of the sternocleidomastoid muscle. The fistula courses through the subcutaneous tissues, the platysma and penetrates the deep fascia to reach the carotid sheath. Above the hyoid bone, the tract turns medially beneath the stylohyoid and the posterior belly of digastric muscle. It passes in front of the hypoglossal nerve, between the internal and external carotid arteries and over the glossohyaryngeal nerve, deep to the stylohyoid ligament, to enter the pharynx as a slit on the anterior side of the upper half of the posterior pillar of the fauces (Fig. 106.4). Occasionally, the opening is in the supratonsillar fossa or even in the tonsil itself.

The branchial sinus or fistula is usually noticed at or shortly after birth (Fig. 106.5).\(^{22}\) In one series, 78% of second arch sinuses and fistulae were diagnosed at the age of 5 years.\(^{10}\) Mucous discharge from the sinus opening along the anterior border of sternomastoid muscle between the hyoid bone and the supra sternal notch is the classical presentation.\(^{23}\) A complete fistula from the external skin to the tonsillar fossa is rare.\(^{10}\) Bilateral branchial sinuses are occasionally encountered.\(^{10}\) Family history is positive in as high as 6% of patients.\(^{10}\) In approximately 5% of patients, there is associated preauricular sinus.\(^{10}\) Most authors believe that the role of preoperative imaging in second arch defects is not helpful.

Excision of the whole tract is the only curative method. The tract should be excised with an adequate amount of supporting stroma to increase the likelihood that all epithelial tissue is removed. The step ladder technique is often used to gain surgical access to the entire tract. In addition to recurrence, transient injury to hypoglossal nerve has been reported.\(^{21}\)

**Sinuses Opening at the Surface**

External sinus tract are rare. They usually arise from the anterior border of the sternocleidomastoid muscle and terminate in a cystic dilatation.
Cysts

The deepest of the second pouch cysts are rare and present as swellings that bulge into the nasopharynx. They are derived from the dorsal portion of the second pouch. Branchial cleft cysts are three times more common than branchial fistulae.\(^{23}\) They tend to present at a later age than fistulae or sinuses, usually in the second decade of life.\(^{22,24}\) The incidence of bilateral lesions is reported as 2%.\(^{25}\) Most of the patients present with a painless, smooth lump typically located along the upper third of the anterior border of the sternocleidomastoid muscle (Fig. 106.6).\(^{22}\) The patient may present with infection, pain and pressure symptoms like dyspnoea or dysphagia.\(^{26}\) An infected cyst may progress to frank abscess formation, rupture leading either to sinus formation or recurrent cyst formation. The treatment of branchial cyst is to complete surgical excision with preservation of surrounding neurovascular structures (Fig. 106.7). Recurrence ranging from 3 to 21% has been reported.\(^{27}\) With higher incidence in patients with history of previous surgery. Infection and prior operation cause adhesions and distortion of tissue planes, which may lead to higher chances of recurrence and increased risk of damage to adjacent nerves and vessels.\(^{22}\)

Third Cleft and Pouch Defects

Complete fistulae of the third cleft and pouch are not known to occur. Cysts lying deep to the internal carotid artery and intimately associated with the vagus nerve are probably remnants of the third cleft or pouch. The incidence of third branchial anomalies is 2 to 8% and fourth branchial arch anomalies 1 to 2% of all branchial anomalies.\(^{28}\) A complete third arch and pouch fistula starts at the pyriform fossa of the hypopharynx and pierce the thyroid membrane. The tract would pass superficial to the hypoglossal nerve, deep to the glossopharyngeal nerve and the internal carotid artery and then pierce the platysma to exit in the lower neck in line with the anterior border of the sternocleidomastoid muscle. The termination of the anomalous tract at the thyroid gland near the superior parathyroid gland suggest fourth pouch origin. Fourth pouch anomalies are diagnosed mostly in childhood and 97% of them occur on the left side.\(^{29}\) The lesion may present even in neonates as lateral neck cysts or abscess with associated obstructive airway symptoms.\(^{30}\) The diagnostic evaluation centers on determining the presence of a sinus tract originating from the pyriform fossa. Plain X-ray may show air inside the cyst. Flexible fiberoptic nasopharyngoscopy is very helpful. Other investigations which are also helpful to localize the sinus opening are direct laryngoscopy and pharyngo esophagogram. The role...
of CT scan is also helpful. Complete excision including the piriform fossa attachment is the treatment of choice.

**Thyroglossal Cyst and Sinus**

Thyroglossal cysts are tubuloembryonic cysts formed due to persistence of the thyroglossal duct. During 4th to 7th week of intrauterine life, the thyroid diverticulum develops at the base of the tongue near foramen cecum and descends in the midline. The tract passes ventral to the 2nd arch mesenchyme from which hyoid develops and may arch anteriorly around the body of the hyoid bone. Normally the tract is obliterated once the thyroid gland reaches its final position. Persistence of the tract leads to the development of cysts which may be located anywhere along the line of descent of the thyroid gland.

**Positions of the Cysts**

Thyroglossal duct cyst never have a primary external opening because embryologically the tract does not reach the surface of the neck. Ectopic thyroid tissue is identified within the thyroglossal duct remnant in about 62% of patients. The diagnostic features of thyroglossal cysts are midline swelling which move on swallowing and on protrusion of tongue. However, 10 to 42% of patients, cysts are located laterally and frequently to the left. Nearly 50% of the thyroglossal cysts present in the first 2 decades of life. Most of the cysts present in the midline (Fig. 106.8A,B). Majority of the patients present as cyst and remainder may present with sinus, either due to spontaneous rupture after infection or following incision and drainage. Anatomically, the cyst may be adjacent to the hyoid bone (60%), above the hyoid bone (24%), below the hyoid bone (13%) and intralingual (8%) (Fig. 106.9). The different conditions which need to be differentiated from thyroglossal cyst are subhyoid bursitis (does not move up on protrusion of tongue but most of the time difficult to differentiate clinically), sublingual dermoid (does not move on swallowing and on protrusion), midline lipoma, enlarged lymph node. Carcinoma arising from the thyroglossal cyst is rare. Allard reported an age range from 6 years to 81 years with a mean age of 39.2 years.

**Investigation**

Preoperative evaluation of a thyroglossal cyst includes a thorough clinical examination, thyroid function test usually TSH estimation. La Rouere MJ et al recommended several criteria for doing thyroid scan in thyroglossal cyst particularly if there is suspicion of an ectopic thyroid tissue or a palpable mass within the cyst. Ultrasonography is being used quite frequently. While fine needle aspiration cytology is frequently done in thyroid nodule, it has not been evaluated for thyroglossal cyst.
Surgical Treatment

Complete excision of the cyst and the sinus tract is the treatment of choice (Fig. 106.10). Sistrunk first described the classical procedure of excision of the tract along with a core of tissue around it and central portion of the body of the hyoid bone. Recurrence rate of 5 to 7% have been reported but the rate is high if the adjacent hyoid is not excised.

Ethanol Injection Sclerotherapy for Thyroglossal Cyst

There are reports of treating thyroglossal cyst with ethanol injection sclerotherapy. Injection is given under sonographic guidance. Following selection criteria are met before injection:
1. Cytologic studies show that the lesion is benign.
2. Cystographic studies indicate that there is no extravasation.
3. A monocystic lesion is present.

The result is reported to be satisfactory.

Dermoid Cyst

Dermoid cyst result due to entrapment of epithelium during the closure of branchial arches. Most common differential diagnosis is the thyroglossal cyst and the correct diagnosis is made during surgery. Dermoid cyst contains hair follicles, sebaceous glands, connective tissue and other epidermal appendages.

Cervical Thymic Cyst

Thymic swelling may present as lump and pain in the neck. Nests of thymic tissue may be found along the descent of the thymic primordia from the angle of the mandible to the mediastinum. Mediastinal extension is seen in 50% of cervical thymic cysts.

Ultrasound and CT scan are both helpful investigations for diagnosis and planning for surgical management. Surgical excision is the treatment of choice.

Ranula

The word Ranula means Frog’s belly (Ranula is very soft and bluish in color simulating frog’s belly. The word Rana means frog).

Ranula is a retention cyst arises due to partial obstruction of the sublingual salivary gland. The cyst is lined by columnar or cuboidal epithelium and contain mucoid fluid. The patient presents with a cystic swelling on the undersurface of the tongue (Fig. 106.11). It is bluish in color due to the presence of sublingual veins. Fluctuation is positive and the cyst is brilliantly transilluminant. When localized inside the
oral cavity, it is termed as simple ranula. When the ranula extends into the neck from the oral cavity along the posterior border of Mylohyoid, it is called a plunging or complex ranula. This lesion lacks a true epithelial lining.\textsuperscript{47} Marsupialization of the cyst is the most common performed for ranula.\textsuperscript{48} Plunging ranula may be excised either orally or combined intraoral and cervical approach.\textsuperscript{48} Excision of the cyst along with the ipsilateral sublingual salivary gland has been shown to decrease the rate of recurrence.

REFERENCES

Torticollis is a Latin word. Torti, meaning twisted, and Collis, meaning neck. Torticollis refers to twisted position of neck. Congenital torticollis is the most common cause of torticollis. Incidence is about 0.4% of all births.\(^1\)\(^2\) Right side is affected more commonly than the left side (60%).\(^3\) Two to eight percent of cases have bilateral involvement.\(^1\)\(^2\)\(^4\)

**ETIOLOGY**

Torticollis is broadly divided into two types, congenital and acquired (Table 107.1). Congenital or idiopathic spasmodic torticollis is the most common cause of torticollis. It is due to the tightness or shortening of sternomastoid muscle on one side. The etiology of acquired torticollis is varied. It includes cervical hemivertebrae, strabismus, retropharyngeal abscess, posterior fossa tumor, and severe gastroesopharyngeal reflux (Sandifer’s syndrome). Acquired torticollis may also occur due to acute atlantoaxial subluxation of the joint during tonsillectomy.

There are various theories to explain the etiology of congenital torticollis.

1. **Intrauterine embryopathy**\(^5\)
2. **Intrauterine compression**—according to this theory intrauterine compression of neck leads to sternomastoid fibrosis.\(^6\)\(^-\)\(^8\)
3. **Traumatic delivery**—20-30% of patients with torticollis are delivered by breech delivery. According to this theory traumatic delivery leads to muscle injury with hemorrhage and fibrous replacement of the sternomastoid muscle.\(^6\)\(^-\)\(^11\)
4. **Neoplastic**—there is little or no evidence to support this theory.

None of the theory is able to answer all the questions. Presence of mature fibrous tissue in sternomastoid tumor of neonates indicates that the process of fibrous replacement of muscle starts in the intrauterine period only.\(^5\)\(^12\)

**PATHOPHYSIOLOGY**

The common histological finding is the fibrous replacement of the muscle bundles. Endomycial fibrosis with fibrous encasement of individual muscle bundles leads to muscle atrophy.\(^5\) Sernat et al studied biopsy of the sternocleidomastoid muscle in children with idiopathic torticollis.\(^13\) They noted extensive fibrosis and nonspecific myopathic changes, i.e.

cytoarchitectural alteration, necrosis, and focal inflammation, mainly in the sternal head of the muscle. The atrophic changes were noted predominantly in the clavicular head. The ultrastructural studies done by Mickelson et al using electron microscope revealed a marked increase in interstitial collagen deposition. Features of immobilization degeneration were also noted with nearly complete loss of myofibrils. Histology has also demonstrated that the fibrous tissue even at neonatal age is mature. The maturity of fibrous tissue at neonatal age indicates that the process of fibrosis had started during the intrauterine period. Sternomastoid fibrosis may prevent the engagement of head during delivery. Thus the high incidence of breech delivery (~20-30%) may be the result of sternomastoid fibrosis rather than being the cause.

CLINICAL FEATURES

Sternomastoid torticollis may present as sternomastoid tumor in about two-third of cases, other one-third of the patients have fibrosis but no tumor. Typically this mass or misnomerly called as the tumor, is not present at the time of birth, but is noted at 3-6 weeks of age. The tumor is hard and painless. The swelling is located within the substance of the sternomastoid muscle, usually in the middle. Size of the tumor varies from 1-3 cm. In the other group of patients, though, the mass is not palpable but a thickened sternomastoid muscle can be palpated along its whole length.

The infant has the characteristic posture; head is rotated to the opposite side of the tumor and tilted towards the ipsilateral shoulder. Older children compensate the head tilt by elevating the ipsilateral shoulder. This maneuver helps them to keep the eyes horizontal.

On clinical examination restricted movement of neck to the ipsilateral side of the involved muscle can be noted. Infant is made to lie at the edge of couch. Assistant holds the shoulders firmly against the surface. Examiner stands behind the patient and tries to rotate the head on either side. Movement of head on ipsilateral side is restricted due to the fibrotic shortening of muscle. When examining the patient with torticollis, one should always do the complete physical examination including palpation of cervical spine, ophthalmological, and neurological examination.

CLASSIFICATION

There are various classifications based either on clinical findings or on ultrasonographic findings.

Clinically Torticollis can be Classified into Three Types

1. Palpable sternomastoid tumor.
2. Muscular torticollis (thickening and tightness of the sternocleidomastoid muscle).
3. Postural torticollis (torticollis but no tightness or tumor).

Classification On the Basis of Ultrasonography

Hsu TC et al divided congenital torticollis into four types.

Type I. A fibrotic mass in the involved muscle;
Type II. Diffuse fibrosis mixing with normal muscle;
Type III. Diffuse fibrosis without normal muscle in the involved muscle; and
Type IV. A fibrotic cord in the involved muscle.

The patients of type IV are most likely to require surgery.

The severity of the torticollis can be graded according to the degree of deficits in passive rotation of the neck.

INVESTIGATIONS AND DIFFERENTIAL DIAGNOSIS

Most of the times clinical examination is sufficient to make the diagnosis (Figs 107.1A and B). Ultrasonography may not be required for diagnosis but it helps in predicting the likelihood of spontaneous resolution of torticollis. The qualitative and quantitative changes in the ultrasound image of sternocleidomastoid have been found to correlate significantly with the severity of rotational deficits of the neck. Ultrasonographic imaging can be used for monitoring the progress of torticollis longitudinally.

Magnetic resonance imaging and computed tomography can also give the similar information but rarely required.

Cervical hemivertebrae can also cause torticollis. Cervical spine abnormality can be detected by inspection or palpation. Plain radiographs of neck (antero-posterior and lateral) can confirm the diagnosis.
Posterior fossa tumor can cause frozen neck with torticollis. Even the passive straightening of neck is not possible. Patient may have features of lower cranial nerve palsy. Computed tomography or magnetic resonance imaging of brain is required. A patient with imbalance of ocular muscles can also present with torticollis. On passive straightening of neck, strabismus gets manifested.

Severe gastroesophageal reflux can cause spasmodic torticollis (Sandifer’s syndrome). Excessive regurgitation of feeds, recurrent episodes of respiratory tract infection, failure to thrive, and supra-esophageal symptoms, i.e. asthmatic features may be present. Barium swallow, radionuclide study and a 24 hour pH monitoring would help in confirming the diagnosis.

Retropharyngeal abscess can also cause head tilt. Patient has fever, difficulty in swallowing and respiration. Lateral radiograph of neck can show soft tissue shadow.

Atlantoaxial subluxation and postural torticollis are the other differentials.

**NATURAL HISTORY AND SECONDARY EFFECTS**

Spontaneous resolution with or without manual stretching has been reported in up to 90% of cases. Various factors have been proposed to affect the rate of resolution of torticollis. These factors include the clinical type, passive rotation deficit of the neck, side of involvement, difficulties with the birth and age at presentation.

Persistent torticollis can cause secondary effects like plagiocephaly, facial hypoplasia, and scoliosis. Small infants have soft head. Due to the fixed position of head, a flattening of the ipsilateral occiput and the contralateral forehead, occurs. As the torticollis resolves or child adopts sitting position, plagiocephaly also has tendency to resolve. It may persist in few patients.

Flattening of the ipsilateral face occurs due to prolonged immobilization of face by fibrotic sternomastoid. The degree of hemihypoplasia can be determined by the angle between the plane of eyes and the plane of the mouth. Facial hemihypoplasia is reversible if surgical correction of torticollis is done early. The severity of the abnormality can also be recorded by measuring the distance between the outer angle of eye and the ipsilateral angle of mouth and comparing the same with the opposite side.

Older children compensate the persistent torticollis by elevating the ipsilateral shoulder. This maneuver helps them to keep the eyes aligned. Compensatory cervical and thoracic scoliosis can also occur.

**TREATMENT**

As majority of patients show spontaneous resolution conservative management is employed initially.
Whether physiotherapy expedites the resolution or not is controversial. If the baby presents within the first few weeks after birth, a regular massage with a baby oil is advised and may be helpful in making the fibrosis soft. The torticollis may resolve completely within few months, provided the therapy has been instituted early and effectively. The massage should be done regularly at least twice a day for about 5-10 minutes each time over the weeks. This may not be effective if the baby is already more than 3 months of age more, possibly by then the fibrosis has already been established.

In older infants, a physiotherapy schedule may be started. Even if it does not help in resolution it definitely make the parents feel that something is being done for their infant. Parents are explained and advised to do regular neck exercises. The infant is made to lie with the shoulders brought out at the edge of couch. One person holds the shoulders firmly against the surface. Other person stands behind the patient and try to rotate the head on either side. This gentle maneuver is done twice a day. Parents may be asked to keep the toys on the ipsilateral side to encourage the infant to rotate his neck to the affected side. Though the usefulness of physiotherapy is questionable but it is safe. It also allays unnecessary parental anxiety by keeping them involved. Some surgeons prefer to give a trial of botox injection in recalcitrant torticollis before resorting to surgery. Botox injection may be helpful in tight but non-fibrotic sternocleidomastoid muscle.

Operative Treatment

The aim of surgery is not only to correct and even the deformity but also to prevent the serious irreversible complications of torticollis, specially the facial deformities.

**Indications**

1. Persistent torticollis beyond 12-15 months of age
2. Persistent torticollis with progressive secondary effects, i.e. facial hemihypoplasia, scoliosis.

Operative Technique

The procedure is performed under general anesthesia. Child is placed supine with a folded towel under shoulders and head rotated to the other side so as to keep the ipsilateral side of neck up. A transverse incision is made about 1 cm above the sternal and clavicular heads of the sternomastoid muscle or over the most fibrotic part of the muscle. The platysma is divided along the skin incision. Muscle is mobilized all around to avoid any inadvertent injury to the underlying major vessels and other structures. The muscle is best divided at its lower end. Although division at upper end, mid-portion, or at both ends have been described. Both the heads of the muscle are divided using diathermy. Use of diathermy and careful ligation and division of larger superficial veins should be done to avoid any hematoma formation. Deep cervical fascia of neck, anterior and posterior to the sternomastoid muscle, is also divided to obtain optimal result. The neck is over stretched and a careful inspection and palpation of the neck is performed for any residual tightness. If required, division of the deeper structures is also done but with great care. Any injury to the internal jugular vein, external jugular vein, the carotid artery, accessory nerve, or the fibers of the cervical plexus, which may also be involved in the process of fibrosis, must be avoided. With the successful release, the two ends of the muscle go apart for a variable distance. The ends of the sternomastoid muscle are not sutured. Hemostasis is ensured and wound is closed in layers. Endoscopic tenotomy of muscle also has been described.

Histological investigations have shown that there is a transition zone from fibrous tissue to normal muscle. It has been recommended to excise a margin of 1-2 mm on each side of fibrous tissue to avoid recurrence (Lehmann recommendations).
POSTOPERATIVE CARE

The procedure can be performed as a day-care surgery. There is no need for any postoperative restriction of neck movement. The success of surgery depends on the preoperative preparation of patients and the parents with the commitment to learn and practice physiotherapy. Physiotherapy is started in the postoperative period as soon as the patient is pain free.33 Full range of neck movement can usually be achieved within one week of surgery. Facial hemihypoplasia and plagiocephaly has the tendency to resolve slowly once the torticollis has resolved.45

COMPLICATIONS

1. Injury to the internal, external jugular vein, carotid artery, accessory nerve, fibers of the cervical plexus.
2. Hematoma formation.
3. Recurrence of symptoms specially if the surgery has been done in older children. The reported incidence of recurrence is, however, less than 3%.

In the Author’s experience at the tertiary care level institute, only a few babies would present in the neonatal period, and most of these are with the cervical tumor. A local message is helpful in those newborns who present only with muscle fibrosis and without the tumor. Majority of these would present during and after infancy, with established torticollis and deformity of the face. The vertebral anomalies are found only occasionally. The post surgical results, combined with pre and postoperative physiotherapy are gratifying.

SECTION

9

Pediatric Surgical Specialties
There are certain milestones in ocular development during neonatal life, infancy, and at least up to 5 years of age, which are important to appreciate, even though visual acuity assessment may be fraught with difficulties.

Generally speaking, all ocular disorders would present to the pediatrician with one or more of the following: history of injury, pain, red eye, watering swelling, a squint or diminution of vision.

Before actually seeing the eye, it is important to have a proper history (such as the exact nature of the injury) as accurate an assessment of the vision as possible (careful observation for both eyes separately, with a proper Snellen's chart in the older and co-operative child), and a quick examination of the adnexal structures. Noting such details would be of great help in the initial diagnosis and treatment, and their first hand recording would afford a lot of useful and reliable information to the ophthalmologist, if the patient has to be referred later.

Examination of an eye after injury should be undertaken with great caution, especially after a suspected perforating injury. Forcible examination is dangerous, as the eye may suffer further damage, and the intraocular contents may be lost. The lids may be gently retracted and held against the bony orbital margins, which sometimes may require sedation or a general anesthetia.

Ocular examination of pediatric age group is actually a challenge to the clinicians, which requires expertisation. To effectively handle common ocular problems, the pediatrician must have some basic ophthalmic equipment (good torch with focal illumination, cotton swab-sticks, eye pads and dressings, and preferably a magnifying device such as a loupe, and an ophthalmoscope). Common drugs must be available, as topical anesthetic agents (2 and 4% xylocaine), antibiotic drops and ointments, mydriatics (phenylephrine drops 2.5 and 5%), and fluorescein paper strips (fluorescein solutions are often contaminated by Pseudomonas). Cycloplegics are not necessary normally to dilate the pupils for a good fundus examination, and drugs like topical atropine, which viciate the pupillary findings, should preferably be avoided unless the ocular condition demands it. Tropicamide 0.5 and 1 percent may be useful.

CONGENITAL ANOMALIES

As for congenital abnormalities anywhere in the body several teratogenic factors have been implicated congenital anomalies of the eye, operating pre or perinatally. These teratogens include physically chemical, mechanical, drugs and poisons (including vasoconstrictors), inflammations and fevers and the (noxious) treatments thereof, malnutrition, and of course irradiation. Any such factor operating very early in intrauterine life in the first 6-8 weeks may produce organogenetic deformities as anophthalmos, microphthalmos, congenital cystic eye, and even cyclopia. These deformities often present with other ocular and systemic associations. Several lesser anomalies of differentiation may be the result of noxious influences later on in intrauterine development.

Congenital Cataract

Congenital cataract (Fig. 108.1) is associated with intrauterine infections (rubella, toxoplasmosis), antenatal malnutrition (zonular cataract), metabolic disease
(galactosemia, hypopcalcemia), chromosomal anomalies (down syndrome), ocular malformations (microcornea, nystagmus, megalocornea, keratoconus, pigmentary retinitis), mental retardation and various cutaneous, neurological, musculoskeletal and endocrine disorders (diabetes mellitus, hyperparathyroidism). Cataract may develop secondary to eye disease such as trauma, retrolental fibroplasias, uveitis and glaucoma. Marfan’s syndrome and homocystinuria may be typically associated with ectopia lentis. Cataracts in children may be hereditary and familial, and require early referral for proper management and visual rehabilitation.

The management of congenital cataract is a semi-emergency because during infancy not only does the cataract blur the retinal image but it also disrupts the development of the visual pathways in the control nervous system. In addition to a complete ophthalmic examination, A and B scan ultrasonography should be performed to record the axial length and assess the posterior segment. Visual acuity should always be recorded. Indication for surgery for congenital cataract is lenticular opacity > +2.5 mm or visual acuity of + ≤ 6/18. Unilateral cataracts should be operated as early as the child becomes medically fit with minimal risk of anesthesia, but must be operated before 3 months of age to prevent amblyopia. In bilateral cataracts, both the eyes must be operated and the optical corrections should be given. Intraocular lens, can be implanted if the child is 2-3 years of age.

Antiamblyopia therapy should be given and continued till both eyes have got an equal vision and preferably up to the age of 7 years.

Acute Glaucoma

Acute glaucoma as typically described in adults, is usually not seen in children. Up to 3 years of age, congenital (or secondary) glaucoma manifests by progressive enlargement of the globe (buphthalmos), hazy cornea, watering, photophobia, and poor vision (Fig. 108.2). After 3 years of age, the eye loses its stretchability, and glaucoma does not manifest with buphthalmos. A suspicion of glaucoma definitely warrants an immediate referral. Intraocular inflammation, metabolic disorders like homocystinuria and tumors like retinoblastoma, may manifest as secondary glaucoma.1

Congenital Ptosis

Classification

- Simple
- Associated with superior rectus underaction
- Associated with blepharophimosis syndrome
- Associated with synkinesis
- Marcus Gunn phenomena
- Misdirected third nerve

Assessment

1. Good Bell’s phenomena and normal corneal sensation are absolute prerequisites for proceeding to ptosis surgery.
2. If the above is intact then we proceed to:
   i. Assessment of visual acuity
   ii. Correction of amblyopia
   iii. Correction of strabismus
   iv. Correction of other lid abnormalities (coloboma, ankyloblepharon).

3. If Bell's phenomena and corneal sensations are not normal then crutch glasses with appropriate refractive correction and amblyopia treatment if required is instituted.

4. Assessment of ptosis
   I. Measurement of palpebral aperture
      a. The upper lid covers 2 mm of the superior cornea
      b. Beyond 2 mm, a droop of ≤ 2 mm comprises mild ptosis
      c. A droop of 3 mm comprises moderate ptosis
      d. A droop of ≥ 4 mm comprises severe ptosis.
   II. In cases of bilateral ptosis, the final position of the lid at surgery is kept such that it covers 2 mm of the superior cornea bilaterally.
   III. In cases of unilateral ptosis the droop in the ptotic eye is aligned according to the position of the lid in the fellow normal eye.
   IV. Absence of lid crease or a furrow in the infra brow area indicates poor levator action.
   V. Any significant head tilt/torticollis has to be assessed.
   VI. In cases of unilateral ptosis, retraction in the fellow eye has to be assessed.

5. Assessment of LPS action:
   - Normal – 12-15 mm
   - Good – ≥ 8 mm
   - Fair – 5-7 mm
   - Poor – ≤ 4 mm
   The LPS action is always measured after occluding the action of frontalis muscle after asking the patient to gradually look upwards from downgaze to upgaze. In a patient not cooperative for assessment of the LPS action, we perform the lliff's test, i.e. we evert the upper lid of the child. A spontaneous reinversion of the lid indicates fair to good LPS action and hence levator resection can be performed.

6. Presence of synkinesis
   i. Marcus Gunn – Mild ≤ 2 mm phenomena
      Moderate 3 mm
      Severe ≥ 4 mm

   ii. Misdirected third nerve

7. Drug test
   i. Pheny- lepherine test – Assessment of hypotropia/Ocular motility disorder/abnormal lid movements, etc.
   ii. Tensilon test – This is to determine preoperatively the effectivity of the Fasanella Servat procedure. If it is positive, then the surgeon can proceed with the tarsoconjunctivomullerectomy.

   This is to rule out myasthenia gravis which is an important cause of acquired ptosis.

Acquired Ptosis
- Neurogenic (Third nerve palsy, Horner's syndrome)
- Myogenic (Myotonic dystrophy, myasthenia gravis)
- Aponeurotic/Senile
- Traumatic.

In cases of acquired ptosis, the assessment of the ptosis and levator action would be similar to that done for congential ptosis. In addition, other associated examination would include:
- Assessment of higher mental function and a complete CNS examination (Third nerve palsy/Horner's syndrome).
- Examination of the pupil (Third nerve palsy/Horner's syndrome/traumatic).
- Examination of the ocular motility and strabismus (Third nerve palsy/Horner's syndrome ophthalmoplegias/myasthenia).
- A high lid crease indicates levator disinsertion (Aponeurotic/traumatic).
- Assessment of the orbital rim surrounding the lid (Traumatic).
- The tensilon test is an absolute must in every case of acquired ptosis.
- Clinical test rule out myasthenia gravis in the form of the lid hopping signs, cogan's lid twitch signs can be undertaken.
• Other tests in the diagnostic armamentarium of myasthenia gravis in the form of repetitive nerve stimulation test, and electromyography can be performed. EMG can also be used to diagnose ocular myopathies.

Surgical treatment of acquired ptosis is undertaken only if the ptosis is stable for 6 months or more. The type and extent of surgery almost commensurates with the extent of surgery done in cases of congenital ptosis. In acquired ptosis, generally the accepted end point of the correction is mild under correction.

Pseudoptosis
• Associated with Anophthalmos/Microphthalmos /Phthisis
• Associated with hypotropia
• Associated with dermatochalasis.

Treatment of pseudoptosis aims towards the treatment of the primary cause of the condition.

The assessment of ptosis is thus aptly elucidated by the following acronym.

D – Drop
E – Excursion (LPS action)
S – Superior rectus function (Strabismus)
T – Tensilon tests (Other drug test)
I – Iliff’s Sign (LPS action)
N – Nerves (Corneal sensation, Bell’s phenomena)
Y – Yawn (Synkinesis)

– Lid crease / Fold
– Brow position.

Surgical Management of Ptosis
• Age at which ptosis surgery is performed is usually at about 3 years of age when proper assessment of visual acuity, strabismus, ptosis, levator action, other lid abnormalities and Bell’s phenomena can be performed correctly. Surgery is indicted in the pre-school age so as to obviate any psychological trauma that the child may suffer after he begins social interaction at school.

• Surgery is indicated prior to this if there is significant sensory deprivation amblyopia present due to the ptosis and significant torticollis present.

• An infant whose pupils are completely occluded by the lid (No reflects seen on distant direct ophthalmoscopy) would require immediate ptosis surgery.

• Assess for the skin fold in the lid as this is an indicator for fair to good levator action and hence LPS resection can be performed. In case of marked frontalis overaction and a chin elevated head posture, a frontalis sling surgery is indicated.

Surgical Protocol

Mild Ptosis (Unilateral/Bilateral)

i. Good LPS action
   a. Positive phenylephrine test
      - Fasanella servat’s procedure
   b. Negative phenylephrine test
      - Fasanella Servat’s Procedure
      - LPS resection (11-14 mm)

ii. Fair LPS action
    - LPS resection (14-17 mm)

iii. Poor LPS action
    - Hypothetical situation. If present, supra-maximal LPS resection (< 23 mm) can be attempted.

Moderate Ptosis (Unilateral/Bilateral)

i. Good LPS action
   – LPS resection (14-22 mm)

ii. Fair LPS action
   – LPS resection (14-22 mm)

iii. Poor LPS action
   – Frontalis sling surgery
   – Supramaximal LPS resection (< 23 mm).

Severe Ptosis

i. Bilateral
   a. Good/Fair LPS action
      – LPS resection (23 mm)
   b. Poor LPS action
      – Frontalis sling surgery

ii. Unilateral
   a. Good/Fair LPS action
      – LPS resection (< 23 mm)
   b. Poor LPS action
      – Levator excision of normal eye with bilateral sling surgery (Beard’s method)
      – Bilateral sling surgery without excision of the levator of the normal eye (Callahan’s method).
Marcus Gunn Phenomena

It is usually, commonly seen in the left eye. It is associated with superior rectus underaction in 75% cases.

i. Mild
   - Mild MG phenomena does not affect the surgical management of the patient which is planned according to the protocol mentioned above.

ii. Moderate/Severe
   - Levator excision and bilateral sling surgery.

Indications for Sling Surgery

i. Severe/Moderate ptosis with poor LPS action
ii. Moderate/Severe Marcus Gunn phenomena
iii. Blepharophimosis syndrome (Fig. 108.3)
iv. Failed LPs resection/Other ptosis procedure
v. Misdirected third nerve phenomena
vi. Total third nerve palsy

Indications for Fasanella Servat Surgery

i. Mild congenital ptosis with good LPS action
ii. Ptosis in Horner’s syndrome
iii. Postcataract surgery blepharoptosis
iv. Steroid induced ptosis

How much Levator to Resect?

There is no exact rule. However, for the sake of some guidelines, the following protocol may be followed (Fox).

i. If levator action is 2 mm or less, no levator resection is performed.
ii. If levator action is less than 5 mm, over correct 2-3 mm, i.e. at least 20 mm
iii. If the levator action is 6-9 mm, correct full, i.e. up to 16 mm of the levator is resected, more if the levator is of poor quality.
iv. If the levator action is 10-12 mm, the ptosis is under corrected. No more than 8-11 mm is resected. The horns are not cut.

Strabismus (Squint)

Early detection and treatment of squint is very important since significant improvement in the vision of the deviated eye and good binocular vision cannot be achieved if proper therapy is not undertaken as early as possible and not later than 5 years of age. Some degree of occasional squint may be normal in the first few months of infancy, since binocular vision is not well developed. If squint persists beyond 2 to 3 months of age, an ophthalmologist should be consulted. A false impression of convergent squint (pseudostrabismus) may be given by epicanthal folds with a wide bridge of nose.

Concomitant squint accounts for most cases. There is no muscle paralysis but the muscles fail to act in coordination. The degree of deviation is the same irrespective of the direction of gaze. In noncomitant (paralytic) squint resulting from ocular muscles paralysis, the eyes deviate most on turning in the direction of the paralyzed muscle. Diplopia may develop and to avoid it, the child learns to suppress the vision in the affected eye. Abnormal head posture may also develop.

The treatment of concomitant squint consists of cycloplegic refraction and corrective lenses, drugs such as cycloplegics or miotics, patching of the normal eye for determined periods to prevent image suppression and amblyopia in the deviating eye, orthoptic exercises and surgery, singly or in combination. Timely referral is vital—children do not "grow out" of squint.
Involuntary ocular rhythmic movements (nystagmus) should also be referred early for complete investigations.

**PHYSICAL AND CHEMICAL TRAUMA**

**Foreign Body**

A conjunctival foreign body should be located and easily removed. It is not quite so easy when the foreign body is lodged in the upper tarsal conjunctiva in the subtarsal sulcus, as this requires the eversion of the upper lid.

A corneal foreign body should be gently removed with wet swab or spud. If find difficulty, apply antibiotic ointment and refer promptly.

A suspected intraocular foreign body should be immediately referred for investigations and urgent management to the eye casualty (Fig. 108.4).

**Chemical Injuries**

Chemical injury to the external eye is one of the common problems presenting to the eye casualty that may vary in severity from mild irritation to complete destruction of the ocular surface epithelium, corneal opacification, loss of vision, and rarely loss of the eye (Fig. 108.5). Most of the victims are young patients and children who become exposed to chemicals during industrial accidents, at home, and in association with criminal assaults. The offending chemical may be in the form of a solid, liquid, powder, mist or vapor. At the home, most injuries result from detergents, disinfectants, solvents, cosmetics, drain cleaners, ammonia, bleach and other common household alkaline agents. Because their more frequent presence in household cleaning agents and in many building materials, alkali injuries occur more frequently than acid injuries. Some of the worst chemical injuries result when strong alkalis (lye) or acids are used as assaultive weapons.

Alkalies increase the pH of tissues, which causes saponification of fatty acids in cell membranes and ultimately cellular disruption. Acids cause coagulative necrosis of the tissue proteins on contact. This denatured and precipitated tissue protein forms a barrier for the chemical (acid) and prevents its further penetration into deeper tissues thereby decreasing damage vis a vis alkalis. This is the reason how acidic solutions tend to cause less severe damage than alkaline solutions.

The most important step to deal with such situation is to give immediate and copious irrigation to the ocular surface, for at least 30 minutes, preferably with normal saline or Ringer's lactate solution. However, if both (Saline and Ringer lactate solution) are not available at the moment, simple tap water can be used. A topical anesthetic (4% xylocaine) may be instilled into the eye prior to the irrigation, which may help in putting eyelid speculum or retractor. Double eversion of the eyelid can visualize the foreign bodies in the fornices, and make their removal easy. Irrigation should be continued until the pH of the conjunctival sac normalizes, that may be checked easily with a pH strip (Litmus paper). After emergency treatment patient should be evaluated thoroughly. The next
phase of therapy for the chemical injury should be directed towards decreasing inflammation, controlling intraocular pressure (IOP), limiting sterile keratolysis and promoting recpithelialization.

**Thermal Burns**

Thermal burns should be treated on conservative lines and efforts should be made to protect the cornea. Explosive injuries by fireworks, crackers and bombs may cause serious damage to the eyes. Ocular fireworks injuries are much more severe and dangerous in children than adults.

**Blunt Injury**

A ball, stone, fist, stick, slingshot, gullidanda, fireworks, etc can cause blunt ocular trauma. Blunt injuries are potentially very dangerous. If the child has significant hyphema, he or she should be administered hypotensive agents as glycerol, diamox (acetazolamide) or intravenous mannitol to reduce the chances of rise of intraocular pressure and corneal blood-staining (Fig. 108.6). Mobilization is avoided to prevent the occurrence of rebleed in the eye. The visual prognosis is guarded, as many more complications may or will take place. Referral without delay is advocated after primary treatment.

**Penetrating Injury**

Penetrating eye injury is a major cause of ocular morbidity and leading cause of monocular visual loss. It is one of the most important surgical ocular emergencies in children and demands urgent treatment (Fig. 108.7). Bandage the eye and refer immediately for proper examination and repair under general anesthesia, with the operating microscope. From management point of view, penetrating trauma can be divided into anterior and posterior ocular trauma. Though a general ophthalmic surgeon can repair most of the anterior segment trauma, it is important that posterior segment trauma cases should be urgently referred to the vitreoretinal surgeon. An extensive injury may sometimes necessitate excision of the globe. The possibility and dangers of sympathetic ophthalmia should always be borne in mind. Lid lacerations also require prompt repair, and canalicular injuries have to be adequately managed.

**Corneal Abrasion**

Corneal abrasion can be very painful with marked photophobia. Trivial injuries may abrade the corneal epithelium as with edges of paper, leaves, twigs, toys and fingernail scratches, etc., and the area of epithelial denudation can be easily demonstrated by fluorescein staining. The treatment is almost the same as for an ulcer, except that atropine is not routinely indicated, and a 24-hour firm pad and bandage is very beneficial in promoting epithelial healing. Analgesics are useful, but topical anesthetics should be used minimally or not at all in view of their epitheliotoxic properties.
Subconjunctival Hemorrhage

Subconjunctival hemorrhage is another common alarming sign for the patient and the parents (Fig. 108.8). The cause should be elicited, as severe coughing (whooping cough), straining, minor local trauma, hemorrhagic conjunctivitis and rarely vitamin C deficiency. More serious entities such as head injury, fractures, and deeper trauma must be kept in mind. Rarely, a small subconjunctival hemorrhage may be overlying a small scleral intraocular perforation, which may be an intraocular foreign body. Small tears of the conjunctiva may result from injury.

Red Eye

A red eye is by and large the most common ocular problem to be seen, and a differential diagnosis has been made between the not so serious conjunctivitis and the more grave conditions of corneal ulcer, iridocyclitis and glaucoma (Table 108.1). However, acute glaucoma as typically described in adults is not usually seen in children.4

Corneal Ulcer

Corneal ulcer is defined as breach in corneal epithelium along with the underlying infiltration.5 It is one of the most significant causes of ocular morbidity around the world (Fig. 108.9). Corneal ulcer presents with a typical corneal picture ciliary congestion, and may be iridocyclitis. It demands immediate attention. Swabs should be sent for culture and sensitivity (preferably from ulcer edge scrapings). Local hygiene should be maintained and start on topical antibiotics (systemic coverage also if required) and topical atropine, application of heat, systemic supportive therapy and if necessary, ocular hypotensive agents as acetazolamide to prevent impending perforation. Steroids should by and large be avoided. Children should be discouraged from touching the eye, if necessary, mechanical restraint, as by a hollow cardboard cylinder over the elbows, may have to be resorted to.

A history of trauma or a corneal foreign body may be evident. Injury with vegetable matter may lead to a fungal corneal ulcer, more recalcitrant to therapy and requiring specific antifungal measures.
A herpetic corneal ulcer may exhibit a typical dendritic figure on fluorescein staining, and may be associated with herpes simplex lesions elsewhere as on the lips, nose and genitalia (Fig. 108.10). Recurrences may be associated with lowering of body resistance. Antiviral therapy topically is indicated to start with. The corneal sensations diminish in this condition, as they also do in keratomalacia.

If the Bowman’s membrane is damaged in a corneal ulcer a corneal opacity will result on healing. Early institution of therapy would restrict the opacity to a minimum, and reduce the chances of corneal blindness. Nonhealing or progression of the ulcer, or the appearance of a hypopyon merits urgent referral.

Early xerophthalmia should be talked most energetically before full-blown keratomalacia develops with irreparable loss of vision.

NEOPLASTIC DISORDERS

Retinoblastoma

A typical “Cat’s eye” reflex or leucocoria is a well-known feature of retinoblastoma (Fig. 108.11). However, many other congenital and acquired conditions may produce an identical pupillary reflex such as retinal dysplasia, retinal vascular folds, persistent hyperplastic primary vitreous (PHPV), retinal detachment, retained intraocular foreign body, endophthalmitis, cataract, uveitis, Coats’ disease, and retrolental fibroplasias (RLF) or retinopathy of prematurity (ROP). Retinoblastoma is usually associated with neovascularization, high intraocular tension features of bilateral involvement, optic nerve extension with distant metastases, and hereditary predisposition. Besides the pathognomic yellowish white reflex, retinoblastoma may present with a squint, red eye pain and secondary glaucoma. These children should be immediately referred for further investigations and management, because delay may adversely affect survival. In spite of various imaging modalities, the differential diagnosis during the early stage may be difficult, and the exact diagnosis may be possible only after histopathological examination of the enucleate eye. Earlier radical treatment modalities, as enucleation are giving way to eye salvaging procedures of cryotherapy, chemoreduction and lens-sparing techniques of modern radiotherapy.

Retinoblastoma (RB), as we all know, is one of the commonest intraocular malignancies in children. Though this is not a common condition, it is one of the few life-threatening conditions that present to an ophthalmologist. A timely diagnosis could thus save the life of the child. Now, with the advent of newer therapeutic modalities like laser, chemotherapy and radiotherapy, an early diagnosis and the use of combination therapy can result in preservation of vision thus avoiding enucleation. The goal of RB therapy now is to save the life and preserve the vision.

How not to miss the diagnosis of Retinoblastoma?

The commonest presentation of retinoblastoma is leucocoria in a child aged 1-5 years. In a typical case it may not be so difficult to make the diagnosis.
However, given the grave consequences of a missed or delayed diagnosis, it is prudent for us ophthalmologists to maintain a high index of suspicion so as to pick up all the cases at the earliest. The clinical features together with the investigations can correctly establish the diagnosis in most cases.

**Age:** Though RB commonly presents between 18-24 months, in our country we often find children presenting at a later age. A word of caution: RB can present in neonates and also in older children (7-8 years) so one should be careful to rule it out in all cases of leucocoria.

**Family history and genetics:** RB is said to be familial in 25-30% but in Indian conditions we are not always able to elicit a positive family history. One should look for regressed lesions in the parents of bilateral cases and ask for a history of deaths in early childhood in the family. Also, screening of siblings (aged less than 5 years) of all cases should be done, whether unilateral or bilateral. Though the genetic abnormality is identifiable in some cases, chromosomal analysis may not be practical in our scenario since it is expensive and the results take a long-time.

**Leucocoria:** Leucocoria, unilateral or bilateral, is by far the commonest presentation of RB. There may be overlying engorged vessels or calcification visible. There is a long list of differential diagnosis of leucocoria usually clubbed a ‘pseudoglioma’. The ones likely to cause a diagnostic dilemma are PHPV, organized vitreous hemorrhage, endophthalmitis and Coat’s disease in older children. The associated anterior segment findings may help, in the form of microcornea in PHPV and a low tension in endophthalmitis. Raised IOP, ektropion uveae, rubeosis and pseudohypopyon are all pointers to a tumor in the eye.

**Squint:** Any squint in a child warrants a fundus examination with dilated pupils. A macular tumor causing the squint can be picked up even with a cursory indirect ophthalmoscopic examination so there is no excuse for telling the parents to bring the child back for squint surgery later, without seeing the fundus.

**Secondary glaucoma:** If the parents miss the initial leukokoria, RB can present as secondary glaucoma with an opaque cornea. Therefore, one should rule out a tumor in these cases by examining the other eye and doing an ultrasound, if possible.

**Pseudohypopyon and endophthalmitis:** Though infections are rare in RB, it can present as pseudohypopyon in an inflamed eye and/or masquerading as endophthalmitis. One needs a high index of suspicion in these cases especially if seen in older children.

**Proptosis:** Unfortunately in India, there are still a large number of children presenting with proptosis. A history of leucocoria may sometimes be forthcoming. Though orbital cellulitis is still the commonest cause of proptosis in children, tumors like orbital RB and rhabdomyosarcoma should be kept in mind.

### How to Investigate a Case of Suspected Retinoblastoma?

Investigations in RB are aimed at confirming the diagnosis and establishing extent of disease both for the prognosis and therapy decisions.

**Ultrasonography:** USG is an important tool in establishing the diagnosis of RB. RB is usually seen as a mass lesion of moderate–high internal reflectivity, arising from the retina. There may be an overlying detachment visible. Calcification, characterized by spikes of 100% reflectivity, is seen in 90% cases and is diagnostic of RB. Optic nerve involvement and scleral infiltration may also be picked up. USG monitoring of tumor height is important when the patient is on chemoreduction.

**CT Scan:** On CT scan, RB is seen as a moderately attenuating mass lesion with calcification. Extraocular spread in the from of optic nerve or scleral infiltration and/or intracranial extension is well demonstrated. CT scan is required for radiotherapy planning as well. **MRI:** MRI is not as useful in the diagnosis of RB except in cases where vitreous hemorrhage/exudative retinal detachment is suspected. Though calcification is not so well demonstrated, the soft tissue visualization is better especially in case of chiasmal involvement.

### Special Investigations

In most cases the diagnosis can be clinched with the above-mentioned clinical features and investigations. In certain cases where the diagnosis is difficult, like leucocoria without calcification, non-responsive uveities/vitritis in children older age groups, etc. some special investigations may be indicated like Fine
Needle Aspiration Biopsy (FNAB) done under indirect ophthalmoscopic guidance and with an experienced cytopathologist.

**PROPTOSIS**

Proptosis of the eye may be due to orbital cellulitis, orbital tumor (hemangioma, rhabdomyosarcoma, glioma, leukemic infiltration, extraocular extension or retinoblastoma, neuroblastoma, etc.) orbital hemorrhage, vascular malformations, and other rarer causes (Fig. 108.12).

The exposure of the eye should be prevented by oily drops (suspensions) and ointments, and if necessary, by a tarsorrhaphy, to prevent the avoidable and tragic complication of exposure keratitis and severe corneal ulceration with resulting blindness.

The above principle of corneal protection extremely important, but often forgotten management of a semicomatose or unconscious. The cornea should always be protected by an oily film especially if a pad and bandage has to be applied though a pad is better avoided unless there is actual keratitis.

**INFLAMMATORY DISORDERS**

**Uveitis**

Uveitis is defined as inflammation of the uveal tissue (i.e. iris, ciliary body and choroid), which is the major source of blood supply to the eye. The etiology of uveitis may be infectious, infestations, trauma, neoplastic disorders or inflammatory reactions secondary to immune disorders. It can be classified based on the anatomical location of the disease process in the eye, its mode of onset and the etiology involved (Table 108.2).

Clinical features of uveitis are produced by an inflammatory response to the etiological factor (i.e. infections, trauma, malignancies, autoimmune process, etc). The chemical mediators of the acute stage of inflammation include serotonin, complement and plasmin. Leukotrienes, kinins and prostaglandins modify the second stage of the acute response through antagonism of vasoconstrictors. Polymorphonuclear leukocytes, eosinophils, and mast cells may all

</table>
contribute to signs of inflammation but the lymphocyte is, by far, the predominant inflammatory cell involved in uveitis in the inner eye.

Uveitis usually present with blurred vision, floaters, pain, redness, photophobia and/or lacrimation. Blurred vision may be because of refractive error (e.g. myopic or hyperopic shift due to macular edema, hypotony, or change in lens position), or opacities in the visual axis from inflammatory cells, fibrin or protein in the anterior chamber, keratic precipitates, or secondary cataract. Pain in uveitis results from acute onset of inflammation of the iris, secondary glaucoma or ciliary body spasm.

Photophobia and increased lacrimation present when iris, cornea or irisciliary body complex is involved. However, occasionally uveitis may be discovered on a routine ophthalmoscopic examination in an asymptomatic patient.

The signs of uveitis in the anterior portion of the eye include keratic precipitates (KP) cells, flare, fibrin, hypopyon, pigment dispersion, pupillary miosis, iris nodules and synechial, both anterior and posterior. In the intermediate anatomical area of the eye, there may be vitreal inflammatory cells and vitreal stands.

Signs of the posterior segment (posterior two-thirds) of the eye include retinal or choroidal inflammatory infiltrates, perivascular inflammatory cuffing, retinal pigment epithelial hypertrophy or atrophy, and atrophy or swelling of retina, choroid or optic nerve head. Retinal or choroidal signs may be unifocal, multifocal or diffuse. The uveitis may be diffuse throughout the eye (panuveitis) or appear dispersed with spill over from the area to another (e.g. toxoplasmosis).

The morphological features present in uveitis are of importance in relation to give clues to diagnose the specific cause of uveitis, though; sometimes laboratory evaluation is required for corroboration.

Generally speaking the treatment of uveitis ranges from case to case. Some patients may need simple observation however; others may require medical or surgical intervention. Medical therapy usually includes topical or systemic steroids along with the cycloplegics. In few cases immunosuppressive therapy may also be required. Treatment should be tailored to the individual patient and adjust according to the response. The treating clinician should also keep in mind and consider the patient’s systemic involvement and other factors such as age, immune status, and tolerance for side effects of the drugs.

Surgical therapy for uveitis may include paracentesis or vitreous biopsy for diagnostic evaluations to rule out neoplastic or manage the particular complications of uveitis (e.g., cataract extraction, trabeculectomy or other glaucoma surgery to control the IOP and vitrectomy for dense vitreous membranes). As a general rule, before performing cataract surgery in such cases, the eye should be quiet for at least 3 months.

Treatment modalities for diseases involving the posterior segment of the eye have been limited by the lack of effective delivery of the drug to the affected area. Conventional approaches for treating noninfectious inflammatory diseases affecting the posterior segment are topical steroid administration, peribulbar steroid injections and systemic steroid and cytotoxic agent administration.

Topical medication does not provide high enough concentrations of the drug for it to be effective in treating posterior uveitis. Peribulbar steroid injections have the advantage of minimizing the systemic side effects while maximizing the local effects. Though this method of treatment may be efficacious it requires repeated intervention and is not desirable for long-term therapy. Also, the local toxicity may be increased due to the regional concentration of the drug immediately after administration. Systemic steroid administration requires high doses to be effective in treating posterior segment diseases. More importantly, these concentrations are associated with debilitating systemic side effects. Similarly, systemic toxicities are also dose limiting for cytotoxic agents.

The novel new technique of intravitreal sustained release drug delivery was first devised to treat CMV retinitis in AIDS patients, in the form of a gancyclovir implant. The intravitreal steroid implant for recurrent noninfectious posterior uveitis is based on the same principle. This mode of therapy has the advantage of maintaining therapeutic levels in the target tissue with minimum systemic exposure and consequently minimum systemic toxicity.

The intravitreal steroid implant for uveitis contains the corticosteroid, fluocinolone acetonide. This form of medication was chosen as it could be prepared in a form concentrated enough to fit into the device and provide the duration needed for long-term delivery.
of steroid. The implant has a polymer coating of PVA and silicone designed to release efficacious levels of the drug inside the eye over an extended time period.

Appropriate patient selection is very essential to ensure favorable results. Only those patients with a history of recurrent intermediate or posterior uveitis treated repeatedly with oral or peribulbar steroids should be considered for this mode of treatment. Those patients showing a tendency towards steroid induced glaucoma should be excluded.

The placement of the implant involves a minor surgical procedure. The device is implanted at the pars-plana region after making an appropriate sclerotomy and secured with the help of non-absorbable sutures.

The intravitreal steroid implant could offer an alternative treatment option for diabetic macular edema and age related macular degeneration.

**Orbital Cellulitis**

Orbital cellulitis is defined as infection of the orbit (Fig. 108.13). It is one of the few ophthalmic emergencies, which can have severe systemic implications besides causing loss of vision, if appropriate management is not instituted in the right time.

Orbital cellulitis is more common in children, and more severe in diabetics and immunocompromised patients. Patients typically present with history of unilateral pain, redness and proptosis of recent onset, often in the seasons when allergies are more prevalent. The patient looks obviously sick, and is usually febrile. This is in contrast to, say, rhabdomyosarcoma and retinoblastoma where the general condition is relatively unaffected till later on in the disease. The common causative organisms of cellulitis are *Staph. aureus, Streptococcus, H. influenzae*, anaerobic bacteriae like *Bacteroides*. Fungi and *Mycobacterium tuberculosis* may be the culprits in recalcitrant cases. Mucor is typically found in diabetics. The microbes usually spread to orbit from infected paranasal sinuses, lids and rarely from infected tooth, pyoderma, CNS and penetrating trauma. Diminution of vision in orbital cellulitis is usually due to optic nerve involvement, which reflects poorer prognosis—the other common cause is exposure keratopathy due to proptosis. Both these poles of the eye have to be taken care of adequately and in time.

**Routes of Infection**

1. *Sinus*: Secondary sinusitis is the commonest cause. Ethmoid sinus is the most frequently responsible sinus due to the very thin wall of this sinus.
2. *Trauma*: Post-traumatic orbital cellulitis is seen secondary to an injury that also damages the orbital septum. It is commoner if a foreign body is retained within the orbit.
3. *Surgery*: This is rare but may complicate a retinal or an orbital surgery.
4. It may also be seen as an extension from adjacent structures, e.g. secondary to a panophthalmitis or a dental infection, very rarely due to dacryocystitis.
5. In our country, it is not uncommon to see cases of very advanced retinoblastoma or rhabdomyosarcoma which present with a cellulitis like picture. This is not true cellulitis, but rarely there may be superadded infection.

On local examination, unilateral axial proptosis is seen which is later noncompressible. The lids are tense and inflamed; conjunctiva is diffusely congested. An equal decrease in ocular movement in all directions is a reliable sign to exclude the possibility of only a preseptal cellulitis where ocular movements are usually preserved; here also, a reactionary postseptal (orbital) edema induced through the still intact septum could also produce features overlapping an actual
orbital cellulitis—the reverse is also true. Examination of the disks and both pupils, although often difficult because of tense lid edema and irritable state, can throw light on optic nerve involvement. Checking the sensation of the skin distributed by ophthalmic division V(1) of trigeminal nerve is essential as it is affected in superior orbital fissure syndrome (paralysis of III, IV, V(1) and VI cranial nerves + dilated pupils + proptosis + ptosis). Associated diminution of vision may indicate optic nerve involvement (Orbital Apex Syndrome). Paralysis of VI cranial nerve and congestion of conjunctival and retinal vessels of the other eye are the early signs of cavernous sinus thrombosis, a dreaded complication of orbital cellulitis. ENT, CNS and evaluation of other systems should be done to find the focus of infection.

The patient has to be promptly admitted for further management. Pain relief should be the first consideration. Orbital ultrasonography can provide valuable information regarding pus pockets, etc. CT scan of orbit, head and paranasal sinuses confirms the diagnosis, and aids in deciding further management and also prognosticating. Hemogram, TLC, DLC, baseline renal function tests and blood sugar levels should be done. Gram stained smears and KOH smears can provide important clues regarding causative organisms and hence, can guide initial antimicrobial therapy. Pus (if any) should be obtained for culture and sensitivity testing before starting antimicrobial therapy. Blood cultures are useful in management but rarely positive after antibiotics have been started even in suboptimal dosage. Antimicrobials should always be given intravenously, at least 2 drugs, and in at least twice the normal dosage. Our protocol of empirical treatment at the center includes:

1. Injection amoxycillin (any suitable semi-synthetic penicillin) 1 gm IV 6 hrly (50-100 mg/kg/day in 4 divided doses) after samples taken form sensitivity testing, and a skin test (Vancomycin used in cases of sensitivity to penicillin).

2. Injection amikacin (or any suitable aminoglycoside) 250 mg IV 8 hrly (20 mg/kg/day in 3 DD) given along with above.

Suitable cephlosporin and/or ciprofloxacin to be considered as second line of defence Ceftriaxone (100 mg/kg/d in 2 divided doses) + Vancomycin (40 mg/kg/d in 2 doses).

3. Injection metronidazole 500 mg IV 8 hrly (30 mg/kg/day in 3 DD), and even antifungal or antitubercular treatment wherever indicated.

4. Corneal lubricants in prevention/management of exposure keratopathy and

5. Multivitamins are to be prescribed too.

Intravenous antibiotics should be continued till an afebrile period of at least 4 days with subsidence of symptoms and signs. Oral antibiotics are started, continued at home thereafter, and stopped appropriately during follow-up. Antimicrobial therapy should of course be modified according to culture and sensitivity reports.

On reviewing the patient, following parameters should be carefully recorded:

2. Proptosis (quantitated by Hertel’s exophthalmometer).
3. Limitation of ocular movements (with diplopia charting when required).
4. Exposure keratopathy.
5. Pupillary reactions.
6. Contralateral VI cranial nerve.
7. Temperature monitoring (for fever).

Orbital abscesses and large subperiosteal collections should be drained. Small subperiosteal abscesses are known to respond to medical therapy alone. Paranasal sinuses, if containing pus, should also be drained by the otorhinolaryngologist, along with the orbital drainage. Help from other specialists, as neurosurgeons, should be sought whenever felt necessary.

Initial presentations may not predict the final outcomes, either functional or cosmetic. Despite the advent of more potent antimicrobials, orbital cellulitis still remains a potential killer especially with virulent and resistant strains inadequately treated. Otherwise, the results are satisfactory, unless the optic nerve or cornea is involved early.

Chlamydia Ophthalmia Neonatorum

Chlamydia ophthalmia neonatorum may be acquired from the maternal birth passage and have a longer incubation period than the earlier more common gonococcal ophthalmia. Proper diagnosis and aggressive therapy are necessary. Trachoma is still widely prevalent in our country, and manifests mostly
in the upper palperbral conjuctiva with follicles and scarring later with cicatrzation. An early diagnosis and tretment prevents serious complication of blinding trachoma.

**Membranous Conjunctivitis**

Diphtheritic conjunctivitis is associated with true membrane formation Pseudomembranes may form in other bacterial infections and also in Stevens-Johnson syndrome. It may be dangerous to peel off the membrane, as toxins may be released with grave conseqenes. A pinkish white elevation appearing at the limbus in the bulbar conjunctiva, could be a phlycten with engorged conjunctival vessels clustering around its base. Phlyctenular keratoconjunctivitis is believed to be an allergic response to tubercular or other bacterial protines often associated with undernutrion and poor health. Treatment consists of topical steroid/ NSAID therapy. A systemic tubercular focus should be ruled out and respiratory infections looked for.

The presence of congested nodules on the sclera is suggestive of episcleritis, or the more severe condition of scleritis (usually with associated underlying uveitis). Episcleritis and scleritis should be differentiated from acture conjunctivitis by their more localized nature and presence of pain and tenderness.

**MISCELLANEOUS DISORDERS**

**Vitamin A Deficiency**

 Conjunctival xerosis and Bitot spots are not emergencies perse, but they may be the forerunners of keratomalacia. Most pediatricians in developing countries are familiar with the grim picture and hopeless visual prognosis of keratomalacia. The treatment consists of administraion of systemic vitamin A, topical and systemic antibiotics, atropine ophthalamic ointment and warm compresses. Vitamin A 100,000-200,000 IU is given orally daily for 2 successive days if the child does not have any diarrhea, otherwise a water dispersible preparation of vitamin A is administered by intramuscular route. This dose should be repeated 2-4 weeks later. The nutritional status and education of these children should be improved. The condition must be identified early before irreversible damage to the eyes has taken place. The alarming magnitude of nutritional blindness in the country can be reduced by vitamin A prophylaxis with suitable short-term, medium-and long-term measures. Besides xerophthalmia, diffuse or focal corneal haze can occur due to several causes; congenital, traumatic, inflammatory (intrauterine or postnatal), neoplastic, degenerative, allergic and metabolic (mucopolysaccharidoeses) disorders.

Night blindness most commonly occurs due to vitamin A deficiency. Pigmentary retinal degeneration (retinitis pigmentosa) as in Laurence-Moon-Bardet-Biedl (LMBB) syndrome and other uncommon hereditary conditions may also produce night blindness.

**REFRACTIVE DISORDERS**

**Hyperopia (Hypermetropia, Far-sightedness)**

Moderately severe hyperopia may cause headache reading difficulty and even squinting. Hyperopia with symptoms may require correctional glasses after cycloplegic refraction.

**Myopia (Near-sightedness)**

In congenital myopia, children are born with high myopia and one or both parents are often myopic. Usually myopia develops between the age of 5 and 15 years because of rapid growth of the eyes. They have few early symptoms, and the detection is often made at school or on routine visual testing. Associated astigmatism may lead to eye fatigue, headache and blepharitis. Corrective glasses (or contact lenses) after cycloplegic refraction should be prescribed for constant use, and the child is encouraged to wear them all the time for distance as well as for near.

**Astigmatism (Inability for Point Focus)**

A mild degree of astigmatism is common. Red eyes, recurring blepharoconjunctivitis, stye and chalazia often indicate the presence of astigmatism. Eye strain (asthenopia), pain in and around the eyeballs, headache, and nausea may occur. Astigmatism may be associated with hyperopia or myopia. If the vision is not subnormal and there are no symptoms, glasses may not be required, but in case of either, correction should be ordered for constant use after cycloplegic refraction.
Retinopathy of Prematurity

The development of retrolental fibroplasias (or retinopathy of prematurity) is probably related to exposure of preterm low birth weight (LBW) infants to high concentrations of oxygen above 40 percent because of the immaturity of the retinal vasculature in these premature eyes.\textsuperscript{9,10} Initially, there is vasoconstriction of retinal vessels. Later the vessels dilate and become tortuous. Hemorrhages occur along the blood vessels. Retinal detachment may occur. Neovascularization and vitreous opacities may be seen at the junction of the detached retina with the normal reina (Fig. 108.14). Organization of vitreous and formation of retrolental membranes follow (retrolental fibroplasias). The eye becomes small with marked visual loss. The anterior chamber becomes shallow. Myopia and strabismus are common. The progression of disease may be arrested at any stage Prevention of the condition is important and depends upon the use of minimal oxygen concentration for least possible time with careful monitoring.

Watering

Watering may be because of inflammation, infections foreign bodies, ENT problems, uveitis, glaucoma, and nasolacrimal obstruction. It can be one of the major causes of anxiety to the parents of a neonate. Persistent watering from one or both the eyes in infants should lead to the suspicion of blockage of the nasolacrimal duct with congenital dacrocystitis. The regurgitation of mucus from the puncta on pressure over the lacrimal sac clinches the diagnosis of dacryocystitis. The discharge should be sent for culture and antibiotic sensitivity. The mother should be advised to massage the sac firmly twice a day, clean the discharge, and instill an appropriate antibiotic as drops. The associated rhinitis should be controlled and the nose kept dry so as to facilitate the opening up of the blocked nasolacrimal duct. The child may be referred for further management to an ophthalmologist. The probing and syringing of the nasolacrimal duct should preferably not be delayed beyond six months of age, though many infants do undergo spontaneous resolution by one year of age with proper conservative treatment.

Even though a congenital obstruction of the nasolacrimal duct and the ensuing dacryocystitis remains one of the prominent causes of watering in the younger patients, one should always keep in mind other important sight threatening entities such as congenital glaucoma and corneal disorders.

Lid Disorders

Lid edema is not uncommon, and it is an alarming sign. It may be due to allergy (topical medications), or due to an insect bite. The loose areolar tissues of the lids allow considerable swelling to occur. Conservative treatment is quite satisfactory. A swelling in the lid may be neoplastic in nature. Injury around the lids and a black eye may be associated with lid edema. Systemic causes of lid edema should be excluded.

Stye (hordeolum externum), a painful tender erythematous infection of the hair follicle of eyelashes, and furuncles may also produce lid edema. The temptation to express the pus should be avoided, as it may lead to development of lid abscess.

A chalazion is a painless granulomatous nodule of the Meibomian tarsal glands in the eyelid. It may start as an acute hordeolum internum, at which stage it may be aborted with timely hot fomentation, antibiotic drops and massage. Once established, a chalazion may require incision and curettage as an elective procedure. Causes of eyestrains as refractive errors and orthoptic problems need to be ruled out in styes, chalazia and blepharitis, especially if recurrent. Squamous and
especially ulcerative blepharitis require energetic treatment. Associated dandruff should also be managed. Vaccinial and herpetic blepharitis are known to occur.

**Others**

Some congenital lid conditions require early surgical intervention such as congenital coloboma with corneal exposure (Goldenhar’s syndrome), and severe ptosis, Entropion (congenital or trachomatous) and distichiasis may require correction if the cornea is endangered. Congenital ectropion is rare, but the more common cicatricial type necessitates repair by skin grafting.

Congenital craniofacial and CNS disorders such as hydrocephalus, microcephaly, mental retardation cerebral palsy (to maximize head control) encephalocoele, meningomyelocele, and craniosynostosis often produce significant ocular features. Corneal exposure and early papilloedema constitute virtually emergency situations for the pediatrician and the pediatric surgeon.

Some inborn errors of metabolism such as homocystinuria (subluxated lens) and galactosemia (cataract), albinism, lipidoses, chromosomal aberrations, Marfan’s syndrome (ectopia lentis), Weill-Marchesani syndrome with spherophakia and “inverse” glaucoma (responding to dilation of pupils), and phakomatoses can also produce urgent ocular situations. Color vision defects are often hereditary and are not yet amenable to any treatment, except eugenics.

Sudden diminution of vision in children may be associated with serious neurological disease, like meningitis and encephalitis and may occur due to optic neuritis, or brain damage (cortical blindness). The importance of careful evaluation of pupillary reflexes cannot be overemphasized. Prompt empirical treatment with systemic corticosteroids and antibiotics along with specific therapy may save the vision. Parenteral administration of vitamins B1 B6 and B12 (as injection. Triredisol-H) may be of some help. In a child with poor vision, common conditions like refractive errors (high myopia) and amblyopia (blunting of vision following sensory visual deprivation due to squint, anisometropia, corneal opacities, cataract, etc.) should be ruled out Other causes of sudden visual deterioration in children include demyelinating and convulsive disorders, vascular lesions, migraine and iatrogenic reasons due to the toxic effects of drugs. Functional blindness may occur in adolescent children and simple tests for visual malingering may help the clinician.

**PREVENTION**

Of all the ocular problems in childhood, injuries, infections and malnutrition form the major bulk, and all are largely preventable. It is hoped that programs for better nutrition, sanitation, dietary education, and control of infectious diseases especially diarrheal disorders will reduce the incidence of blinding malnutritions. Prophylactic administration of vitamin A to preschool children can eradicate blindness due to vitamin A deficiency. The current recommendations by the Government of India are to administer first dose of prophylactic vitamin A 100,000 IU at 9 months (along with measles vaccination) followed by second dose of 200,000 IU around the age of 15-18 months (along with first booster of DPT/OPV) and three more doses at an interval of every 6 months.

Children should be discouraged from playing with pointed objects and sharp toys. The hazards of arrows, airguns, catapults and fireworks should be highlighted through the mass media. Eyes are precious and must be protected both at work and play. The teachers should be well informed to teach preventive and promotive aspects of eye health care of the students.

Gonococcal ophthalmia neonatorum can be prevented by prophylactic topical instillation of either silver nitrate 1 percent or erythromycin 0.5 percent ophthalmic ointment to newborn babies at risk. The erythromycin prophylaxis provides additional protection against eye infections due to chlamydiae. However, if the eye damage has occurred, the earlier it is effectively managed, the better are the chances for salvaging useful vision. Injuries and inflammation of other parts of the body may heal with minimal or no side effects, but the delicate ocular tissues are greatly compromised by the reparative process leading to serious cosmetic and visual handicaps.
REFERENCES

In this chapter, special emphasis is laid on the pediatric otolaryngologic emergencies and their management as would be of interest to the pediatric surgeons.

I. THE EAR

ACUTE OTITIS MEDIA (AOM)

Acute otitis media is the most common bacterial infection in children and the most frequent indication for medical or surgical therapy. Known risk factors are young age, male gender, bottle feeding, crowded living conditions, smoking in the home, heredity and a variety of associated conditions such as cleft palate, immunodeficiency, ciliary dyskinesia, Down syndrome and cystic fibrosis.

AOM is typified by the symptoms and signs of acute infection (fever, pain, red bulging tympanic membrane). The pathophysiology of AOM is the result of bacterial entry into the middle ear. This entry is due to an abnormally patent (compliant) eustachian tube. The bacteria commonly implicated in the infection are *Streptococcus pneumoniae*, *Hemophilus influenzae*, *Branhamella catarrhalis*, *Streptococcus pyogenes* and *Streptococcus aureus*. Viruses have been recovered from the middle ear in 20% of early cases and in some cases as the sole agent, but more often with pathogenic bacteria.

Antibiotic therapy is the mainstay for treatment of AOM. A 10-day treatment is the usual course prescribed. Amoxicillin is the first line drug of choice, but if the inflammation does not show signs of response, then the initial agent is discontinued and a second line drug (e.g., Cefaclor or amoxicillin-clavulanate) is used. Because of the frequent association of OM and upper respiratory tract infection, the use of a nasal decongestant to open the airway may be helpful. Antihistamines should be avoided because their antihistamine-like effects leads to drying of secretions.

Myringotomy promptly relieves severe pain in cases of AOM, but adds little to either remission of infection or clearance of middle ear effusion in cases of AOM treated with amoxicillin-clavulanate. In complicated cases of AOM as in facial paralysis, meningitis, or other central nervous system event, myringotomy should be done without delay to prompt drainage and collect material for culture.

Untreated or incompletely treated cases of AOM leads to infection spreading and causing mastoiditis or a frank abscess. Infection may cause meningitis, intracerebral abscess, labyrinthitis or facial nerve paralysis.

CHRONIC SUPPURATIVE OTITIS MEDIA (CSOM)

Tubotympanic Type

This variety usually follows a benign course and is virtually always a complication of acute otitis media where there is a persisting perforation in the tympanic membrane. This usually starts in early childhood and is a common entity. The persisting or recurring infection in the middle ear cleft spreads via the eustachian tube which is shorter and more horizontal in young children. The edges of the perforation get epithelised in due course and then the child is likely to have persistent or recurrent discharge secondary to upper respiratory tract infections. The infection may also result from bacteria gaining access to the middle ear cleft via the external auditory canal. The children
present with mucopurulent discharge which is intermittent or occasionally persistent. Examination confirms the presence of central perforation. In all the cases the nasal cavities, the nasopharynx and pharynx must be examined because the source of infection may be found in the upper respiratory tract. The common causes are in the infected tonsils, adenoids or the sinuses. Hearing tests including tuning fork tests and pure tone audiometry usually reveals the presence of conductive deafness. Radiography of the mastoids would reveal a cellular mastoid, but if the infection has been long standing then it may be sclerotic. Treatment includes eliminating upper respiratory tract infection first. The ear is cleaned under direct vision (preferably under a microscope) and the patient advised to use antibiotic ear drops active against gram negative infections such as *Pseudomonas Pyocyanea* or *B. Proteus*. The patients should be warned not to get water into their ears while washing or swimming. If the child gets a cold, then he should not blow his nose as this may cause massive movement of nasal discharge up the eustachian tube into the middle ear. If there is bilateral perforation causing severe hearing handicap, then Myringoplasty is advised, otherwise this surgery is usually done at our center when the child has attained 15 years of age when the eustachian tube function has stabilised.

**Atticoantral Type**

In this type of infection the bone of attic, antrum or mastoid process is involved as well as the mucosa of the middle ear cleft. An erosion of the bone may extend to adjacent vital structures by direct spread or via osteothrombophlebitis causing intratemporal complications (facial nerve palsy, labyrinthitis, sensorineural hearing loss) or intracranial complications (meningitis, intracranial abscess, lateral sinus thrombosis).

**Cholesteatoma**

Cholesteatoma consists of a sac of keratinizing squamous epithelium surrounded by granulation tissue. The granulation tissue on the outside of the sac produces lysozymes and this gradually erodes the ossicles, ear drum and the mastoid bone. In children cholesteatoma tends to be more aggressive and destructive.

The symptoms and bacteriology are very similar to those of tubotympanic otitis media. The discharge however is purulent rather than mucopurulent and frequently very foul smelling. Deafness is usually present and may vary from trivial to profound depending upon the involvement of the ossicular chain and the inner ear. If granulations or polyps are present, bleeding from the ear may be noticed.

On examination the discharge is very offensive to smell and is scanty in amount. The deep retraction pocket is usually seen in the attic or the posterosuperior quadrant area of the tympanic membrane. Hearing tests may usually reveal varying levels of conductive deafness, but if the inner ear is involved then sensorineural deafnes may be seen. Radiography of the mastoid may reveal a cholesteatoma cavity as an area of translucency with a clearly outlined bony margin. Surgery is the mainstay of treatment of this condition. The basic aims of the surgery are to make the ear safe, dry and if possible to improve hearing. If the residual hearing is present then a modified Radical Mastoidectomy is done, but if there is no cochlear reserve then a Radical Mastoidectomy is done.

**OTITIS MEDIA WITH EFFUSION (OME)**

OME is one of the commonest chronic otological conditions of childhood. It results from alteration of the mucociliary system within the middle ear cleft where serous or mucoid fluid accumulates in association with a negative pressure. The pressure change is almost invariably caused by a malfunction of the eustachian tube. Although there are no signs of inflammation, bacteria can be cultured from the effusion in almost 50% of cases. Chronic Otitis media with effusion is usually present in children with cleft palate. It frequently occurs in association with chronic upper respiratory tract infection and conditions affecting the nose and sinuses. The condition occurs in childhood as an overt or covert hearing loss presenting as educational or behavioral problem. In younger children it may present as speech and language delay or as an articulation defect. Treatment varies widely and is dependent on the duration and severity of the problem. Mild forms of the disease resolve spontaneously. Unilateral effusion as is expected is less detrimental to normal childhood development than bilateral effusion. Topical and
systemic vasoconstrictors, antihistaminics, antibiotics and systemic steroids have been tried, but none has been established as a proven modality or treatment. If there is persistent otitis media with effusion, a myringotomy and insertion of ventilating tube (grommet) is recommended.

DEAFNESS IN CHILDREN

An attempt should be made to diagnose hearing impairment in children as early as possible. For acquisition of speech, the important years of life are the first 2 years and hence it is vital that children born with a significant loss should be identified before reaching the age of 1 year. If a definite diagnosis is made, then a hearing aid can be fitted from as early as 3 months of age.

Hearing assessment can be made by:

i. Distraction Techniques: At the age of about 6-7 months a normal baby will search for the source of sound by turning his head towards the noise. A fairly accurate assessment can be made of the child’s hearing thresholds at a variety of frequencies. Beyond the age of 1 year, voice distraction techniques can be used.

ii. Conditioning Techniques: At the age of 2-5 years the child can be taught to make some simple movement in response to sounds. When the child has been conditioned, an accurate assessment of hearing loss is possible and actual audiograms can be plotted.

iii. Pure Tone Audiometry: Most children between the ages of 4-5 years can be persuaded to co-operate so that pure tone audiogram can be obtained.

iv. Impedance Audiometry: This test is essential to indicate the status of middle ear conducting mechanism.

v. Brainstem Evoked Response Audiometry: This test is now widely used to estimate hearing thresholds in children. In a neonate it can be performed when the child is sleeping or after a feed. Once the infant is 3 months old, sedation can be given. Surface electrodes are applied to the mastoid, vertex and forehead and the auditory stimulation is by 2000 or 4000 broad band click or tone bursts. The response is recorded and the intensity reduced until the N5 wave disappears. The V wave form is normally seen 6 or 7 msec after the stimulus, depending on the age of the child.12

vi. Electrocochleography: In this test an insulated needle electrode is inserted through the tympanic membrane to lie on the promontary. A series of clicks or tone bursts are used. The number varies from the size of response from 64-512 or more. The threshold is estimated by identifying the action potential and reducing the intensity of auditory stimuli until the action potential is no longer seen.

The types of deafness can be classified as:

1. Congenital Conductive Deafness: The complicated embryology allows for a great variety of congenital malformations involving the pinna, the external meatus, the tympanic membrane, the middle ear cavity and the ossicles. Important among them are the defects in the external meatus which prevent sound waves from reaching the tympanic membrane and the abnormalities of the ossicular chain which interfere with the transmission of sound to the inner ear. With a bilateral meatal atresia, surgery should be considered and the accepted age for this is between 18 months and 2 years of age.

2. Sensorineural Deafness: Sensorineural hearing loss should be identified as early as possible and hearing aids may be fitted as early as 3 months of age. If the child is detected to have a profound hearing loss not benefiting by a hearing aid, then a cochlear implant is advisable.13 This device is implanted in the temporal bone in the post-auricular region, with the electrodes being introduced in the cochlea via the promontary or the round window. The device is switched on 6 weeks later when the surgical wound has healed. Vigorous rehabilitation is employed for a period of 6 months to several years for the device to be effective.

II. THE NOSE

DEVELOPMENTAL ABNORMALITIES

1. Choanal Atresia occurs in 1 in 5000-8000 live births.14 Of these 50% have associated anomalies whereas the rest have isolated anomalies. About 65-75% of these anomalies are unilateral, whereas the rest are bilateral.15 Patients with long standing unilateral nasal obstruction and discharge may not present until later in life, whereas those with bilateral atresias present as new born with cyclic
cyanosis relieved on crying. Bilateral atresia is an emergent situation as the neonates are obligate nose breathers. An oropharyngeal airway should immediately be inserted to save life. Choanal atresia can simply be diagnosed by passing a catheter through the nose into the nasopharynx or by flexible endoscopy. Computed tomography is the radiographic procedure of choice which can show the nature and thickness of the constructing membrane. Surgical repair of choanal atresia involves transnasal, transpalatal, transantral and transeptal approaches.

2. **Encephaloceles and Gliomas:** An encephalocele is a herniation of cranial contents through a defect in the skull. It may include meninges only termed as meningocele, or it may involve brain and meninges, termed as meningoencephalocele. A glioma is thought to be an encephalocele that has lost the intracranial connection although 15% remain attached to the central nervous system via a fibrous stalk. Diagnosis is confirmed both by CT scan and MRI. The definitive management is surgical and a neurosurgical consultation is mandatory.

**EPISTAXIS**

The commonest cause of epistaxis is either from external trauma or from picking of the nose. Most epistaxis originates from the Little’s area, not only because of the highly vascular nature of this region but also because inspired air tends to be directed onto it causing undue drying and crusting. When this is removed, some of the mucosa is also removed with it causing bleeding. Other common etiologies include upper respiratory tract infections, foreign bodies, tumors, disorders of blood vessels and clotting mechanisms. First aid measures include sitting the patient forwards and pinching the nostrils tight. Ice is sucked and put over the forehead until the bleeding stops. The simplest method to stop bleeding is to insert a pledget of cotton wool soaked in adrenaline solution into the nostril. If bleeding persists, an anterior or a post-nasal pack may need to be inserted.

**THE CATARRHAL CHILD**

Nasal catarrh and history of frequent colds are commonly encountered conditions in general practice. Certain factors that predispose to the condition are:

i. **Environment:** Hygiene, overcrowding, illness in the family and general nutritional factors and environmental pollution are contributing factors.

ii. **Viral Infections:** There are two main types of respiratory viruses. The first type enters the cells of the respiratory tract where they multiply to cause respiratory infections, and among these are the influenza and the parainfluenza viruses, the adenovirus, the respiratory syncytial virus and the rhinovirus. The second type enter the respiratory cells where they cause no local damage but spread by the blood stream to give rise to exanthemata such as measles, rubella, varicella, etc.

iii. **Allergy:** Allergy is frequently hereditary in origin, and the child of two atopic parents stands a 75% chance of producing symptoms of nasal allergy.

iv. **Nasal Polypi:** In children, unilateral polypi is more common requiring surgery. Multiple bilateral ethmoidal polypi are rare in children and if seen, a search for mucoviscidosis should be made.

v. **Vasomotor Rhinitis:** This is as common in older children as it is in adults. The turbinates appear congested and hypertrophied and do not have the pallor of the allergic turbinate. The major complaint is that of nasal obstruction, but persistent rhinorrhea with or without sniffing is not common.

vi. **Immotile Cilia Syndrome:** Children with recurrent unexplained chest infections or chronic obstinate nasal catarrh may have this problem. Detailed investigation is needed to diagnose this condition.

**SEPTAL DEVIATION IN CHILDREN**

Trauma to the nose of the fetus can occur in the mother’s womb or during delivery because of the pressure effects as the fetus passes through the birth canal. The new-borns to be tested for nasal septal deformity should undergo external nasal examination. They should also undergo the test for tip instability, cotton wool test, metal plate test, and examination by a small auriscope and strut.

Nasal septal deviation occurs more frequently in childhood, although it occurs at any age due to trauma. Due to the deviation, eustachian tube and middle ear functions are also affected. Septoplasty in childhood does not produce any untoward events in terms of developmental delay of the nose and face.
Though deviation of the septum has a greater chance of recurring after surgery, the results of septoplasty in children are fairly satisfactory.

**SINUSITIS IN CHILDREN**

Chronic sinusitis among patients referred for evaluation has a peak incidence of approximately 3 years of age followed by gradual tapering. The variables that cause chronic and recurrent sinusitis are: (1) Inflammatory problems such as upper respiratory tract problems and allergies, (2) Mechanical obstruction include adenoid hypertrophy, nasal polyps, foreign bodies and choanal atresia, (3) Systemic diseases such as cystic fibrosis, immotile cilia syndrome and immune deficiencies. The anterior ethmoids, Frontal sinuses and Maxillary sinuses drain into the area known as the ostiomeatal complex. If this area is obstructed because of anatomic deformity or mucosal edema, the cilia do not function normally. Secretions accumulate and the patient is predisposed to recurrent or chronic sinusitis.

Symptoms of sinusitis vary with the age of the patient and the severity of infection. Young patients often have nasal congestion, cough, and anterior purulent rhinorrhea as primary symptoms. Older children do not have anterior discharge as the primary symptom, but may complain of sore throat or post-nasal drip. The most consistent symptoms are nasal airway obstruction, purulent nasal discharge, headache, irritability and coughing both in the day and night.

Anterior rhinoscopy (can be effectively done by the otoscope) and Nasal endoscopy (only older children may allow) is done to examine the nasal cavity. CT has become the standard for diagnosing the extent and severity of chronic sinusitis.

**Bacteriology:** Acute and recurrent sinusitis is usually caused by *S. pneumoniae, M. catarrhalis,* and *H. influenzae*. Brook found increased anaerobic bacteria in patients who had symptoms that lasted longer than 3 weeks. The most common anaerobes were *Peptococcus, Peptostreptococcus* and *Bacteroids;* the most common aerobes identified were α- *Hemolytic Streptococci,* and *Staph aureus.*

**Treatment:** Medical treatment includes antibiotics, effective amongst them are Amoxicillin with clavulanate potassium and second generation cephalosporins such as Cefuroxime axetil. Antibiotics are given for 10-14 days in acute sinusitis and for a period of 3-4 weeks for chronic sinusitis.

**Endoscopic Sinus Surgery:** Preservation of normal structures and mucosa is especially important in pediatric population because the sinuses are small and still developing. Surgery should be considered only after appropriate medical management, including several courses of long term (4-6 weeks) broad spectrum antibiotics and probably nasal corticosteroid sprays have proved unsuccessful.

**III. THE THROAT**

**TONSILS AND ADENOIDS**

The tonsils are grouped as secondary lymphatic organs. It has been suggested that tonsillar hypertrophy is a physiological process, indicating B-lymphocyte proliferation, while sunken atrophic tonsils indicate a collapse of the B-cell activity and a ‘collapse’ of the defence process. It may therefore be that small atrophic tonsils are more often the seat of infection of a chronic sort.

**Indications for Tonsillectomy**

1. Recurrent acute tonsillitis (more than 6 episodes per year or 3 episodes per year for more than or equal to 2 years).
2. Recurrent acute tonsillitis associated with cardiac valvular disease or recurrent febrile seizures.
3. Chronic tonsillitis that is unresponsive to medical therapy and associated with halitosis, persistent sore-throat, and tender cervical adenitis.
4. Peritonsillar abscess and tonsillitis associated with abscessed cervical nodes.
5. Obstructive sleep apnea and sleep disturbances.

Adenoid hypertrophy or chronic adenoiditis may cause significant problems requiring adenoidectomy in situations in which the tonsils themselves are not diseased and are not contributing to the symptomaticity.

**ADENOIDECTION**

Adenoid hypertrophy or chronic adenoiditis may cause significant problems requiring adenoidectomy in situations in which the tonsils themselves are not diseased and not contributing to symptomaticity.
Indications for Adenoidectomy

1. Purulent adenoiditis.
2. Adenoid hypertrophy associated with chronic otitis media with effusion, chronic recurrent acute otitis media, chronic otitis media with perforation and otorrhea or chronic tube otorrhea.
3. Adenoid hypertrophy associated with excessive snoring and chronic mouth breathing.
4. Sleep apnea or sleep disturbances.
5. Adenoid hypertrophy associated with cor pulmonale, failure to thrive, dysphagia and speech abnormalities.
6. Craniofacial growth abnormalities and occlusion abnormalities.

STRIDOR AND AIRWAY MANAGEMENT

Stridor is an abnormal or unwanted noise made by turbulent airflow in the airway. Not every child with stridor requires endoscopy because a thorough history and a limited physical examination can in some conditions (e.g. mild laryngomalacia) provide sufficient diagnostic probability to avoid initial endoscopy. The common causes are listed below:

I. Nasopharyngeal causes of airway obstruction
   A. Neonates
      1. Neonatal rhinitis
      2. Choanal atresia or stenosis
      3. Craniofacial abnormalities
      4. Micrognathia
   B. Children
      1. Allergic rhinitis
      2. Adenoiditis
      3. Adeno-tonsillar hypertrophy
      4. Foreign bodies

II. Laryngeal causes of airway obstruction
   A. Neonates
      1. Laryngomalacia
      2. Intubation trauma
      3. Reflux laryngitis
      4. Laryngotracheal stenosis
      5. Vocal cord palsy
   B. Children
      1. Croup (Laryngotracheobronchitis)
      2. Hemangiomas
      3. Papillomatosis
      4. Intubation trauma
      5. Vocal cord palsy

III. Tracheal causes of airway obstruction
   A. Neonates
      1. Tracheobronchomalacia
      2. Tracheal stenosis
      3. Vascular compression
   B. Children
      1. Foreign bodies
      2. Tracheal stenosis.

Stridor at birth is unusual and generally denotes fixed congenital narrowing (e.g. a laryngeal web, subglottic stenosis, tracheal narrowing). Dynamic conditions such as laryngomalacia and congenital vocal cord palsy become evident in the first few weeks of life. A gradually increase in severity of stridor or airway compromise implies growth of an obstruction which may be luminal as in a subglottic hemangioma or extrinsic as with a mediastinal mass. Hoarseness suggests a laryngeal lesion such as laryngeal papillomatosis but also occurs in vocal cord palsy. Inspiratory stridor is caused by extrathoracic obstruction such as larynx or high trachea; bronchial obstruction causes expiratory stridor.

Endoscopy should be done for diagnosis and flexible endoscopes afford a comprehensive view of the lesion with very few risks. Once the airway is stabilised, then rigid endoscopy can be undertaken with a view to diagnose and treat the offending pathology.

The management has to be emergent. If chronic hypercarbia is present then oxygen is useful in the management of airway obstruction. Intravenous corticosteroids are beneficial in croup. Inhaled corticosteroids have a similar effect.

Intubation is increasingly being used as an alternative to tracheotomy in acute airway obstruction, partly because of technologic advances in anesthesia and partly because of the realisation that even short term pediatric tracheostomy is not without complications. Sometimes intubation may fail and then tracheostomy has to be done to secure the airway.

Vocal Cord Palsy

Vocal cord paralysis is rare in children. Central lesions are more often associated with bilateral cord palsy and peripheral lesions with unilateral palsy. Congenital vocal cord palsy typically presents in the first month of life. Stridor, cyanosis and apnea are the most
frequent symptoms of bilateral paralysis; unilateral paralysis usually presents with dysphonia. Infants with unilateral vocal cord paralysis requiring tracheostomy can usually be decannulated following growth of the airway, between 1 and 2 years of age without further surgical intervention even if paralysis persists. In patients with bilateral vocal cord paralysis, vocal cord lateralization can improve the airway permanently and permit decannulation when spontaneous recovery of function does not occur.

**Subglottic Hemangioma**

The usual age of presentation is 6 weeks and is nearly always in the first 6 months of life. The most common symptom is stridor, often initially intermittent and misdiagnosed as recurrent croup but usually progresses to become constant, may be inspiratory or biphasic and is exacerbated by crying or upper respiratory tract infections. The diagnosis is made by direct laryngoscopy. The classical appearance of the tumor is pink or bluish sessile mass arising from the lateral wall of the subglottis and often extending to involve the subglottis. Airway maintenance is bypassing the obstruction by a tracheostomy. Systemic corticosteroids, carbon dioxide laser vaporization, Interferon α-2A and selective embolization are some of the recommended modalities of treatment.

**Respiratory Papillomatosis**

Recurrent respiratory papillomatosis is characterised by benign, non-keratinizing, squamous papillomas that may be sessile or pedunculated, multiple and are typically recurrent. They have a predilection for the squamo-ciliary junctions of the airway. The disease is caused by epithelial infection with human papilloma virus (HPV) types 6 and 11. Peak age incidence is between two and five years of age. Presenting symptoms may vary from hoarseness, abnormal cry to frank stridor. Carbon dioxide laser vapourization is the preferred modality of treatment. Adjuvant therapy like podophyll and photodynamic therapy have also been used. Tracheostomy for airway maintenance may be required in severe cases, though the disadvantage is that the chances of stomal seeding by the papillomas is very high. Human leukocyte interferon has a well documented benefit in respiratory papillomatosis.

**FOREIGN BODIES OF THE AIRWAY AND ESOPHAGUS**

Airway foreign bodies pose a diagnostic and therapeutic challenge to the pediatric otolaryngologist. Foreign body aspiration mimics other conditions of the airway causing stridor and hence a high index of suspicion is required to come to a diagnosis. The introduction of rod-lens telescope in the 1970s greatly improved the visualisation of bronchoscopic foreign body removal. Up to 25% of patients with airway or esophageal foreign bodies are less than 1 year of age. Vegetable matter is seen in approximately 80% of the airway foreign bodies. The most common esophageal foreign bodies are coins.

Most airway foreign bodies become lodged in the bronchi because their size and configuration allow passage through the larynx and trachea. Larger foreign bodies may become impacted in the larynx or trachea causing at times complete obstruction, which is a dire emergency. Most esophageal foreign bodies become impacted in the cervical esophagus, just below the cricopharynx.

Complete airway obstruction resulting from a foreign body is an absolute emergency. The Heimlich maneuver is of a great help in this situation. For children less than 1 year back blows and chest thrusts are recommended. Children older than 1 year require gentle abdominal thrusts when supine. Older children are positioned standing, sitting, or recumbent for the Heimlich maneuver.

Foreign body aspiration is suspected when the victim develops acute choking, gagging, and paroxysms of severe coughing with respiratory distress. Neck and chest radiography should be done to identify the location of the foreign body. The basic principles of endoscopic foreign body has not changed since the days of Chevalier Jackson. The type and size of the endoscope depend upon the age of the patient and the location of the object. Foreign body removal is done under general anesthesia. Extraction of sharp or pointed objects can be very challenging. Locating the point is crucial. Usually the tip of the pointed object engages the mucosa, causing object to tumble and proceed with the point trailing. The endoscope is aligned parallel to the long axis of the esophagus or the airway to minimise the likelihood of damage to the surrounding mucosa. During extraction, the object is at first moved distally to disengage the point.
Pneumonia and atelectasis are the most common complications after bronchial foreign body removal. Esophageal perforation is a grave but very real complication in the attempt to remove foreign body from the esophagus.

Prevention is ideal, with increased education of parents on age appropriate foods and household objects and strict industry standards in the manufacture of toys.

REFERENCES

HISTORY OF LARYNGOLOGY

In India, Charaka Samhita (Circa AD 100) and Susruta (Circa AD 300) mentioned remedies for disorders of the voice. The earliest mention of the larynx is by Aristotle (Circa 350 BC).¹

Sir William Macewin in 1878 was first to intubate the larynx for purposes of general anesthesia in a 55 years age old man, although anesthesia through a preliminary tracheotomy tube was advocated by Trendelenburg in 1869 (Davison MHA 1965).

EMBRYOLOGIC DEVELOPMENT
(FIGS 110.1 TO 110.6)

The first evidence of respiratory system appears at three weeks of embryonic stage as a median pharyngeal groove or respiratory diverticulum (RD). The respiratory diverticulum (RD) is a ventral outpouching of the foregut lumen that expands into respiratory primordium (RP). The site of the origin of the RD is called the primitive pharyngeal floor which eventually develops into the infraglottic region of the adult larynx. It is separated from the pharyngeal floor by a segment of foregut originally described by Aaw –Tun and Burdi as the primitive laryngopharynx that eventually becomes the supraglottic larynx.²

At approximately 24 days of embryonic age, respiratory pulmonary primordium divides into right and left lobes (Fig. 110.4). The respiratory primordium descends in a proximal to distal sequence. Once the outgrowth of the lung bud begins, the digestive and

Fig. 110.1 and 2: Shows respiratory diverticulum as a ventral outpouching of the foregut lumen, which expands into respiratory primordium
Fig. 110.3: Showing primitive laryngopharynx, a segment of foregut between 4th pharyngeal pouch and primitive pharyngeal floor (Infragottis)

Fig. 110.4: At approximately 24 days, the respiratory primordium divides into right and left lobes

Fig. 110.5: Vascular compromise of trachea shows (A) tracheal stenosis with complete tracheal rings and (B) tracheal agenesis

Fig. 110.6: Compression of primitive laryngopharynx ventrally gives rise to epithelial lamina, which forms, supraglottic structures. Incomplete recanalization of the epithelial lamina give rise to supraglottic and glottic webs and atresia

respiratory tubes pursue independent courses. The lung bud grows caudally into the mesenchyme ventral to the foregut. The mesenchyme that lies between the respiratory and digestive tubes constitutes the tracheoesophageal septum.³

In subsequent stages the right and left lung buds are more evident, and the trachea becomes identifiable. Angiogenesis begins in the mesenchyme and serves to mark off the esophagus from the bronchial investment. Vascular compromise to the developing esophagus may cause esophageal atresia or tracheoesophageal fistula. Vascular compromise to the trachea may cause tracheal agenesis or tracheal stenosis with complete tracheal rings. These anomalies are associated with relatively normal laryngeal and pulmonary development because the insult is limited
to the region of the developing trachea. The hypopharyngeal eminence and arytenoid swelling appear in the floor of the pharynx. The inlet of the embryonic larynx is identifiable.

At 33 days of embryonic stage, the primitive laryngopharynx is seen. It develops from the foregut segment extending from the fourth pharyngeal pouch above to the infraglottis below. The superior laryngeal nerve can be identified. Lobar buds are present and esophageal and bronchial territories are differentiated from each other by capillary plexus. The ventral portion of primitive laryngopharynx becomes compressed bilaterally by the mesoderm of laryngeal cartilages, muscles and branchial arch arteries. Eventually, obliteration of the ventral lumen of the primitive laryngopharynx occurs to give rise to the epithelial lamina. The epithelial lamina which later form laryngeal structures recanalize from dorsocephalic to ventrocaudal direction. The last portion to recanalize is at the glottic level. Incomplete recanalization can give rise to supraglottic and glottic webs and atresia.

ANATOMY OF PEDIATRIC LARYNX AND TRACHEA

The larynx acts as both an air conduit and a protector of lower airway during swallowing.

Characteristics of Pediatric Airway

Apart from being smaller in size than adult, it is different in following aspects.

Infants are obligatory nasal breather. Hence, conditions with nasal obstruction, such as choanal atresia or stenosis can cause severe respiratory difficulty.

Tongue in an infant is proportionately bigger in size and occupies a larger volume of the oral cavity. Position of larynx is higher in infants than adults.

The tip of infant epiglottis corresponds with the junction of first and second cervical vertebra. This high position helps the infant to use its nasal airway to breathe while sucking (Fig. 110.7).

The pediatric airway axis has greater curvature than in the adult. This is of some relevance during intubation, laryngoscopy and bronchoscopy (Figs 110.8A and B).

The connective tissue composing the infant larynx are more pliable than adult. This causes tendency of soft tissues to be sucked with negative intraluminal pressure. The classic example is larygomalacia (during inspiration) and tracheomalacia (during expiration). The cricothyroid ligament is relatively short, making emergency cricothyrotomy extremely difficult.

The mucosa of laryngeal inlet is lax; hence inflammation causes rapid formation of edema. The narrowest part of infant larynx is subglottis measuring 3.5 mm in diameter, than adult where it is glottic region. There are multiple glandular tissues in the region of aryteroid cartilage and saccule is relatively large.
Relationship among hyoid-, thyroid- and cricoid cartilage is different in infant. It is important to identify them before proceeding to any airway surgery. There is no gap between hyoid and thyroid cartilage, in fact hyoid overlaps the upper part of thyroid cartilage, obscuring the thyroid notch. The shape of thyroid cartilage is more rounded, without a prominent midline vertical ridge (laryngeal prominence); the cricoid cartilage is not prominent; the cricothyroid membrane is very small.

Unlike the adult, the neonatal subglottic cavity extends posteriorly as well as inferiorly an important fact to be considered during intubation.

Trachea is relatively small in relation to the larynx in the neonate. The walls of the trachea are relatively thick and the tracheal cartilages are relatively closer together. The ability to resist external compression is also less in infant trachea. The trachea commences at the upper border of sixth cervical vertebra, a relationship conserved with growth, it bifurcates at the level of the third or fourth thoracic vertebra.

The larynx, which is an air passage, a sphincteric device and an organ of phonation, extends from the tongue to the trachea. Above, it opens into the laryngopharynx and forms its anterior wall; below, it continues into the trachea.

**LARYNGEAL FRAMEWORK**

Skeleton of larynx is formed by cartilages, interconnected by ligaments and fibrous membranes. Muscles provide movement. Hyoid bone, though not a part of the larynx, is intimately related with it.

**Laryngeal Cartilages**

The thyroid, the cricoid and the greater portions of the arytenoid cartilages are composed of hyaline cartilage. The corniculate, cuneiform, epiglottic cartilages and the apices of the arytenoid cartilages are composed of elastic fibrocartilage and don’t undergo calcification (Figs 110.9A and B).

**Cricoid Cartilage**

The cricoid (cricos = “ring” Greek) is the only cartilage which forms a complete ring in the larynx. It is the skeletal foundation of the larynx, attached below to the trachea and articulated by synovial joints to the thyroid cartilage and two arytenoids. It consists of a narrow anterior arch, and a broad flatter posterior lamina.

**Thyroid Cartilage**

The thyroid cartilage (Thyrus = “shield” Greek) is the largest laryngeal cartilage. It consists of two quadrilateral laminae, which are joined anteriorly to form an obtuse angle of 110 degrees in an infant, posteriorly they diverge. The posterior borders being prolonged as slender horns, the superior and inferior cornu. On the external surface of each lamina lies the oblique line, which runs downwards and forwards from the superior thyroid tubercle to the inferior thyroid tubercle, to which are attached the
sternothyroid, thyrohyoid and the thyropharyngeus part of the inferior pharyngeal constrictor.

The superior border gives attachment to thyrohyoid membrane. The inferior border provides attachment to cricothyroid ligament anteriorly.

The posterior border of each lamina receives fibers of stylopharyngeus and palatopharyngeus. The superior cornu provides attachments to lateral thyrohyoid ligament. The inferior cornu articulates on the side of the cricoid cartilage.

A narrow, rhomboidal, flexible strip, the intrathyroid cartilage, lies between two laminae and joined by fibrous tissue in infancy.

**Arytenoid Cartilage**

Arytenoid cartilages, are pyramidal in shape, present on each side, on the superior surface of cricoid, posterolaterally. The lateral angle called muscular process gives attachment to the posterior cricoarytenoid muscle behind and the lateral cricoarytenoid in front. The anterior angle called vocal process provides attachment to the vocal ligament. The arytenoids have low mass, thus allow for rapid abduction and adduction in less than 0.1 second.

**Epiglottic Cartilage**

Consists of elastic fibrocartilage is connected by the thyroepiglottic ligament to the back of laryngeal prominence just below the thyroid notch. Its sides are attached to the arytenoid cartilages by aryepiglottic fold. Anteriorly, the mucosa over it forms a median glossepiglottic and to lateral glossoepiglottic folds. Vallecula is a depression on both sides of the median glossoepiglottic fold with no function in humans.

There are two pairs of synovial joints in the laryngeal framework—one for the cricoid and inferior horn of the thyroid cartilage and one for the arytenoids and cricoid.

**Laryngeal Ligaments and Membranes**

**Extrinsic Ligament**

Thyrohyoid membrane bridges the gap between the upper part of thyroid cartilage and the hyoid bone. It is fibroelastic membrane, thicker in median and lateral parts. It is pierced on both sides by superior laryngeal vessels and nerves.

**Intrinsic Ligaments**

There is fibroelastic membrane, beneath the laryngeal mucosa. Its upper part called quadrangular membrane extends between arytenoid and epiglottis. Its lower larger part forms well defined cricothyroid ligament, connecting thyroid, cricoid and arytenoid cartilages (Fig. 110.10).

Rima glottidis or glottis is a space between vocal folds anteriorly (constitute three fifth of it anteroposterior length) and between arytenoids posteriorly. It is the narrowest part of the larynx in adult.

Subglottis—Lined by respiratory epithelium, its walls are made up of cricothyroid ligament above and cricoid cartilage below. Subglottis forms the narrowest part of the larynx in pediatric age.

Trachea—It begins at the level of the cricoid cartilage and usually bifurcates at the level of the sternal angle. There are 18 to 22 cartilaginous rings in the human trachea. The only complete cartilaginous ring in the normal airway is the cricoid cartilage of the larynx. The remainder of the rings is C-shaped, connected posteriorly by the fibroaerolar connective tissue and smooth muscle fibers oriented transversely. The lumen of the trachea is lined by a mucosa consisting of a thin lamina propria and a ciliated pseudostratified columnar epithelium. Goblet cells and some small subepithelial glands are interspersed among the columnar cells. Scattered lymphoid elements are also

---

**Fig. 110.10:** Coronal section of laryngeal cavity
present within the lamina propria. The right bronchus is usually more in line with the tachea and wider and shorter than the left. However, in children the left bronchus is less horizontal than in the adult, hence the incidence of foreign bodies in the two bronchi is approximately equal.

**Laryngeal Musculature**

The muscles of the larynx can be divided into two groups (a) **Extrinsic** and (b) **Intrinsic**.

a. **Extrinsic muscles** connect larynx with the surrounding structures and are responsible for movement of the larynx as a whole, during phonation or swallowing. They include thyrohyoid, sternothyroid, inferior constrictor, stylopharyngeus, palatopharyngeus and salpingopharyngeus.

b. **Intrinsic muscles** connect the cartilaginous elements of the larynx. They are described in detail in Table 110.1.

### Action of the Intrinsic Muscles

Among intrinsic muscles, only *posterior crico-arytenoids* open the glottis. They can be placed into three groups according to their action.

a. **Varying the rima glottidis**: Posterior cricoarytenoid opens the glottis. Lateral cricoarytenoid and transverse arytenoids close the glottis.

b. **Regulating tension in the vocal ligaments**: Cricothyroid, posterior cricoarytenoids, thyroarytenoids and vocales.

c. **Modifying the laryngeal inlet**: Oblique arytenoids, aryepiglottici and thyro epiglotti.

It is considered that tension of vocal folds determine the pitch of voice.

### Laryngeal Vessels and Nerves

Larynx is supplied by a pair of superior and inferior thyroid arteries. Drainage is by the corresponding veins. Superior thyroid artery is a branch of external

carotid artery. Inferior thyroid artery is a branch of thyrocervical trunk, which is turn, is a branch of first part of subclavian artery. Superior thyroid vein drains into the left brachiocephalic vein.

Lymphatic system above the vocal folds drains into the deep cervical node near the bifurcation of the common carotid artery.

Lymphatic system below the vocal folds drains to lymph nodes, along inferior thyroid artery, in front of trachea and to the deep cervical nodes.

The lower trachea shares its supply with the esophagus from the bronchial arteries. The upper trachea is supplied by three branches from the inferior thyroid artery with fine collateral pathways between these branches. In mobilization of the trachea care is therefore taken to free the trachea anteriorly and posteriorly, leaving the lateral pedicle intact except for a short distance which is to be used in the anastomosis.7

Sensory supply above the vocal fold is by superior laryngeal nerve and below the vocal fold by recurrent laryngeal nerve.

**SYMPTOMS AND DIAGNOSIS OF LARYNGEAL ABNORMALITIES**

The larynx has three functions, respiration, protection of airway and phonation. The signs and symptoms of airway obstruction are dyspnea, air hunger, attacks of cyanosis, cough, increase respiratory rate, and retractions of the suprasternal, substernal, infracavicular and intercostal regions.

The quality and type of the stridor may indicate the location of the anomaly. A high pitched crowing type of stridor, present only during the inspiratory phase of respiration indicate problem at larynx most of the time (supraglottic, glottic and subglottic). High pitched inspiratory stridor with low pitched prolonged expiratory phase (biphasic, double or to and fro strider) suggests main airway obstruction below the larynx (i.e. trachea). Low pitched inspiratory sound (stertor; snoring) is produced by obstruction above the level of larynx, i.e. nasopharynx, pharynx or soft palate.

Infants with airway obstruction often fail to thrive. Deglutition and respiration share a common pathway at oropharynx. Hence during feeding, there is aggravation of respiratory obstruction. Conversely, tachypnoea and prolongation of inspiration impede normal swallowing activity.

Weak feeble cry or aphonia suggests a glottic web or neurological dysfunction. Hoarseness, suggests changes in the structure and/or function of the vocal cords, may raise possibility of laryngeal inflammation, trauma, tumors or vocal cord immobility.

Severity of stridor/stertor is assessed clinically by its character, i.e. (continuous or intermittent, loudness) and associated features like cyanosis, shortness of breath, difficult or labored breathing and periods of apnea.

Symptoms of congenital stridor (laryngomalacia) may not develop immediately after birth. It may happen after a child get infection, or due to increased physical activity, he developed stridor in a compromised airway. Congenital causes of stertor on the other hand usually present soon after birth (e.g. choanal atresia)8 (Tables 110.2 to 110.4).

Besides laryngotracheal abnormalities, it is important to exclude cardiac, neurological or systemic problems. Information concerning the birth history, previous intubations, surgery or similar episodes must

be elicited. Foreign body aspiration must be kept in mind especially in toddlers (age 2 or 3) presented with acute onset dyspnea. Esophageal foreign bodies in young children may compress the cervical airway and give respiratory symptoms.

**PHYSICAL EXAMINATION**

**General Examination**

A “hands off” approach with careful observation of the patient is very important. History with mother, regarding degree of obstruction during awake, asleep, during feeding and prone position is valuable. Skin should be examined for hemangioma, as 50% of children with subglottic hemangioma also have cutaneous hemangioma. Degree of respiratory distress is estimated by respiratory rate, stridor, air movement, supraclavicular and suprasternal retractions, indrawing of subcostal space, consciousness level and oxygen saturation (Table 110.5). Reflex apnea, after coughing or during feeding, may indicate the presence of innominate artery compression of the trachea. Chest wall deformities, like scoliosis, barrel chest, or pectus deformity may indicate lower airway obstruction.

**Nose and Oral Cavity**

Nasal patency is evaluated by cold spatula test or by bringing a whisp of cotton in front of nostril. A red rubber catheter should be passed to check choanal patency. Nasal examination may reveal septal deviation, septal hematoma or abscess, congenital cysts or swellings, nasal polyp and choanal atresia. Nasal cavity should be evaluated for presence of discharge, color of nasal mucosa to rule out infective or allergic rhinitis. Examination of the nasopharynx can be done by mirrors but nasal endoscopes either rigid or flexible are better option to rule out adenoidal hypertrophy, or tumors of the nasopharynx.

Examination of oral cavity and or pharynx should be done to rule out micrognathia or retrognathia (Treacher collins and Pierre Robin syndromes), macroglossia (Down’s syndrome, Beckwith’s syndrome), and tonsillar hypertrophy. Rare conditions, such as hypertrophy of lingual tonsil or thyroid, cystic hygroma, hemangioma, teratoma or branchial cleft cysts may be found.

**Auscultation**

Chest auscultation assesses symmetry and quality of breath sounds. Very quiet stertor or stridor is often audible only when stethoscope held close to the child’s nose or open mouth.

**Palpation**

Palpation of the neck may reveal lymphadenopathy, congenital thyroid enlargement thymic tumors or cysts.

**RADIOLOGIC EVALUATION OF THE UPPER AIRWAY**

Frontal and lateral radiographs of the neck are usually taken, at the end of inspiration, with the head and neck extended and held in true lateral position. Radiographs of the upper airway should include all structures between the nasopharynx and the carina.

Lateral Radiographs

For assessment of adenoidal size lateral radiograph should be taken with the mouth closed and not during swallowing to avoid overestimation of adenoidal size relative to the size of nasopharynx. Radiographically visible adenoidal tissue should never be seen in neonates but should be noted routinely in full term infants > 6 months of age. Posterior nasopharyngeal masses in a child < 1 month of age are abnormal; the differential diagnosis should include teratoma, hemangioma neuroblastoma, and basilar encephalocele. Absence of adenoidal tissue in a child of > 6 months of age who had no prior surgery is also abnormal and indicates immunodeficient state.

The classic radiographic finding in acute epiglottitis is the thumb sign. Normally, the epiglottis is thin in anteroposterior diameter, whereas inflamed epiglottis appears shorter and has an increased AP diameter. Besides in acute epiglottitis, there is obliteration of vallecular air-space, thickening of the aryepiglottic folds, distention of the hypo-pharyngeal airway and straightening or reversal of normal cervical lordosis.

Frontal radiographs of the neck provide the clearest evidence of the subglottic narrowing that is found in Laryngotracheo-Bronchitis.

Normal prevertebral soft tissue anterio-posterior thickness gradually decreases as the child grows older and should not exceed ¾ times the anteroposterior dimension of C4 in infants, or more than 3mm in older children. One of the most reliable signs of prevertebral space – occupying pathology is the loss of the normal step-off between air-filled pyriform sinuses and the upper airway resulting in an abnormal, straight vertical air-soft tissue interface in the prevertebral region.

Retropharyngeal abscess is one of the commonest causes of retropharyngeal mass in the pediatric population, which results from local or lymphatic spread of nasopharyngeal or inner ear infections.

Frontal (AP) Radiographs

It is essential for evaluation of vocal cord contour and motion, the laryngeal ventricle, and the subglottic airway. Vocal cord granulation tissue and papillomas appear as non specific soft tissue densities outline by air. Symmetric or asymmetric loss of this “squared” configuration due to subglottic airway narrowing of at least 1 cm in length suggests the presence of congenital or acquired subglottic stenosis.

The most common cause of stridor in children is viral laryngotracheal bronchitis which produces a radiographic appearance like a sharpened pencil or a funnel, also called steeple sign. Steeple sign is also found in subglottic stenosis, acute epiglottitis, and as a sequel to prolonged intubations.

The normal trachea is slight deviated towards right side due to presence of left aortic arch. A trachea that is completely midline is a significant and abnormal finding, suggesting a double aortic arch.

Airway Fluoroscopy

Airway fluoroscopy is a noninvasive way of documenting dynamic changes in airway caliber and position during different phases of respiration.

Lateral fluoroscopy is used to document the inspiratory nasopharyngeal and oropharyngeal collapse in the sleep apnea lab. The inspiratory anterior and inferior buckling of aryepiglottic folds and the downward bending of the epiglottis is seen with laryngomalacia and the excessive expiratory collapse of the intrathoracic trachea in children with congenital or acquired tracheomalacia.

Frontal fluoroscopy is used to assess the motion of the vocal cords and hemidiaphragms. Anterior fluoroscopy is used as a supplemental technique for evaluating children suspected of foreign-body aspiration, in which chest X-rays are equivocal. Normally, the heart and mediastinum remain in the midline during all phases of respiration. If they shift during inspiration or expiration foreign body is suspected in the airway. This results due to atelectasis or post obstruction air trapping.

CONGENITAL ANOMALIES OF THE LARYNX AND TRACHEA

Congenital airway anomalies (CAA) comprise greater than 85% of the stridor cases in children < 2.5 years of age.

A thorough analysis of the nature of the stridor, including its quality and timing, postural change, and association with feeding or crying is essential to evaluate any laryngeal lesion Fig. 110.11 outlines the diagnosis for stridor.
High-voltage, soft tissue, anterior-posterior and lateral airway films may help localize the lesion. A barium esophagogram can detect external compression or a tracheoesophageal fistula (TEF). Computed Tomography or magnetic resonance imaging (MRI) is useful in defining vascular anomalies including vascular rings, pulmonary artery slings or aberrant innominate artery.

When stridor is not severe, flexible fiber optic endoscopy can be done, to establish the lesion. In severe cases, an awake flexible endoscopy is performed to assess cord mobility. When possible, the anesthesiologist should maintain spontaneous ventilation during general anesthesia. Sometimes, it is possible to assess the movement of vocal cords during recovery period of anesthesia.

**LARYNGOMALACIA**

Laryngomalacia is the most common congenital anomaly of the larynx and is defined as supraglottic collapse of the larynx during inspiration. The stridor is inspiratory. The sound varies in pitch and is often coarse and jerky during inspiration, giving it a fluttering character. The stridor is mild in prone position and worsens with agitation. The cry is normal and cyanosis is absent. The onset of stridor is usually within the first few weeks of life, worsens with growth and increasing oxygen demands and then slowly resolves between 6 and 18 months of age.

The cause of laryngomalacia is suggested as either an intrinsic abnormality in the supraglottic larynx or a hypotonicity of the airway. Three abnormalities in the supraglottis have been described in laryngomalacia. An omega-shaped epiglottis, short aryepiglottic folds and redundant bulky arytenoids. Infants with gastroesophageal reflux disease (GERD) may be affected more severely by laryngomalacia. Airway symptoms often are improved with antireflux medications. Central neurological disorders associated with neuromuscular co-ordination difficulties are likely to exacerbate laryngomalacia.
Awake flexible fiberoptic laryngoscopy (FFL) confirms the diagnosis (Figs 110.12A and B). FFL evaluation should be postponed until the time of bronchoscopy if operative evaluation is warranted.

Watchful waiting is the treatment of choice, since majority of the patients improves by themselves. Holinger and Brown in a review of 650 patients with laryngomalacia, found that only two required surgical intervention because significant respiratory distress during feeding and need for hospitalization other studies have shown the incidence of severe laryngomalacia to be 5-22%.16,17 These children have associated feeding difficulties, respiratory compromise, apnea or cor pulmonale and are candidates for surgical intervention, such as tracheotomy.

Several surgical techniques are described treatment. Use of laser is preferred. Surgical procedures include division of the aryepiglottic fold, partial amputation of the epiglottis, epiglottopexy with glossoepiglottic adhesion, removal of redundant supra arytenoid mucosa and lateral borders of the epiglottis, removal of the cuneiform and corniculate cartilages and the surrounding mucosa, and in extreme cases, tracheotomy. The most commonly recommended management appears to be endoscopic laser trimming and removal of the prolapsing aryepiglottic fold with cuneiform cartilage or division of a tight, short aryepiglottic fold (Fig. 110.13).

Differential diagnosis of laryngomalacia includes severe neurological impairment and pharyngeal and hypopharyngeal hypotonia. They may develop a chronic acquired flaccidity of the supraglottic larynx with similar symptomatology. Another condition, called pharyngolaryngomalacia18 associated with complete supraglottic collapse during inspiration without shortened aryepiglottic folds or redundant mucosa and with accompanying pharyngomalacia. These patients don’t respond with usual surgical intervention aimed for laryngomalacia. Some require tracheotomy and some may respond with bi-level positive airway pressure.

**VOCAL CORD PARALYSIS**

Vocal cord paralysis (VCP) accounts for 10% of all congenital laryngeal anomalies and is the second most common cause next to laryngomalacia.19 VCP manifests early in life, and is without gender predilection. The majority is recognized before the age of two. Cohen et al, 1982, reported 100 children with VCP, 58% of whom presented within the first 12 hours of birth.20

Isolated unilateral or bilateral VCP is rare in the pediatric age group. Usually, it is only one manifestation of a multisystem anomaly. Although most frequently associated with central nervous system (CNS) malformations, VCP can be seen in conjunction with other congenital anomalies such as cardiovascular or pulmonary malformations. A higher incidence of other associated laryngeal malformations such as clefts or stenosis also has been reported.21

Etiology of VCP in children has been divided into two broad categories: congenital and acquired. The etiologies include Arnold-Chiari malformation or hydrocephalous alone, idiopathic and local trauma (including iatrogenic), birth trauma, and following bronchiolitis.21

Arnold-Chiari malformation is the most common cause of bilateral VCP in newborns. VCP in children with Arnold-Chiari malformation may be due to stretching of vagal nerve rootlets, altered vascular supply to the brain stem, dysplastic changes in the vagal nuclei, or a lack of afferent input from carotid bodies.22 Prompt neurosurgical correction of the elevated intracranial pressure usually results in improvement. The return of stridor in a patient with a
VP shunt is often an indication of shunt malfunction and the need for revision.

Familial bilateral abductor vocal cord paralysis has been reported. The cause of vocal cord paralysis is dysgenesis of the abductor portion of the nucleus ambiguous.

Bilateral abductor vocal cord paralysis in a neonate or infant presents with high pitched inspiratory stridor and evidence of airway compromise. The stridor may be biphasic and voice is usually normal. The respiratory compromise may be more obvious with increasing age due to the increased oxygen requirement. Unilateral vocal cord paralysis typically presents with a weak breathy voice and signs of aspiration, such as coughing, feeding difficulties and aspiration pneumonia. Usually there is no respiratory compromise.

Once suspected, the diagnosis of VCP requires endoscopic visualization of the larynx. The method of choice is flexible fiberoptic nasopharyngolaryngoscope (NPLS). It provides an undistorted view of the larynx compared with the view obtained when the base of the tongue is being lifted anteriorly with a rigid fiberoptic laryngoscope, is atraumatic, can be done bedside and a camera can be attached to provide the ability for playback in slow motion so that subtle abnormalities can be carefully analyzed. Ultrasound evaluation of larynx has been found to be an accurate, reproducible method for the evaluation of VCP in children.

Acoustic analysis of cry has shown to differentiate an abnormal cry from a normal cry in an infant with unilateral vocal cord paralysis.

Management

Factors that influence management decisions include etiology of the paralysis, prognosis for recovery, unilateral or bilateral vocal cord involvement, length of impairment, severity of symptoms or associated conditions and existing facilities for monitoring the patient. Some suggest that in cases in which the potential for airway improvement is good, the airway should be secured with nasal tracheal intubation for at least 4 weeks before considering tracheotomy.

The rate of spontaneous resolution of laryngeal paralysis, unilateral or bilateral, in pediatric population varies from 16 to 64%. Recovery has been noted from 6 weeks to 5 years after the initial diagnosis. It is essential in children to observe them for reasonable period of time before any decision is made concerning irreversible laryngeal procedure.

Surgical Procedure for Bilateral Abductor Vocal Cord Paralysis

Tracheotomy (Figs 110.14A to I)

When indicated, the initial surgical procedure of choice is tracheotomy. It is potentially reversible procedure, allowing time for potential spontaneous laryngeal recovery. Approximately 50 percent of children that need a tracheotomy for VCP require cannulation for more than 3 years. Most physicians recommend waiting at least 12 months before an irreversible lateralization procedure is attempted. Laryngeal electromyography can provide prognostic information about laryngeal nerve function and the potential for nerve recovery.

Tracheostomy is done in pediatric age group under general anesthesia with spontaneous breathing. Airway is maintained by endotracheal intubation. If endotracheal intubation is not possible due to laryngeal stenosis, nasopharyngeal airway mask or ventilation or jet ventilation is used.

Patient is positioned in supine position with gentle neck extension. Too much extension of the neck causes risk of mediastinal contents (thymus, innominate artery, plura of lung) to shift to the lower neck area.

Neck is cleaned with antibiotic solution. Sterilized draping done. Suction and cautery (monopolar and bipolar) are attached. Gentle palpation with pulp of index finger is done over neck, to identify the laryngeal framework and suprasternal notch. It is easy to identify the hyoid bone and cricoid cartilage over the neck with finger; as they are more prominent. With gentian violet, markings are made over these points in the midline. Now, a horizontal marking made in between the criocoid cartilage and suprasternal notch, between medial margins of the sternocleidomastoid muscles. Xylocaine (1%) with 4,00,000 adrenaline; infiltrated over the horizontal marking (according to body weight). After waiting for five minutes, incision is made over the intended site. Skin, subcutaneous tissue and platysma are sharply cut. Bleeding from the margins is coagulated with bipolar cautery. Blunt, right angle retracters are placed on sides, and tissue is retracted gently towards own sides by the surgeon and
the assistant. Care should be taken, that retraction should be equal on each sides. Now tracheal position is palpated with finger tips, to make sure that dissection is in right direction. Blunt dissection is done with artery forcep in the middle, along the direction of the trachea. Strap muscles are separated in the midline, and retractors are placed in new positions on both sides (Fig. 110.14A). Before further dissection, tracheal position is again checked because it is easy to displace the trachea inadvertently with retractors. Thyroid isthmus is visible after retraction of strap muscles. Thyroid isthmus is retracted with single hook retractor, superiorly or it may be ligated and cut (Figs 110.14B to D). Tracheal rings are visible beneath the thyroid isthmus. One percent xylocaine solution is taken in a 5 ml syringe with 24 gauze needle (Fig. 110.14E). Needle is inserted into the trachea, and aspiration done with syringe. (Fig. 110.14E) Air bubbles comes into the syringe if needle is into the right place (i.e. trachea). This technique is helpful in locating the trachea in revision cases, where fibrosis makes trachea less identifiable. In a small child, tracheal rings are very soft and can be mistaken for esophagus with a feeding tube or carotid artery. 2-0 or 3-0 silk sutures are placed around tracheal rings (2nd or 3rd) in a vertical direction, around the proposed site of tracheostomy (Fig. 110.14F). These sutures are used as traction for the tracheal wall incision. This maneuver also prevents injury to the posterior membranous tracheal wall.

With 11 number sharp blade with B.P. handle oblique incision is made over anterior wall of trachea from below upwards, to prevent damage of mediastinal structure (Fig. 110.14G). Tracheal wall is not excised in children, as done in adult. The ends of stay sutures are brought outside the skin incision on either side and fixed over neck skin with tapes (Fig. 110.14H). It helps in initial period of tracheostomy tube placement (Fig. 110.14I). Stay sutures are removed after one week later following the first tracheostomy.
tube change. Appropriate size of tracheostomy tube is chosen and its tip is lubricated with xylocain gelly. Now, tracheostomy is gently retracted with the help of silk thread on both sides. Endotracheal tube is clearly seen into the trachea if child is intubated and or ventilating gases are coming out of it. Anesthetists is asked to withdraw the endotracheal tube, upto the upper edge of the tracheostoma. Tracheostomy tube is placed through the tracheostom. Without disturbing the endotracheal tube position, it is disconnected. Ventilation is now done through the tracheostomy tube. Anesthetist check the air entry on both sides of lungs. After confirmation of proper positioning of tracheostomy tube, endotracheal tube is removed.

Tracheostomy tube is secured in position with 1.0 silk and tape. Loose sutures are placed around the tracheostoma, and dressing done. Care of tracheostomy is required postoperatively. In initial few days, patient had lot of secretions, due to irritation of trachea by the tracheostomy tube and previous chest infection; pooled section due to obstruction. Frequent suctioning of the tracheostomy tube is required. Tracheostomy tube should be changed, at least once in a week. Patient’s relatives should be taught about the care of tracheostomy tube.

Points to remember during tracheostomy:
- Patient neck should be extended.
- Incision should be adequate, so that tracheal position can be palpated each time before blunt dissection.
- Do not resect the anterior wall of trachea, only make oblique incision to prevent post-decanulation problem.

**Lateralization Procedures**

It can be divided into two broad categories: (1) static or vocal cord lateralization techniques and (2) dynamic or reanimation techniques. Static techniques employ excision of laryngeal tissue (vocal cord or the arytenoids cartilage) and mechanical lateralization of the vocal cord. Surgical widening of the glottis must balance voice and airway patency. The lateralization of the vocal cord can be accomplished using a transoral arytenoidectomy mobilization technique or with an open laryngofissure technique. Laser arytenoidectomy or cordectomy is relatively difficult in children in comparison to adult because of its small size. Also there are higher rate of later failures in children because of scar formation and the smaller glottic diameter in children.

**Transverse Partial Laser Cordectomy** *(Ventriculotomy)*

It is performed through suspension microlaryngoscopy using the CO₂ laser has shown promise in children with bilateral vocal cord paralysis (VCP). In this technique, a posterior triangular wedge of the posterior one-third of the paralyzed true vocal cord, false cord, and ventricle is delineated. The dissection is carried out laterally to the level of thyroid cartilage, with vertical extension from the level of the false vocal cord to the immediate undersurface of the true vocal cord (Fig. 110.15).

**Reanimation Techniques**

It include phrenic nerve to recurrent laryngeal nerve anastomosis, phrenic nerve to posterior cricoarytenoid muscle, and omohyoid nerve muscle pedicles. It is still a theoretical and experimental approach to VCP in children.

**Unilateral Laryngeal Paralysis**

Children usually adjust well to persistent, unilateral vocal cord paralysis with little sequelae. It is uncommon for a child with unilateral laryngeal paralysis to require a tracheostomy. Laryngeal augmentation procedures and thyroplasty techniques are not indicated in infants and young children. When unilateral vocal cord paralysis contributes to poor voice production, the treatment of choice remains speech therapy.
**SUBGLOTTIC STENOSIS**

Subglottic larynx is the region extending from the insertion of the conus elasticus into the free edge of the vocal cords above to the inferior margin of cricoid cartilage below. Subglottic stenosis could be due to *congenital* or *acquired* causes.

**Congenital Subglottic Stenosis**

It is the third most common congenital laryngeal anomaly after laryngomalacia and vocal cord paralysis. However, it is the most common congenital laryngeal abnormality causing serious respiratory obstruction and requiring a tracheotomy in infants. By definition, congenital subglottic stenosis exists when this anatomic area has a diameter of less than 4 mm in a full term newborn or less than 3 mm in a premature infant, in the absence of endotracheal intubation or other apparent cause. It may also be a component of the acquired stenosis seen after prolonged neonatal intubation. Subglottic stenosis may be associated with other congenital anomalies, such as vocal cord paralysis or Down’s syndrome.

Congenital subglottic stenosis is due to a defect in the development of the conus elasticus or cricoid cartilage. The most common abnormality is generalized circumferential stenosis of the cricoid cartilage (Fig. 110.16).

It may present with various degrees of symptomatology ranging from minimal airway obstruction to severe airway obstruction at birth. Recurrent croup is another common presentation for congenital subglottic stenosis. It affects males twice as often as females. The usual symptoms are biphasic stridor and a weak cry from the decrease in airflow.

Lateral and anteroposterior radiograph may help in diagnosis. Patients have a classic *hourglass* narrowing or *squared-off* configuration on this portion of the airway in an anterior posterior cervical airway radiograph. Flexible fiberoptic laryngoscopy should be performed to rule out other glottic or supraglottic pathology, such as vocal cord paralysis or laryngomalacia. Endoscopy under general anesthesia is necessary to confirm the diagnosis, plan further therapy and evaluate for other coexistent lesions. Typically, the larynx should admit an endotracheal tube that allows an air leak of 20 cm of water pressure or less around the tube.

Most children with congenital subglottic stenosis don’t require any open operation. The child should receive aggressive medical therapy during upper respiratory infections to avoid intubation or tracheostomy. Severe cases may require tracheostomy or laryngotracheal reconstruction using costal cartilage grafting for expansion of the subglottic airway.

**Acquired Subglottic Stenosis**

Acquired subglottic stenosis is a complication of medical therapy and is generally more severe. Endotracheal tube intubation is the most common cause. Other causes are external trauma, high tracheostomy, cricothyroidotomy, infections, burn, tumor and dystrophic cartilage.

In children, the subglottic region is prone to injury from endotracheal tube intubation, because, (1) Complete circular cartilaginous ring at cricoid, prevents outward extension of edema, (2) Lining epithelium (pseudostratified ciliated columnar) is delicate and tends to get traumatized easily, (3) Subglottic mucosa has loose areolar tissue that allows edema to develop easily and quickly, and (4) The subglottic region is the narrowest part of the pediatric airway.

The pathophysiology is well described. The endotracheal tube causes pressure necrosis at the point of interface with tissue, leading to mucosal edema and ulceration. This causes mucociliary stasis leading to secondary infection and perichondritis. Healing occurs...
by secondary intention with granulation tissue proliferation and deposition of fibrous tissue in the submucosa. Primary healing of laryngeal injury is hindered by the presence of loose and mobile subglottic mucosa, poor blood supply of the cartilage, and constant motion of the larynx associated with swallowing and neck movement.32

Duration of intubation is the most important factor in the development of laryngeal stenosis.33 Premature infants tolerate more prolonged intubation (weeks rather than days) due to relative immaturity of the laryngeal cartilage, rendering it more pliable and the high location of the neonatal larynx with its posterior tilt and funnel shape. To prevent stenosis in children, the tube size should allow an air leak at 20 cm water pressure if possible. Polymeric silicone and polyvinyl chloride are considered safest materials for prolonged intubation. Nasogastric tubes can cause pressure necrosis and cricoid chondritis. Coexistence of endotracheal and nasogastric tubes may increase laryngeal complications.33 Besides, systemic factors and nursing care also affect the outcomes.

Diagnosis

History and Physical Examination: In acquired subglottic stenosis, symptoms usually occur 2 to 4 weeks after the original insult. There is biphasic stridor. Symptoms gradually progress with increasing respiratory difficulty, dyspnea and air hunger. The cry and voice may not be affected till the true vocal cords are involved. Dysphasia and feeding abnormality with recurrent aspiration and pneumonia can occur. Auscultation should be performed to assess air entry, and of the anterior part of the neck to look for restricted air movements at a particular level of the upper airway.

Radiologic Evaluation

Radiography helps assess the exact site and length of the stenotic segment, especially for totally obliterated airway (Fig. 110.17). Also, the lower tracheal air column and the bronchial air column should be evaluated for the possibility of further distal lesions. Xeroradiography (selenium-coated charged plate is used) has a better tissue—air interface and therefore enhances the edge and better documents soft tissue details than does computed tomography (CT). CT examination may be used to determine the degree of loss of cartilaginous support of the cricoid. MR imaging of the neck and chest is required for suspected coincidental vascular lesion. In presence of swallowing or feeding disorders a modified barium swallow is essential.30

Endoscopic Evaluation

Flexible Endoscopy: Vocal cord function, as well as general dynamic motion of the larynx, may be evaluated in the awake patient if possible. Examination should include both nares, the hypopharynx, supraglottis and glottis. Hypopharyngeal visualization assesses the degree of hypopharyngeal tone and degree of hypertrophy of tonsils. The supraglottis is assessed for edema, erythema, or a cobblestone appearance suggestive of gastrolaryngopharyngeal reflux, and for laryngomalacia.34 Flexible retrograde tracheoscopy through the tracheotomy site may provide useful information in some cases.

Rigid Endoscopy: It should be performed under spontaneous ventilation anesthesia. The subglottis, if patent is best evaluated using a Hopkins rod telescope of appropriate size, with the determination of site (anterior, posterior, and circumferential), maturity, length, and consistency of the obstruction (Table 110.6). When assessing vocal cord function it is
important to realize that laryngeal neuromuscular function changes with growth. Very young infants may exhibit laryngeal dyskinesia and transient unexplained vocal cord paralysis, including paradoxical vocal cord movements.34

Evaluation of Gastroesophageal and Gastroaryngopharyngeal Reflux

Presence of gastroesophageal reflux (GER) and gastroaryngopharyngeal reflux (GLPR) is likely to play a role in the development and exacerbation of subglottic stenosis and may affect adversely the successful outcome of laryngotracheal reconstruction (LTR). Treatment should be done simultaneously.

Functional Endoscopic Evaluation of Swallowing

Dysfunctional feeding may complicate airway reconstruction by increasing the risk of aspiration postoperatively. This can be assessed by
1. Videofluoroscopic swallowing studies (VSS),
2. Functional endoscopic evaluation of swallow (FEES).

Pulmonary Function Test

Maximum inspiration and expiration flow rates, flow volume loops, or pressure flow loops show characteristic changes in upper airway stenosis and can be used to compare the postoperative results with preoperative values.

Voice Analysis

Psychoacoustic evaluation and acoustic analysis of the voice may be used to establish the degree of vocal abnormality before surgery and compare it after surgery.

Management

Selection of the proper therapy should be individualized according to pathologic findings, patient age, degree and consistency of stenosis.

Patient with mild obstruction may be observed. If patient develops respiratory infection, it should be treated aggressively with antibiotics, and steroids. If airway symptoms continue or worsens, then surgical intervention is required.

Tracheostomy

Usually done below the stenotic segment. Smallest tube that permits adequate ventilation should be used. This allows air leakage to occur to avoid injury to the tracheal mucosa and simultaneously preserve phonatory potential. In cases of congenital subglottic stenosis, the cricoid may grow and allow decanulation within 2 years. The child with severe subglottic stenosis may be completely tracheostomy dependent. Mortality rates in children with complete subglottic stenosis and tracheostomy is very high (from 5 to 24%). Hence, most authors propose some type of intervention to allow decanulation.

Endoscopic Management

Dilatation

Usually performed with round, smooth dilators. We use red rubber dilators (Rouch). Dilators are kept on warm water for few minutes to become softer. The maximum size of dilator to be used depends upon the expected size of lumen of subglottis, according to age of the patient. After the procedure, mitomycin-C is applied over the raw area for few minutes. Corticosteroids are also used locally or systemically after the dilatation. Balloon dilatation has also been used in subglottic stenosis in children. Dilatation is not recommended for mature, firm stenosis or cartilaginous stenosis.

Scar Excision: Endoscopic scar excision is done with microcatorization, cryosurgery, serial electrosurgical resection and CO₂ laser. CO₂ laser is more popular because of its precision and minimal damage to healthy areas. The laser is helpful in early or mild subglottic stenosis. Laser techniques have been refined

to excise scar tissue using serial microtrapdoor flaps, preserving airway mucosa (Figs 110.18 and 110.19A to D).

Cases involving circumferential subglottic scarring, scarring of the interarytenoid area, vertical scar extending more than 1 cm, or tracheomalacia should not be treated with endoscopic management alone and usually require open surgical repair. Endoscopic management is also contraindicated if laryngeal framework is significantly deficient.

**External Surgical Reconstruction**

There are two broader groups of surgical options that are available for laryngotracheal reconstruction externally—expansion surgery with or without prolonged stenting and resection surgery with or without prolonged airway management. Usually grades III and IV lesions require external methods.

Expansion of the laryngotracheal airway can be done in various ways.

1. Splitting the stenosed anterior segment of cricoid lumen and associated upper few rings of trachea if stenosis is primarily involving the anterior subglottic area.
2. Combined laryngofissure and posterior cricoid division for persistent posterior glottic pathology or primarily posterior subglottic pathology.
3. Combination of the above procedure.

**Anterior cricoid split operation** has been used for congenital subglottic stenosis (Fig. 110.20). Criteria for patient selection are:30

1. Extubation failure on at least two occasions secondary to subglottic laryngeal pathology.
2. Weight of the patient should be greater than 1500 gm.
3. Off ventilator support for at least 10 days before procedure.
4. Supplemental oxygen requirement less than 30%.
5. No congestive heart failure for at least 1 month before procedure.
6. No acute respiratory tract infection.
7. No antihypertensive medication for at least 10 days before the procedure.

Complications of anterior cricoid split and ICU management include malposition of the endotracheal tube, accidental extubation, persistent tracheocutaneous fistula, and subcutaneous edema.

Various types of grafts; autologus costal cartilage (Figs 110.21A to E), ear cartilage, free thyroid cartilage

---

**Fig. 110.18:** Lateral view of larynx and subglottis showing vertical thickness of subglottic stenosis and horizontal incision in the proximal aspect of the stenosis

**Figs 110.19A to D:** A. Horizontal incision made with laser in the superior portion of the scar, B. Submucosal flap raised, and scar is vaporized with the laser proceeding distally in the subglottis, keeping in the submucosal plane, C. Vertical mucosal cuts are made, D. Inferior based microtrapdoor mucosal flap replaced in its position after underlying scar was vaporized.
grafts, composite nasal cartilage grafts, hyoid bone – muscle flap, free hyoid bone has been described. The purpose of graft is to augment the lumen and or to support the laryngotracheal framework, if deficient. In children, autologus costal cartilage is the graft material of choice. Cartilage grafts are contraindicated in unstable diabetic patients and patients on continuous steroid therapy.

Stents: Stents are usually used after reconstruction of the chronic stenosis. Stents counteract scar contractures and promote a scaffold for epithelium to grow. It prevents disruption during physiological movement of larynx and trachea, e.g. swallowing and coughing. In single stage laryngotracheal reconstruction, endotracheal tube is used as a stent for 7-14 days. Short-term (4-6 weeks) stenting is useful in mild subglottic stenosis. Long-term (more than 2 months) stenting is indicated for severe or complete subglottic stenosis, for poor graft stability, or with placement of most posterior cricoid graft.

Selection of the proper stent is done, keeping in mind, the material and its size. The location of the stenosis and duration to be kept is also very important. A variety of stents have been used, including finger cots, (made from surgical gloves), Montgomery T-tubes, polymeric silicone sheet rolls, and Aboulker prosthesis. Silastic sheeting in “Swiss roll” exerts a constant gentle pressure during healing but is associated with excessive granulation tissue formation. The Cotton-Lorenz stent, a variation of the aboulker stent, is the stent of choice in children in western countries. At All India Institute of Medical Sciences, we use Montgomery silicon T-tube because it is easily available here.

Montgomery T Tube is made up of silicon, is soft with little tissue reaction. It is self secured and allows normal respiration and speech.

Cotton-Lorenz stent is available in various sizes (from 7 to 16 mm outer diameter). It is made of highly polished polytef, which is harder, provides better support, is more inert than silicone, and does not adhere to tissue. A laryngofissure may be required because the superior tip of the stent should be inserted at the level of the superior edge of the arytenoid. Stent may be fixed using a Hollinger tracheostomy tube (Figs 110.22A and B).

Single Stage Laryngotracheal Reconstruction

This implies the use of cartilage grafts to obtain stability of the reconstructed airway and compress the prolonged stenting period of traditional methods into a briefer period endotracheal intubation. It is indicated primarily in subglottic stenosis without significant obstructions in the trachea or significant tracheomalacia. It may include all types of cricoid
Pediatric Surgery—Diagnosis and Management

Cricotracheal Resection with Thyrotracheal Anastomosis

The results are superior due to complete resection of the stenotic segment with restoration of a lumen using a normal tracheal ring, preservation of normal laryngo-tracheal support structures and full mucosal lining thus minimizing or preventing granulation tissue and restenosis. Due to absence of widening of anterior commissure by graft, voice quality is good in cricotracheal resection anastomosis. Cricotracheal resection is used when the stenosis is entirely subglottic or upper tracheal with a normal lumen of at least 10 mm below the glottis.

SACCULAR CYSTS AND LARYNGOCELE

Laryngeal saccule is a pouch that opens into the laryngeal sinus ascends laterally between vestibular fold and thyroid cartilage, occasionally reaching the cartilage’s upper part. Normally secretions from the saccule lubricate true vocal cords. Laryngocele is an abnormal dilatation of saccule, is filled with air and communicates with internal laryngeal lumen; whereas saccular cyst is filled with thick, mucoid fluid, and usually doesn’t communicate with internal laryngeal lumen. These children typically present with stridor that begins soon after birth and 20% require emergent airway intervention.

Soft tissue lateral radiography of the neck shows a cyst in all cases. CT may be helpful in determining the extent of these lesions. The diagnosis can be confirmed only at the time of direct laryngoscopy. Surgical management of saccular cysts include endoscopic marsupialization using CO₂ laser or with sharp dissection, aspiration and incision drainage. There is high recurrence after endoscopic marsupialization in comparison to excision via laryngofissure.

Laryngoceles typically cause intermittent symptoms during acute inflammation or infection. For internal laryngocele treatment usually is not required, although endoscopic deroofing can be done if symptomatic. External and mixed laryngocele require open excision (Figs 110.23A to C).

LARYNGEAL CLEFTS

Posterior laryngeal cleft is rare and is frequently missed. They can involve the entire tracheoesophageal spectrum or be isolated to the posterior larynx. It is due to arrested medial fusion of the lateral aspects of the laryngo-tracheal groove. Posterior laryngeal clefts may be an isolated anomaly or associated with other congenital anomalies, e.g. VATER association (vertebral, anal, tracheal, esophageal and renal anomalies), tracheoesophageal fistula, esophageal atresia, cleft lip and palate, congenital heart defects (transposition of great vessels), gastrointestinal anomalies (imperforate anus, rectal stenosis, meckel’s diverticulum), genitourinary anomalies (hypospadias, hypoplastic kidneys), subglottic stenosis, Hamartomas, G syndrome (Opritz-frias syndrome), Pallister-Hall syndrome or BBB syndrome (hyperterolism – hypospadias syndrome).

Depending on the extent of the cleft, the cardinal presenting feature, especially with oral feeding, is aspiration, which causes choking, and cyanosis. Stridor is unusual, when present; it is usually caused by tracheobronchial obstruction from aspirated secretions. There may be radiographic evidence of
Pediatric Larynx and Trachea

Benjamin and Inglis (1989) classified type I as a supraglottic interarytenoid cleft above the vocal cords, type II as a partial cricoid cleft, type III completely involving cricoid with or without extension into part of the tracheal esophageal wall and type IV as a laryngotracheal esophageal cleft (Fig. 110.24). For definitive diagnosis, careful direct microscopic laryngoscopy and esophagoscopy is required. Findings may be missed easily during evaluation, hence a laryngeal probe should be used to separate the redundant mucosa between the arytenoids and palpate for a possible cricoid defect. The diagnosis can also be confirmed by examining the patient under general anesthesia. The typical finding is that despite the endotracheal being in situ the whole length of vocal cord is visible and the tube appears partly or completely buried between the arytenoids.

A 93% mortality rate is associated with laryngotracheal esophageal clefts with significant intrathoracic involvement. A 43% mortality rate however is associated with clefts limited to the laryngeal region. Surgical repair must be undertaken in all cases of symptomatic posterior laryngeal cleft.

Repair of laryngeal cleft can be done, depending upon severity, through endoscopic, anterior laryngofissure, lateral cervical or thoracotomy approach. To improve results of surgery in severe cases, use of interposition tibial periosteum graft, and extracorporeal membrane oxygenation have been described (Figs 110.25A to D).

LARYNGEAL WEBS AND ATRESIA

Laryngeal web, subglottic stenosis and congenital laryngeal atresia result from different degrees of failure of the epithelium’s resorption during the seventh and eighth weeks of intrauterine development. Webs occur primarily at the level of the glottis. Other types include the posterior glottic web, causing interarytenoid vocal cord fixation, subglottic webs, which may occur with or without cricoid cartilage involvement and subglottic stenosis; and very rarely supraglottic webs. Complete
atresia is the rarest of these lesions and causes immediate respiratory obstruction at birth unless there is a concomitant tracheoesophageal fistula or if the obstruction is relieved by tracheostomy.

Majority present with an abnormal cry or voice, respiratory distress, and stridor. Laryngeal webs always should be considered in children with a congenital history of hoarseness and recurrent cough presenting before 6 months of age. Many patients have associated abnormalities of other systems, principally of the upper respiratory tract, most often subglottic stenosis (Benjamin B 1998).

The diagnosis of laryngeal webs or atresia is made by fibreoptic laryngoscopy or direct endoscopy under general anaesthesia. A lateral radiograph or xeroradiogram may give valuable information about the anterior thickness of the web, the presence or absence of congenital subglottic stenosis and the site of a subglottic we. CT scan is advisable to assess involvement of laryngeal skeleton.

Surgical management includes endoscopic management versus open laryngotracheal reconstruction. Small limited webs may be treated endoscopically by dilatation, microsurgical excision or laser excision. Recurrence after the surgery can be prevented by staging the procedure, repeated use of dilators, endoscopic insertion of a keel, or using sutures through the cut edge of the web. A thick anterior laryngeal web or one extending into the subglottic space requires a tracheostomy followed by a laryngofissure and insertion of a keel at the anterior commissure or laryngofissure and possible costal cartilage graft and stents. Posterior interarytenoid webs alone usually don’t require any kind of surgery, unless associated with other congenital anomaly (subglottic stenosis, dysmorphic facies or midface hypoplasia). Most patients are managed with watchful waiting or tracheostomy with subsequent decancellation after 3 to 5 years.

SUBGLOTTIC HEMANGIOMA

Hemangiomas are only present at birth 30% of the time, with the majority presenting within the first few weeks or months of life. About 80-90% will present within the first 6 months of life. About 50% will have lesions elsewhere, usually cutaneous. Yet only 1-2% of children with cutaneous hemangiomas also have subglottic hemangiomas. Females are more affected than males (2:1). The natural history of hemangioma is one of rapid growth for 8-18 months (i.e. the proliferative phase) followed by a slow regression (i.e. the involutive phase) over the next 5-8 years. About 50% show complete regression by 5 years and 70% by 7 years. One case of malignant transformation of a subglottic hemangioma has been reported.

The lesion is usually localized to the subglottic region on one side as a sessile, fairly firm and compressible pink, red or bluish lesion that is poorly delineated from the surrounding tissues. However, if there is any doubt about the diagnosis, biopsy should be performed. With precautions taken to maintain the airway in the unlikely event of excessive bleeding. Preoperative fluoroscopy or anteroposterior radiographs of the neck may demonstrate an asymmetric subglottic narrowing, however tumours or subglottic cysts may also present with the same radiographic characteristic. Besides airway obstruction, subglottic hemangiomas associated with compound hemangioma or multiple large lesions may be associated with high cardiac output failure or
Kasabach-Merritt syndrome resulting from platelet sequestration and destruction as well as consumptive coagulopathy.

For symptomatic patients management options include tracheostomy, laser ablation using CO₂ or potassium titanyl phosphate (KTP) laser, external beam radiation, radioactive gold grain implantation, cryotherapy, sclerosing agents, corticosteroids therapy, (systemic or intralesional injection), open surgical excision and interferon alpha –2α. The tracheotomy allows the tracheal lumen to enlarge with growth of the child and giving the hemangioma an opportunity to involutes spontaneously. However, tracheostomy may have to remain in place for 3 to 4 years and has associated morbidity (tube obstruction, language delay and mortality). Radiotherapy has a cure rate of 93%, but the risk of secondary malignancies and often more acceptable alternatives now preclude their general use. The most common intervention is CO₂ laser ablation. However, 20% subglottic stenosis rate following laser excision has been reported in a large series of cases. Corticosteroid therapy is considered by some authors as an alternative method of managing airway hemangiomas, either alone or in conjunction with laser therapy. Ohlms et al (1994) suggest the use of interferon alpha –2α when traditional therapeutic modalities such as steroid and laser therapy fail, and especially when subglottic hemangioma is massive.

Open surgical excision has also been advocated. This technique may be used when airway obstruction is significant enough to require a tracheostomy.

**MISCELLANEOUS ABNORMALITIES OF LARYNX**

**Bifid Epiglottis**

Bifid epiglottis is a rare laryngeal anomaly may be associated with other laryngeal abnormalities or congenital syndromes. Patients with bifid epiglottis should undergo an endocrine evaluation because of the possibility of associated hypothyroidism or hypothalamic abnormalities. The presenting symptoms are usually feeding difficulties owing to aspiration and respiration compromise owing to enfolding of the two epiglottic halves. In cases of severe airway obstruction, surgical management is necessary that includes tracheostomy and amputation of epiglottis.

**Cri du Chat Syndrome**

It is due to partial deletion of the short arm of chromosome 5. The newborn infant has a cry similar to that of a cat’s mew. There is a characteristic congenital high-pitched stridor. Classically, upon inspiration, the vocal cords of these patients have a narrow diamond-shaped appearance. On phonation, the posterior part of the larynx shows an open triangle, probably caused by paralysis of the interarytenoid muscle. Other associated abnormalities include microcephaly, hypertelorism, generalized hypotonia, severe mental retardation and low-slung ears with a beak-like profile. In general, the prognosis is poor.

**Cystic Hygromas (Lymphangiomas)**

These are congenital developmental malformations of lymphatic vessels present at birth or within the first 2 years of life. Most commonly they involve the soft tissues of the lateral neck as diffuse, compressible, smooth, non tender masses. They are usually asymptomatic, sometimes compress tissues of the pharynx and larynx to produce airway obstruction. A cystic hygroma is virtually always a supraglottic mass. Aspiration or external excision of the bulk by laser or some other modality may be required.

**CONGENITAL ANOMALIES OF THE TRACHEA**

**TRACHEOMALACIA**

Tracheomalacia is characterized by abnormal flaccidity of the anterior wall of trachea. Tracheomalacia is defined as collapse of the trachea during expiration, which results in greater than 10-20% obstruction of the airway. Primary tracheomalacia is a rare congenital deformity, caused by an inherent weakness of the cartilaginous ring (Figs 110.26A and B). Secondary tracheomalacia occurs as a result of extrinsic compression by a mass by vascular structure. It may be secondary to surgical intervention, such as tracheoesophageal fistula repair or by pressure from tracheostomy or endotracheal tube cuff.

Clinically, the patients exhibit expiratory stridor secondary to collapse of the anterior tracheal wall against the posterior membranous wall. Stridor may be present at birth, but often later on, when infant becomes more active. Patients may present with reflex apnea and recurrent pneumonitis secondary to their chronic obstruction.
Dynamic assessment of the tracheo-bronchial tree is needed to diagnose the luminal obstruction during expiration. Airway fluoroscopy (and rigid bronchoscopy) in normal condition and rigid bronchoscopy under spontaneous ventilation technique is helpful for that purpose. Barium swallow excludes any vascular compression. In cases of suspected vascular compression or cardiac anomalies contributing to tracheomalacia, MR imaging with contrast or MR-angio and echocardiography also may be warranted.

Mild cases of tracheomalacia often resolve within the first 1 to 2 years of age. In severe cases, it may be necessary to place a tracheostomy tube or stent the trachea during development. In cases of vascular compression of the trachea surgical decompression of the trachea may lead to significant improvement.

Surgical procedures, used to correct diffuse tracheomalacia include placement of internal stents, segmental resection, cartilage grafting of the trachea and external tracheal stents.

VASCULAR COMPRESSION OF THE TRACHEA

Vascular rings completely encircle the tracheoesophageal region, whereas vascular slings are non-circumferential. Patients with vascular rings present earlier than vascular slings as more severe the compression, the earlier the symptoms present. Besides stridor, these patients are more prone to recurrent respiratory infections resulting from difficult clearing of secretions past the narrowed segment.

Innominate Artery Compression

(Figs 110.27 and 110.28)

It is the most common cause of vascular compression of the tracheobronchial tree. Cases usually present within the first year of life. Signs and symptoms gradually disappear over months to years in most patients. Tracheal compression is more pronounced in the expiratory phase, often obliterating the tracheal lumen when the child coughs.

Chest radiography or airway fluoroscopy may show persistent compression of anterior trachea at the thoracic inlet. The definitive diagnosis however may be made using rigid bronchoscopy. Typically the compression is relatively short segment, located a few
centimeters above the carina. Pressure with the tip of the bronchoscope may decrease the right radial and temporal pulses.\textsuperscript{43}

In patients, with severe symptoms, aortopexy (where the innominate artery is suspended from the sternum to relieve compression over trachea) is indicated. The innominate artery may also be divided and reimplanted more proximal on the aorta to the right side so that it does not cross and compress the trachea.\textsuperscript{39}

\textbf{Double Aortic Arch}

It is the second most common cause of vascular compression of the tracheobronchial tree. In most cases, the left arch is smaller and even atretic or non-patent in some cases (Fig. 110.29).\textsuperscript{39} Bronchoscopy reveals anterior and posterior pulsatile compression of the trachea just above the carina, usually involving one or both main bronchi. Compression with bronchoscope does not affect the radial pulse. Management consists of division of the small arch.\textsuperscript{44}

\textbf{Anomalous Subclavian Artery}

An aberrant right subclavian artery passes behind the oesophagus, causing dysphagia termed \textit{dysphagia lusoria}.

\textbf{Right Aortic Arch (Fig. 110.30)}

With a right aortic arch, the aorta courses over the right bronchus, to the right of the trachea, curving downward to lie just right of the midline posteriorly. It can be similar to a vascular ring if a persistent ligamentum arteriosum or ductus arteriosum is present. Management consists of division of the
ligamentum arteriosum or ductus arteriosum to relieve the obstruction.\textsuperscript{43}

**Pulmonary Artery Sling (Fig. 110.31)**

The anomaly results when the aberrant left pulmonary artery, arises from the right pulmonary artery, encircles the trachea and passes between the trachea and esophagus. It is often associated with congenital tracheal stenosis and complete tracheal rings. If the trachea is normal, there is usually marked compression of the right main branches. Surgical reanastomosis of the aberrant vessel may not relieve the respiratory symptoms unless the tracheal abnormality is addressed.\textsuperscript{43}

**Pulmonary Artery Dilation**

Large left to right shunts can result in dilation of the pulmonary arteries, with resulting compression of the trachea and bronchi directly or by displacing the aorta against the left wall of the trachea. Pulmonary arteriopexy may relieve the compression.\textsuperscript{43}

**TRACHEAL STENOSIS**

**Congenital Tracheal Stenosis**

Three types of congenital tracheal stenosis have been described by Cantrell and Guild in 1964. (1) Segmental stenosis, (2) Funnel shaped stenosis and (3) Generalized hypoplasia (Figs 110.32).\textsuperscript{43} The association of congenital tracheal stenosis with H-Type tracheoesophageal fistula, pulmonary hypoplasia, vascular ring, skeletal abnormalities, and subglottic stenosis has been established.

Presentation of symptoms depends upon severity of disease; some present at birth, whereas others develop symptoms months later. The usual presenting symptom is stridor, classically biphasic, if stenosis is located high within the trachea or primarily expiratory if located lower in the tracheobronchial tree. Other signs and symptoms include wheezing, recurrent pneumonia, cyanosis, apnea and failure to thrive. A definitive diagnosis of tracheal stenosis usually is made by a combination of radiographic studies and rigid endoscopy. CT and MRI can be used in conjunction with endoscopy to identify intrathoracic relationships and associated anomalies. Endoscopy should be done under great caution; even minimal trauma to the stenotic segment may lead to edema and acute airway obstruction. In severe stenosis, evaluation is done under apneic technique using small 2.2 mm telescope. Passage of instrumentation through the stenosis should be avoided, unless definitive repair at that time.\textsuperscript{39}

Treatment depends upon the severity of stenosis. Because, stenotic segments appear to grow faster than normal surrounding trachea, mildly symptomatic children may be treated by observation alone. Severe stenosis requires surgery. Short segment stenosis is treated with resection and anastomosis. For more
diffuse lesions, tracheoplasty is done. These include; anterior tracheal split with pericardial patching or cartilage grafting, slide tracheoplasty and homograft tracheal transplantation. Mortality ranges from 20 to 80%.43

**Acquired Tracheal Stenosis**

Besides congenital causes, increased use of endotracheal intubation has resulted in increased incidence of tracheal stenosis although the use of low pressure, high volume cuffed endotracheal and tracheotomy tubes has been shown to decrease the rate of tracheal stenosis.45 Diagnosis and surgical management of tracheal stenosis remains a challenge. Success of any surgical procedure is predicted upon several elements—(1) Accurate topographic diagnosis of stricture(s), (2) Associated complicating factors, and (3) Appropriateness of the surgical philosophy in relation to the histopathology of induced changed.45

Tracheal stenosis caused by endotracheal intubation and/or tracheotomy can occur at any one or more of four predictable locations. (1) Strictures that occurred above the tracheotomy site were caused by a high tracheotomy, trauma to the anterior wall during tracheotomy, or intubation trauma. (2) At the level of the tracheotomy, inflammatory changes associated with infection, polyps or granulation tissue resulted in loss of cartilaginous support. (3) Granuloma formation or ulceration secondary to excessive cuff pressure below the tracheotomy site, while loss of cartilaginous support and circumferential stenosis were identified at the same level in the chronic stage of this disease. (4) At the tip of the endotracheal tube, excessive pressure against the anterior tracheal wall leads to granuloma formation and loss of cartilaginous support.

**Diagnosis**

Presentation of tracheal stenosis includes difficulty in extubation or decanulation, stridor (inspiratory and expiratory), atypical asthma, recurrent respiratory disease, poor weight gain and sometimes poor feeding.

Endoscopic evaluation with a rigid bronchoscope is the most accurate means of diagnosing tracheal stenosis and assessing its length, degree and character. The rigid bronchoscope can be placed above the stenosis while the smaller fibreoptic bronchoscope (1.9 mm outer diameter) is guided past the stenosis through the rigid bronchoscope. This arrangement allows for positive-pressure ventilation while one is examining the length and degree of distal stenosis.46

Associated aerodigestive anomalies such as laryngomalacia, laryngeal clefts, subglottic stenosis, tracheoesophageal fistula, hypoplastic and lung agenesis, severe gastroesophageal reflux, vascular compression when only complete tracheal rings are suspected or complete tracheal rings when only external vascular compression is noted.

**Radiologic Evaluation**

Lateral neck and the anteroposterior view under high kilovoltage with maximal inspiration and expiration is done. Fluoroscopy is useful in cases of suspected or proven tracheomalacia.

Barium esophagrams may show pharyngeal incoordination, vascular rings, pulmonary slings, occult tracheoesophageal fistulae and gastroesophageal reflux. Some advocate laryngotracheogram (using tantalum dust, Dionosil or suspension of 50% barium in isotonic Saline) to determine the length or thickness of the stenosis, its degree of airway occlusion, the distance between its upper edge and the free edge of the vocal cords or anterior commissure and determining the vocal cord fixation or paralysis. But there is a risk of life-threatening mucosal reaction to contrast material.

Airway fluoroscopy provides a dynamic view of the airway below the vocal cords to screen for isolated as well as synchronous lesions of the lower airway. They have a sensitivity of 80% for subglottic, 73% for tracheal and 80% for bronchial sites of obstruction.47 The main disadvantage is increased radiation exposure (10 rads).

Computed tomography and magnetic resonance imaging provide accurate evaluation of the airway. The contrast and spatial resolution of CT is superior to other cross-sectional imaging techniques such as MR imaging, and compares favorably to fibreoptic endoscopy.

**Surgical Management of Tracheal Stenosis in Children**

The surgical management of tracheal stenosis in children can be categorized as endoscopic or open techniques.
Endoscopic

Dilation by balloon or rigid dilators, laser vaporization of scar with or without intraluminal stent placement. Postoperative intraluminal granulation tissue can be controlled by endoscopic application of steroid or mitomycin-c.

Dilation

In cases of early, soft stenosis, before mature, firm stenosis has developed. Rigid dilation is done by Jackson, maloney or by red-rubber (rousch) rigid dilators. Balloon tracheoplasty is less traumatic (Figs 110.33A and B).

Laser Excision

Lesions most amenable are soft granulation and short segments of mature fibrosis. Laser excision of high grade stenosis sacrifices a significant amount of epithelium resulting in further contraction and restenosis of the airway. Preservation of the epithelial islands either by radial incisions and dilation or by elevation of mucosal flaps, followed by ablation of underlying fibrous tissue has been advocated for success. CO₂ laser, and KTP laser is used commonly for this purpose (Figs 110.34A to D).

Stents

For stenoses that are not suitable for segmental resection or expansion, in high surgical risks, after dilation of stenosis, or the likelihood of progression of the neoplastic stenosis. Generally airway stents can
be subdivided into two categories—metallic and silicone. An important advantage of silicone stents is the relative ease of removal once no longer clinically necessary. Deaths have been reported during attempts at metallic stent removal. Other problems associated with stents include obstruction, granulation tissue formation, infection, malposition, and perforation. In our Institute, we use Montgomery silicone T-tube in pediatric age group.

A. Open technique: Various surgical techniques ranging from tracheoplasty to tracheal resection and reanastomosis can be used when conservative therapy fails or is deemed inappropriate.

Other materials proposed as augmentation patches for tracheoplasty are esophagus; solvent preserved dura, periosteum, pulmonary homograft, aortic homograft, cartilage from either chondral or auricular sources or omentum.

**Rib Cartilage Tracheoplasty**

Autologous cartilage derives its nutritional support through diffusion and can survive without a direct vascular supply. The approach to the trachea may be by cervical incision, thoracotomy or sternotomy, depending on site and extent of the stenosis. Physiologic gas exchange during tracheal reconstruction is maintained either by a previously placed tracheotomy or endotracheal intubation or by cardiopulmonary bypass. Rigid bronchoscopy is performed to identify the degree of stenosis and its proximal extent. After exposure of the trachea, a 25 gauze needle is inserted in the midline of the anterior wall at the proximal end of the stenosis, guided by bronchoscopic visualization. A scalpel is used to open the anterior wall of the stenotic segment down through the distal end of the stenosis as identified by the bronchoscopic examination. The external appearance of the trachea can underestimate the extent of the stenosis. A segment of rib-cartilage is harvested from the sixth or seventh rib. The perichondrium is preserved on the anterior surface of the rib graft and becomes the luminal surface of the airway. The graft is secured in place with interrupted stitches of nonabsorbable monofilament suture. Care is taken to avoid exposure of any suture material to the lumen of the airway in an attempt to minimize the subsequent formation of granulation tissue. The endotracheal tube is again removed and repeat bronchoscopy is done to confirm the adequacy of the reconstruction and clear any retained secretions. The endotracheal tube is replaced, with the distal end of the tube positioned proximal to the distal end of the cartilage graft (Figs 110.35A to H).

During postoperative period, the patient is kept under heavy sedation with the addition of muscle relaxants if necessary to minimize the motion of the endotracheal tube. Approximately 7-10 days after operation, the patient is returned to the operation theatre for examination with rigid bronchoscope after removal of the endotracheal tube. If necessary, granulation tissue is removed. If the airway is believed to be stable and adequately healed, the patient is extubated. If the granulation tissue is believed to be excessive or if healing is judged inadequate, the patient is extubated. This process continues until extubation is successful.

Problems with cartilage (Rib) Tracheoplasty are granulation formation, difficult to achieve an airtight seal due to rigidity and displacement into the lumen.

**Pericardial Patch Tracheoplasty**

After a standard median sternotomy, pericardial patch is harvested from the diaphragmatic surface to the reflection of the pericardium at the great vessels. The patch is typically 4-6 cm in length and 2-3 cm in width. After cardiopulmonary bypass has been initiated an 11 blade is used to incise the trachea through the extent of the tracheal rings under bronchoscopic guidance. The pericardial patch is sutured in place using interrupted 6.0 vicryl suture. The suturing starts at the most inferior aspect of the incision adjacent to the carina and is carried superiorly. This helps prevent collection of blood and secretions in the tracheobronchial tree clear. Then the endotracheal tube is reintroduced so that the tip of the tube is just above the carina. The endotracheal tube stents the patch open. Two small hemoclips are placed at the upper and lower aspects of the patch for radiographic identification of the patch location in the postoperative period. The patient is ventilated and weaned from cardiopulmonary bypass. Over the next week the patient is weaned from the ventilator and the patient is usually extubated 2-3 weeks following surgery (Figs 110.36A to C).
Figs 110.35A to H: A, B. The costal cartilage is longitudinally split, C, D. Longitudinal slits are made to obtain flexibility of the graft, E to H. Tracheoplasty in congenital tracheal stenosis using autologous rib cartilage.

Figs 110.36A to C: A, B. Harvesting pericardial flap, C. Pericardial patch stiched over tracheal stenosis site.
Advantages of pericardial tracheoplasty are; easy availability of pericardium, easy to obtain an airtight seal and its re-epithelialization with ciliated pseudostratified columnar epithelium. Mortality ranges from 17-47%. Long-term complications include prolonged hospital stay secondary to patch tracheomalacia, recurrent stenosis and exuberant granulation tissue particularly at the distal end of the trachea where the pericardial patch interfaced with the native trachea and carina.

Tracheal Autografts

The entire trachea is mobilized circumferentially. The anterior trachea is incised with a No. 11 blades through the extent of the complete tracheal rings. After this, an assessment is made as to how much trachea can be resected without causing excessive tension at the anastomosis. The excised midportion of the trachea is used as the free tracheal autograft. The two remaining ends of the trachea are anastomosed posteriorly with multiple 6.0 PDS suture, care being taken to keep the suture and knots out of the tracheal lumen. The corners of the harvested autograft are trimmed and it is anchored in place with interrupted 6.0 PDS sutures (Figs 110.37A to C). If the tracheal autograft is not sufficient, to augment the entire anterior opening in the trachea, then autologous pericardium is used to cover the remaining part (usually, i.e. superior part of the anterior tracheal opening). Tissell glue is used to seal the suture lines and the patch is checked for air leaks. Endotracheal tube is kept above the tracheal autograft for 7-10 days. Repeat bronchoscopy is done during this period, and during follow up for patency, and granulation tissue.

The advantages of tracheal autograft are— 1. The cartilage intrinsically maintains the tracheal contour, hence during postoperative period; endotracheal tube is kept above it. 2. Readily available. 3. Lined with respiratory epithelium and 4. Has potential for growth.

Complications reported with autograft are residual stenosis (21%), failure, granulation formation and operative mortality (7%).

Slide Tracheoplasty

Long segment of stenosis is divided transversely in its midpoint, a vertical anterior incision made through the full length of the upper half of the stenotic segment and a corresponding vertical slit made posteriorly in the distal half of the divided stenotic segment (Figs 110.38A to D). The right angled corners where the
vertical incisions met the transverse incision were trimmed. The ends were slid together, doubling the circumference of the trachea. This resulted in a fourfold increase in cross-sectional area of the airway. The stenotic segment was shortened by half of its length. Grillo HC (1994) has modified it by incising the upper stenotic segment vertically posteriorly and the lower segment anteriorly for the full length of stenosis.51

Problems with slide tracheoplasty are exact identification of the midpoint of stenotic segment before the initial tracheal transection. After completion of sliding tracheoplasty the spring of the tracheal rings tends to form a figure of the eight contours in cross section in 9% cases.52

Tracheal Homograft
Cadaveric trachea is harvested, fixed in formalin, washed in thimerosal (methiolate) and stored in acetone. The stenosed tracheal segment is opened to widely patient segment proximally and distally. The anterior cartilage of the stenosed trachea is excised and the posterior trachealis muscle or tracheal wall remains. A temporary silicone rubber intraluminal Stent (Dumon stent) is placed and absorbable suture secure the homograft. Regular postoperative bronchoscopic treatment clears the granulation tissue. The stent is removed endoscopically after epithelialization over the homograft (Figs 110.39A to E). Advantages of tracheal homografts are nearly circumferential tissue for reconstruction, a carina that may be used for distal reconstruction and the procedure can be repeated if required. Ciliated columnar respiratory epithelium has been shown to cover the lumen of the homograft. However, growth potential is not known.

Presently, indications for tracheal homograft reconstruction are recurrent short segment upper tracheal stenosis and as a reserve for children in whom other alternative do not seem suitable.

Tracheal Resection and Reanastomosis
Indication for tracheal resection and reanastomosis in children are– 1. Short segment (upto 30% of tracheal length).52 2. Presence of normal subglottic space. Some author feels that tracheal resection and anastomosis is the treatment of choice when feasible. Technically, the most important aspect of tracheal resection and anastomosis is providing a tension-free closure. Following endoscopy to outline the extent of the lesion, the dissection is kept to a minimum in order to

Figs 110.39A to E: A. The anterior part of trachea is removed leaving only the posterior tracheal wall and trachealis intact B, C. Homograft cut to size and sutured in place D. Dumon stent, E. Stent is placed to support the homograft internally until re-epithelialization has occurred

Figs 110.40A to C: Tracheal stenosis—resection and anastomosis
preserve the vascular supply to the trachea. It is crucial in dissecting around the trachea to dissect directly on the tracheal cartilage so as not to damage the recurrent laryngeal nerves. The head of the patient should flexed intraoperatively to help reduce tension during closure. Sutures (3-0 polyglactin, vicryl) are placed submucosally and tied extraluminally. In addition, four separate 2-0 polypropylene (prolene) sutures are interspersed along the anastomotic site to reduce tension on the anastomosis. It is important to maintain cervical flexion postoperatively, using a heavy suture extending from the chin to the chest. In children, sedation and, in some cases, neuromuscular paralysis is required for immobilization. After 24-48 hrs patients are weaned from the ventilator and extubated. Surveillance bronchoscopy is performed prior to extubation and prior to hospital discharge (Figs 110.40A to C). Results of tracheal resection and anastomosis are good.

FEATURES OF THE PEDIATRIC MUSCULOSKELETAL SYSTEM

There are quite a few differences between the pediatric and the adult musculoskeletal system. The long bones in growing children contain the growth plate or the physis at both the ends, which contributes to longitudinal growth of the bone by the process of endochondral ossification (bone formation in preformed cartilage). The physis is an area of structural weakness and it often gets separated when injured. Such epiphyseal/physeal injuries occur exclusively in the growing skeleton and can potentially cause disturbances of growth. Other disorders such as infections or tumors occurring in the vicinity of the physis may also compromise the longitudinal growth of the bone or may result in angular deformities. Conversely, growth stimulation may occur in children following trauma (as in fracture shaft of femur or infection (growth stimulation due to hyperemia in the vicinity of growth plate)). The periosteum in children is loosely adherent to the bone in contrast to adults where it is densely adherent. Consequently, the pus originating in the medullary canal can travel to the surface of the bone through the Volkmann’s canals and strip away the periosteum from the bone. This, coupled with the peculiar vascularity of the cortex in children where outer two thirds of the cortex is supplied by the periosteal vessels, results in avascularity of large segments of diaphyseal bone—the so-called "tubular sequestrum". Tumors from the medullary canal also can strip the periosteum and the triangular reactive bone formation at the corners where the periosteum is still attached to bone is called Codman’s triangle.

The bones in children are porous as they are undergoing remodeling. These bones tolerate deformation better than the adult skeleton. Consequently children may have bent bones without fracture (Plastic deformation of bones), fracture of one cortex on the tension side when subjected to bending force (greenstick fracture) or buckling of the cortex when subjected to compression (Torus fracture). The ligaments and capsular attachments are strong in children while physis or the porous bones are weak. Consequently, children sustain sprain of the ligaments or dislocation rarely, while the physeal injuries or avulsion injuries involving attachments of ligaments or musculotendinous structures are common.

Healing occurs rapidly in children and non-union is rare except in untreated avulsion fractures, displaced intra-articular fractures, fractures with inadequate bony contact due to soft tissue interposition, over-distraction (due to mal-treatment) or bone loss in compound fractures.

Malunion in children often corrects itself by remodeling. Remodeling is most evident in children who are younger, when the deformity is close to the growth plate, when the plane of deformity is close to the growth plate and when the plane of deformity coincides with the plane of motion of the nearby joint. However, the remodeling does not correct rotatory malalignments and the abnormal tilt of the articular surface resulting from injury. The different regions of the pediatric bone have propensity for different pathologies. Infection has prediction for metaphysis. Other pathologies, which favor metaphysis, are simple bone cyst, osteochondroma and osteosarcoma. Epiphysis may be affected in chondroblastoma or the
aneurysmal bone cyst while diaphysis is preferentially involved in Ewing’s tumor.

CONGENITAL AND DEVELOPMENTAL CONDITIONS

Sprengel Shoulder

Scapula occupies a high cervical position in embryo. This is also evident by the nerve supply of the muscles acting on scapula (C3-5). During the development, the scapula descends down. Failure to descend results to a variety of abnormalities such as unilateral high scapula (sprengel shoulder) or Klippel-Feil syndrome where bilateral high scapulae are associated with fusion of cervical vertebrae and short neck.

Sprengel shoulder is the commonest congenital abnormality of the shoulder girdle (Fig. 111.1A). It is always associated with a fibrous or bony structure extending from supero-medial border of the scapula to the lower cervical vertebrae (Omovertebral Bar)\(^6\) (Fig. 111.1B). The mild cases have no functional disability whereas severe cases may be associated with restriction of abduction at the shoulder joint.

Treatment of sprengel shoulder is done purely for cosmetic reasons.\(^7\) Surgical treatment options range from extra periosteal resection of prominent supero-medial border of the scapula with attached omovertebral bar to the repositioning of scapula inferiorly. Repositioning is a major undertaking and is reserved for patients with severe elevation of one scapula without wide spread congenital abnormalities. The operation should not be delayed beyond the age of 5 or 6 years after which the secondary changes compromise the results.

Obstetric Birth Palsies

Brachial Plexus injury arising from obstetric injury to the newborn is the most important and serious injury. It commonly occurs in primigravida mothers with large babies after difficult deliveries. Fractures of clavicle and humerus may be associated. Most commonly the stretching of the brachial plexus is caused by an increase in the angle between the neck and the shoulder due to the forcible lateral flexion of the head to the opposite side. It is not uncommon for the upper limb to be completely paralyzed after birth. With passage of time, some muscles regain power and thereafter the arm assumes a characteristic deformity depending upon the resultant muscular imbalance. It is important to distinguish the traumatic brachial plexus neuropathy from osteomyelitis, septic arthritis or birth fractures as all these conditions can cause a pseudo paralysis of the extremity.

Erb-Duchenne Palsy (The Upper Arm Type)

It is the commonest palsy.\(^8\) It is caused by excessive lateral traction on the emerging head at birth resulting in increased angle between head and shoulder. It involves 5th and 6th cervical nerve roots producing weakness of deltoid, biceps, brachialis and forearm supinators. As a result, the arm and forearm assume
the characteristic posture of adduction and internal rotation at shoulder, pronation at forearm, extension at wrist and elbow and flexion of fingers (Policeman Accepting Tip).

There is usually a full range of painless motion at the shoulder. If there is no skeletal injury almost 20% cases recover completely. Adduction and internal rotation contracture develops in cases which do not improve and humeral head often subluxates posteriorly.

Treatment is expectant initially while waiting for recovery. All joints of upper limb are moved through the full range at least once a day to prevent stiffness. In refractory cases, exploration has no role, as the lesion is always a traction injury in continuity. Muscle transfers (L’Episcopo, Zachary) are described in these cases and the procedure essentially comprises of releasing latissimus dorsi and teres major (the deforming factors) and transferring them behind to the posterolateral aspect of the proximal humerus where they serve as external rotators.

In longstanding cases with complex secondary changes such as posterior subluxation of shoulder, external rotation osteotomy of the humerus can considerably improve function.

Klumpke’s Palsy

Klumpke’s paralysis affects the lower roots, C8 and T1. These patients have a flaccid hand with absence of grasp reflex in the involved extremity. The classic attitude of the limb reveals extension at the wrist and clawing of the fingers. Shoulder and the elbow are spared. Damage to the cervical sympathetic fibers may lead to Horner’s syndrome. The prognosis in Klumpke’s palsy is worse and it is often impossible to restore useful function.

Total Plexus Involvement

Involves all the roots of the plexus and the entire extremity is flaccid. The prognosis for recovery is very poor.

CONGENITAL AND DEVELOPMENTAL ABNORMALITIES OF THE CERVICAL SPINE

Klippel-Feil Syndrome (Brevicollis, Congenital Synostosis of the Cervical Vertebrae)

Klippel-Feil syndrome is the condition of congenital fusion of two or more cervical vertebrae caused by the failure of the normal segmentation of the cervical spine during the third to the eighth weeks of gestation.

These patients have short neck, low posterior hairline, restriction of neck motion and frequently associated abnormalities such as scoliosis, genitourinary abnormalities, sprenkel shoulder, deafness, ocular abnormalities, congenital heart disease and upper limb abnormalities (such as upper extremity hypoplasia, hypoplastic thumb, syndactyly, and supernumerary digits). Torticollis, facial asymmetry and webbing of neck (Pterygium colli) are also commonly associated with Klippel-Feil syndrome.

Plain X-rays show vertebral synostosis with absent or hypoplastic disk spaces. Occipitalization of the atlas may be seen.

Treatment

Majority of these patients are asymptomatic. Patients are advised to avoid trauma to the cervical spine. When degenerative changes occur, conservative treatment is adequate for most patients. However, spinal fusion may have to be undertaken in selected unstable spines with spinal cord impingement. Treatment of cosmetic aspects of this deformity has met with limited success.

Torticollis (Congenital Muscular Torticollis, Congenital Wryneck)

This is the most common neck problem in childhood. It manifests in the first 6-8 weeks of life. The deformity is caused by the ischemia and contracture of the sternomastoid muscle ostensibly due to ischemia. Head is tilted to the involved side and the chin is rotated to the opposite side. A mass is usually palpable in the neck (sternomastoid tumor) within the first four weeks of life and usually disappears by four to six months. There is a preponderance of the right side involvement (in almost 85% cases). Congenital dislocation of the hip may be associated in 20% cases.

Clinically, the contracture of muscle is associated with typical deformity and reduced range of neck motion (Fig. 111.2). Contracted sternomastoid is prominent. Facial asymmetry (Plagiocephaly—flattening of the malar prominence and a lowering of the position of eye and ear on the involved side) is present in longstanding cases. The ipsilateral occiput is flattened. Mild dorsal compensatory scoliosis may be present.
Differential Diagnosis

Differential diagnosis includes congenital cervical spine abnormalities such as basilar impression, atlanto-occipital fusion, odontoid abnormalities, etc. Tuberculosis of cervical spine, fractures of the cervical spine, inflamed cervical lymph nodes, cervical disc prolapse, extraocular muscle imbalance and hysteria are the causes of acquired torticollis and must be differentiated from the congenital variety.

X-rays are imperative to rule out bony causes of torticollis when suspected.

Treatment

The condition resolves spontaneously in about 90% patients within one year. Surgery should be undertaken after 1 year if head tilt, facial asymmetry and restricted neck motion persist.

Surgery consists of release of clavicular head and Z-plasty of sternal head (for better cosmesis, to preserve ‘V’ of neck especially in female patients). Mastoid head may be released in older patients while bipolar release or Z-plasty may be indicated in longstanding deformity. Posterior auricular and spinal accessory nerves should be carefully protected during surgery at mastoid attachment.

Facial asymmetry and limitation of motion of more than 30° usually precludes good result. However, cosmesis can be expected to improve if surgery is done even as late as up to 12 years of age.

CONGENITAL CONDITIONS AFFECTING ELBOW

Congenital Radio-ulnar Synostosis

Is characterized by bony fusion/fibrous union between the proximal radius and ulna, placing forearm in pronated position. The synostosis may be limited to the proximal third of the radius and ulna (Fig. 111.3), or may be extensive.

The condition is often bilateral. It may be associated with the developmental dysplasia of the hip, clubfoot, chromosomal abnormalities or fetal alcohol syndrome (proximal radio-ulnar synostosis, bradydactyly and camptodactyly). Clinically the child presents with lack of the forearm rotations. Proximal dislocation of the radial head (anterior or posterior) may also be present.

Treatment is difficult. Recurrences are common after surgery. Surgery should be considered if motion, function and potential growth of fused segments are interfered with. Osteotomies are performed through the fusion mass in younger children between the ages of 4 and 10 years for disabling pronation deformities. If bilateral, the dominant arm should be left pronated and the non-dominant arm is osteotomized distal to the fusion to achieve 20-30° of supination.

Congenital Absence of the Radius (CAR) (Radial Club Hand)

Is the most common long bone deficiency in the upper extremity. Disorders of the radial development lead to radial deviation of the hand, of males absent scaphoid and sometimes a hypoplastic thumb. Right hand is most commonly involved and the deformity is bilateral in 50% cases. Partial or complete absence
of the radius, with or without adjacent hand deficiencies can be seen as an isolated finding or in association with several syndromes. Fanconi’s syndrome and Vater syndrome should be considered when the radial dysplasia is bilateral. Fanconi’s syndrome is an autosomal recessive disorder with pancytopenia, brown skin pigmentation, hip dislocation and aplastic thumb. The prognosis in these cases is poor.

VATER syndrome comprises of vertebral anomalies, imperforate anus, tracheo-esophageal aplasia and renal abnormalities. Other syndromes associated with CAR are thrombocytopenia (along-with knee dysplasia), heart abnormalities (Holt-Oram-Lewis syndrome) and chromosomal abnormalities (trisomy 17). The terminal variety of CAR has absent radial ray and abnormalities of radial artery and median nerve; while the intercalary variety includes an absent radius with normal carpus and first ray.

The wrist in these patients is in radial deviation and flexion and the thumb may sometimes be rudimentary or absent (Fig. 111.4A).

Treatment consists of early splinting and passive stretching. Later, centralization of the distal wrist and hand over the ulna is performed\(^4\) (Fig. 111.4B).

Pollicization is needed for the patient without a functional thumb. A stiff, nonfunctional elbow and associated medical problems are contraindications to the surgery.

**CONGENITAL DISORDERS OF HAND**

The cause of congenital hand disorders can be genetic (30%) or environmental (10%). However, almost in two third cases the cause is unknown. The congenital hand disorders can threaten the extremity (as in case of constriction bands), can cause tethering and disorders of growth (as in club hand), or can compromise appearance and function.

**Syndactyly**

It is one of the commonest congenital hand deformities. It involves ring and middle fingers most commonly. Syndactyly can be simple, involving only the skin or complex, involving the bones.\(^5\) The fingers may be joined over the entire length of digits (complete) or over partial length (incomplete) (Fig. 111.5).

Syndactyly can be associated with several syndromes such as Apert’s syndrome (syndactyly of all digits, mental retardation, skull and facial abnormalities), Poland syndrome and Streeter’s dysplasia. Apert's syndrome is classically associated with acrosyndactyly (tips of the fingers are fused).
Treatment is release, done between 18 months to 5 years of age. Skin grafting in usually required to cover areas of skin defect after release.

**Polydactyly**

Usually involves ulnar digits. It can be one of the three types:

a. Presence of only extra soft tissues;

b. Extra digit with its own bone, tendon and cartilage and

c. Complete with its own metacarpal. Polydactyly of thumb is usually associated with a generalised syndrome. The presence of a flail extra digit is treated by excision whereas the treatment of a separate digit is for cosmetic reasons.\(^{16}\) The least developed digit is amputated; care must be taken to ligate neurovascular bundle and protect the ulnar collateral ligament.

**Congenital Trigger Thumb**

Congenital trigger thumb is caused by the stenosing tenosynovitis at A1 pulley. It presents with fixed flexion contracture of the thumb at birth and is often bilateral. It should be differentiated from the clasped thumb in which the flexion contracture is at IP as well as MCP joint of thumb and is caused by deficient extensors of the thumb. Trigger thumb can be left for one year when nearly 30% will resolve spontaneously. Splinting and passive stretching should be tried. Recalcitrant cases should be treated by surgical release of A1 pulley at the MCP joint.\(^{17}\)

**Macrodactyly**

It is non-hereditary congenital enlargement of one or more digits corresponding to the distribution of one or more peripheral nerves; thus it is also called nerve oriented macrodactyly. It occurs most commonly in the territory of the median nerve. The enlargement affects distal part more than proximal and phalanges are affected more frequently than metacarpals (Fig. 111.6).

Joint stiffness is often present as is deviation of digits due to uneven overgrowth of the borders of the digits. Condition should be differentiated from cavernous hemangioma clinically (consistency and vascular examination) and radiologically. Treatment is difficult and consists of reduction of the size of digit (osteotomies, defatting, epiphyseodesis) or amputation of the affected digit.\(^{18}\)

**Constriction Ring Syndrome (Streeter’s Dysplasia)**

It consists of congenital constriction ring/band affecting digits or more proximal part of limb. When severe these cause severe, lymphoedema or even amputation. Constriction rings are associated with club feet, syndactyly or acrosyndactyly (distal fusion of digits with cleft or separation proximally) and neurological abnormalities.\(^{19}\) Treatment consists of early release of constriction rings with multiple, circumferential Z - plasties if the edema is gross.

**Congenital Amputations**

It can result either from failure of development or Streeter’s syndrome. Amputations often involve only one or two fingers when associated with congenital constriction rings and good function is usually achieved with remaining digits. Amputation of the thumb, however, requires reconstruction with metacarpal lengthening, toe transfer or index finger pollicization. Complete absence of the hand in blind children is classically treated by a Krukenberg procedure, which involves creation of a radio-ulnar claw.
CONGENITAL AND DEVELOPMENTAL DISORDERS OF THORACOLUMBAR SPINE

Scoliosis

Scoliosis is an abnormal lateral curvature of the spine. It is a complex deformity with significant transverse and sagittal plane components. The scoliosis can be classified into two main categories:

Non-structural

Non-structural or secondary scoliosis is caused by a number of conditions, which produce an apparent scoliosis without rotation of the vertebrae. There is no true, intrinsic spinal deformity in these cases. These conditions include poor posture, hysteria, limb length discrepancy, hip deformity spasm (sciatic scoliosis) and inflammatory conditions. Non-structural scoliosis is often mobile and disappears once the underlying disorder is treated.

Structural

Structural scoliosis is associated with rotation of the vertebrae, and is fixed. It is a true, intrinsic spinal deformity. Structural scoliosis can be further divided into various types depending on the etiology:
1. Idiopathic (without a primary cause) accounts for 85% of all cases. A genetic influence is strongly suggested in these cases. There is a female preponderance for curves (5:1) and a familial tendency. It is believed to be a sex-linked trait or autosomal dominant pattern with variable expressivity and incomplete penetrance.
   Idiopathic scoliosis is divided into three types depending on the age of the patient at the time of onset of scoliosis:
   a. Infantile (before 3 years of age)
   b. Juvenile (3-10 years of age)
   c. Adolescent (from 10 years to skeletal maturity).
2. Congenital: Congenital scoliosis is caused by congenital bone malformation and the causes include diastematomyelia, hemivertebra, wedge vertebra, unilateral unsegmented bar, etc.
3. Neuromuscular: Neuromuscular or Paralytic scoliosis is caused by neuropathic causes (such as cerebral palsy, poliomyelitis, syringomyelia, spinal muscular atrophy, Fredrich's ataxia) or myopathic causes (such as arthrogryposis, muscular dystrophy).
4. Neurofibromatosis
5. Mesenchymal disorders such as Marfan's syndrome and Ehlers- Danlos syndrome.
6. Trauma
7. Metabolic disorders such as mucopolysaccharidosis
8. Miscellaneous (uncommon) causes such as bone dysplasias, extraspinal contractures, osteogenesis imperfecta, thoracic surgery, infections, tumors, etc.

Evaluation

Evaluation should establish the diagnosis assess the severity and allow the estimation of the potential for progression. These deformities are detected either incidentally on X-ray in early stages or are noticed by patient or the parents. History should provide information about the age of onset, progression and family history. Age at menarche is important for the female patients. History of pain is important as it points to an inflammatory or neoplastic cause for the scoliosis.

On physical examination, the initial screening should attempt to diagnose the constitutional disorders associated with scoliosis. The presence of café-an-lait spots suggests neurofibromatosis while body habitus in patients with Marfan's syndrome is characteristic. The patient presents with asymmetry in the level of the shoulders and waist crease. Scapula may be prominent on one side and inequality of breasts is present. The iliac crest is higher and more prominent on one side.

A rib hump is present posteriorly and it gets exaggerated on forward bending. The flexibility of the curve should be assessed by longitudinal traction and asking the patient to bend forwards. Balance of the spine should be assessed using a plumb line. Any paraspinal spasm or mass should be noted and tenderness over the spinous processes should be elicited. Leg length measurements should be taken for any discrepancy. A complete neurological examination should be performed in all cases.

Imaging

The radiographs of the spine (Lateral and AP views-errect and supine AP views in right and left bending positions) establish the extent, severity, rotation of vertebrae, presence of any bony abnormalities and
flexibility or correctability of the curve. Angle of the curve is measured by Cobb method (Fig. 111.7).

Mini Mehta’s rib-vertebra angle difference is used to predict the progression of infantile idiopathic scoliosis (a difference of > 20° between the convex and concave sides is significant). Additional X-rays can be taken to establish the skeletal maturity or the skeletal growth remaining. Various methods used for the purpose are pelvis X-ray (Risser sign), ring apophysis of the vertebra and X-ray of the wrist for bone age.

Presence of certain danger signs (such as pain, left sided thoracic curve, stiffness and midline skin lesions) are indications for additional studies.

MRI may be indicated when spinal dysraphism, diastematomyelia, infection or tumor is suspected to be the cause of scoliosis. Bone scan may be indicated in patients with stiffness and pain.

Pulmonary function test should be performed in all cases with curve measuring more than 60° to document decreased vital capacity.

The factors associated with poor prognosis are listed in Table 111.1.

### Treatment

The aims of treatment are to reduce the progression of curve, correct the curve and maintain the correction. Cosmesis is often the primary concern of the patient. Respiratory function usually does not improve after the surgery though the correction of the severe curve may check the deterioration of the respiratory function. Pain and neurologic problems are unusual and should be thoroughly investigated to rule out any intraspinal pathology. The following treatment modalities are commonly employed for the treatment of scoliosis.

**Observation:** A curve less than 20° in skeletally immature patients and less than 50° in mature patients is observed. Patients are asked to follow-up for clinical examination and radiographs every 4-6 months. If a curve in skeletally immature patient shows progression of more than 5°, these children are braced.

**Exercises:** Exercises are advised as an adjunct for the patients who are under observation or mature patients with less than 30° curve where the surgical treatment is not contemplated. Exercises are particularly useful for patients with obesity, back pain and exaggerated lumbar lordosis. Postural exercises, lateral bending and pelvic muscles exercises are commonly prescribed.

**Orthosis:** A curve more than 30° (but less than 45°) at the initial visit or more than 25° with documented progression in an immature patient is an indication for the brace treatment. The goal of brace treatment is to prevent progression of the curve. The spinal orthosis or brace is contoured to provide a corrective force to the spine while the child grows. Hence, the curve should be flexible and more than one year of skeletal growth should be remaining before the brace treatment can be instituted. Braces are not very effective for cervicothoracic curves. The following types of braces are commonly used:

1. **Milwaukee brace** or Cervico-Thoraco-Lumbo-Sacral Orthosis (CTLSO) is used for dorsal curves. It has adjustable supports made of steel and is distracted periodically. It has a chin support, which can cause deformation of teeth and malocclusion. Hence careful supervision and orthodontic care is required. CTLSO is used in curves above D9 vertebra.

### Table 111.1: Poor prognostic factors in scoliosis

- Female sex
- Onset before Menarche
- Positive family history
- Type of curve
  - Severe curve
  - Shorter curve
  - Higher curve (e.g. Cervico-dorsal curves)
  - Rigid curves
ii. Boston brace or Thoraco-Lumbo-Sacral Orthosis (TLSO) is used for thoraco-lumbar or lumbar curves. This type of brace has polypropylene shell, which is contoured to provide corrective force to the spine. It does not have the chin support. TLSO is used in curves below D9 vertebra. The braces are worn 23 hours a day till skeletal maturity and then are weaned off.

Contraindications to brace treatment are:
- Curve more than 40°
- Non-compliant patient
- Thoracic lordosis; and,
- Less than one year of growth remaining.

Considerable guidance, direction and emotional support is required to the patient and family to ensure compliance with brace treatment.

iii. Plaster: Localiser casts are applied on special tables where head and pelvic traction reduce the curve. POP jacket is applied to maintain the correction. Alternatively, hinged casts are applied with turnbuckle, which allows gradual correction of the deformity.

iv. Electrical treatment: Electrical stimulation of paraspinal muscles has been described to correct the scoliotic curve but has been shown to be less effective than brace treatment.

v. Halo-Pelvic traction is effected through adjustable steel rods fixed to the pelvis through a hoop with pins passing through the ilium and to skull using halo ring. Gradual distraction of these steel rods gradually corrects the curve.

vi. Operative treatment: Operative treatment is indicated for thoracic curves more than 40°, progressive curves and curves which fail the brace treatment. Curves, which are not cosmetically deforming especially when congenital, can be fused in situ when they show progression. Usually a posterior spinal fusion is done but when the posterior elements are deficient, anterior fusion using a rib graft can be done. The extent of fusion is decided by extent of the curve and must include neutral or non-rotated vertebrae on either end of the curve. Surgical stabilization often has to be supplemented with corrective instrumentation. Various anterior (Zielke, Dwyer, Kaneda Anterior Spinal System-KASS) and posterior (Harrington, Luque, CD, Hartshill, Moss Miami) instrumentation systems are available to correct the scoliotic curves. The newer instrumentation systems provide segmental fixation, which is more secure and derotate the curve to provide improved cosmetic results.

Spondyloysis and Spondylolisthesis

Spondyloysis implies a break in the pars inter-articularis resulting in the loss of bony continuity between the superior and inferior articular processes. Condition occurs most commonly at L5 vertebra. Spondyloysis is believed to be the results of non-union of stress fracture. Spondyloysis is commonly seen in athletes who undergo hyperextension stress activities (gymnasts, football linemen). There is also high incidence among soldiers with heavy backpacks and Eskimos. Other causes of defect in the pars inter-articularis are infection, trauma, tumor, congenital or developmental defects.

Spondyloysis can be asymptomatic or may present with activity related back pain in preadolescent or adolescent children. Pain may radiate to buttock or thigh. Physical examination reveals spasm in paravertebral muscles and hamstrings and flattening of the lumbar lordosis. The neurological examination is usually normal.

Radiographs, (especially oblique views) are helpful in visualizing the pars defect, which is seen as a “Collar” (break) in the neck of “Scotty dog”. Bone scan is extremely useful investigation for screening in a child with back pain before the plain radiographs show the bone defect. CT Scan can help in identifying the pars defect.

Treatment of spondyloysis is restriction of activities (especially hyperextension), stretching, abdominal strengthening and spinal flexion exercise and bracing for severely symptomatic patients. Severe unrelenting pain may need L5 - S1 fusion rarely.

Spondylolisthesis implies an anterior displacement of the vertebral column on a lower vertebra resulting from spondyloysis, articular process malformation or elongation of the pars interarticularis (Fig. 111.8). The condition is seen most commonly as anterior slippage of L5 vertebra over S1. Spondylolisthesis is classified, depending on etiology, into dysplastic, isthmic, degenerative, traumatic and pathologic. The severity of slip is graded according to the percentage of the superior anteroposterior extent of the vertebra below
by which the vertebral column has slipped forward; Grade I is 0-25% slip, Grade II is 25-50% slip, Grade III is 50-75% slip, Grade IV is 75-100% slip while grade V is > 100%, i.e. spondyloptosis when the vertebra above slips completely and comes to lie in front of the vertebral body below.

Spondylolisthesis occurs commonly around the adolescent spurt and progression occurs during 10-15 years of age (degenerative and pathologic varieties present late). Patients may be asymptomatic but low back pain or L5 radiculopathy may develop. A prolapsed intervertebral disc is commonly seen one level above the listhesis. Examination reveals restricted forward flexion of hips and back, hamstring tightness, flat buttocks (due to vertical sacrum) and lumbosacral kyphosis with compensatory hyper lordosis of lumbar spine. A pelvic waddle gait may be seen. Palpation of lumbosacral junction may reveal a step and an attempt to press spinous process from side to side elicits pain (due to loose lamina). Female patients may present with obstetric problems due to reduced antero-posterior dimensions of the pelvis.

Treatment

The goals of treatment are pain relief, return to activity and prevention of deformity. Grade I and II slips are treated with observation especially if they are asymptomatic. Symptomatic grade I and II slips are treated by restriction of activities, brace and physical therapy. Surgical treatment is required when patient is unresponsive to conservative treatment, shows progression of slip (especially in skeletally immature patient), when the patient has neurological deficit or when a severe degree of spondylolisthesis exists. Surgical treatment consists of in situ posterolateral fusion (from tip of transverse process to alae of sacrum—transalar fusion) from L4 to S1. Decompressive procedures, such as laminectomy (for radiculopathy or cauda equina), or Gill’s procedure (removal of loose lamina) are required for neurological deficit. Gill’s procedure (operculectomy) alone is contra indicated in children as it can lead to rapid worsening of the slip. Decompression in adults is combined with posterolateral fusion or pedicular screws and segmental fixation. The availability of modern instrumentation has made it possible even to reduce the slip and fix it in the reduced position. Surgical fusion should always be combined in these cases to control pain and progression.

CONGENITAL AND DEVELOPMENTAL DISORDERS OF THE HIP

Developmental Dysplasia of Hip (DDH)

The term DDH is used to include dysplasia without subluxation, subluxatable hip and the dislocated hip. This spectrum has been identified because of the fact that a hip normal at birth may become dysplastic in early months of life. Congenital dislocation of hip may be teratologic (occurs at 12-18 weeks of intrauterine life) or typical (occurs in perinatal period). Teratologic dislocations are characterized by severe deformity of both the acetabulum and proximal femur.

Incidence of congenital dislocation is 4 -10 per 1000 live births with considerable racial variation. DDH is more commonly associated with intrauterine crowding (other uterine packing problems such as metatarsus adductus, torticollis and calcaneovalgus are commonly associated), breech presentation (10× higher incidence), hyperextension at knees, oligohydramnios, twins and ligamentous laxity. Genetic predisposition is known and the disease often has a familial pattern (Polygenic inheritance with 10% incidence in cases with positive family history). Postnatal factors are also involved in causation especially when infants are carried in a position of extension and adduction at the hips or in a cradle board.
Almost 60% of cases of congenital dislocation of hip (CDH) are first born and it affects females more frequently than males (6:1). The left hip is more commonly affected (60%) while 20% cases are bilateral. CDH is often associated with diseases like Ehlers-Danlos syndrome, Larsen’s syndrome, myelomeningocele, arthrogryposis, etc.

**Pathology**

CDH is characterized by marked laxity of hip joint capsule. Acetabulum is often shallow and maldirected. The proximal femur has a small ossific nucleus, which appears late. There is excessive proximal femoral anteversion and coxa valga. Labrum is inverted into the joint. The capsule may have an hourglass constriction often caused by a tight iliopsoas tendon traversing the front of the hip joint. Ligamentum teres is hypertrophied. The hip joint is filled with pulvinar, the hypertrophic fibrofatty tissue.

**Diagnosis**

Every newborn should be screened for signs of hip instability. CDH is diagnosed most commonly in infants by positive Barlow test and Ortolani’s test.

**Barlow’s Test**

It is a provocative test to detect a dislocatable or subluxatable hip. Adduction and axial loading (or depression) of the femur dislocates the hip.

**Ortolani’s Test**

It is a reduction maneuver for a dislocated hip in a newborn. Elevation and abduction of the femur relocate the hip, often with an audible or palpable “clunk”. The signs of DDH change with the infant’s age. In a child older than 2 months of age, the best test is demonstration of reduced abduction (less than 60°), especially with hips flexed as the Barlow and Ortolani’s tests may no longer be positive. In older children, there may be asymmetry of the gluteal, inguinal and thigh skin folds. Bilateral dislocations usually are associated with widened perineum. The limb is shortened and externally rotated. The greater trochanter on the affected side is higher. With the knees and hips flexed and feet together, the knee on the affected side is lower (Galeazzi sign). Telescoping is strongly positive.

When the child presents after walking, limp is the main complaint. Trendelenberg test is positive.

**Radiographic Examination**

Ultrasonography of hip should be obtained in infants with suspected CDH, as it is the most sensitive investigation in the newborn. Plain X-rays are useful in children over 3 months of age. The radiological features seen on plain radiographs are shown in Figure 111.9.

1. Delayed appearance of femoral ossific nucleus on the affected (left) side. (Normally appears by 6-12 months. Compare with opposite side).
2. Lateral and superior migration of proximal femur
3. Shenton’s line is broken
4. Increased acetabular slope (Acetabular index > 40°).

Arthrography is useful in diagnosing mechanical blocks to reduction and in confirming shape and congruence of femoral head and the acetabulum. It can also be used post operatively for evaluation of the adequacy of reduction.

CT Scan is useful after ossification of femoral ossific nucleus, in children older than 6 months of age. Its real usefulness, however, remains in documenting concentric reduction when the patient is in a plaster cast.

MRI is now becoming popular as the investigation of choice before 6 months age when the proximal femoral ossific nucleus is still cartilaginous. It is useful to
diagnose CDH as well as to confirm concentricity of reduction during treatment.

**Treatment**

The management of CDH is challenging.

The principle of treatment of dysplastic hip is to obtain and/or maintain reduction to allow for normal development and it should be achieved as early as possible. Treatment of CDH is categorised according to the age of presentation.

**Birth to 3 Months of Age**

Instability in neonatal period often resolves spontaneously persistent instability is treated by gentle manipulation and reduction. The reduction is maintained in a Pavlik harness or von Rosen splint. Splintage should be continued for duration of twice the age of infant with a minimum of 2 months.

**Three Months to Eighteen Months of Age**

Children with CDH in this age group are initially treated conservatively. Traction may be continued at home to overcome hip contractures.

Closed reduction under anesthesia with adductor tenotomy if necessary and spica cast is the treatment of choice. The reduction is maintained in a Pavlik harness or von Rosen splint. Splintage should be continued for duration of twice the age of infant with a minimum of 2 months.

**Eighteen Months to Three Years**

Operative treatment is usually necessary in this age group. Pelvic osteotomy is often performed at the same time to correct acetabular dysplasia. Open reduction, usually by anterolateral approach is required. Femoral varus derotation osteotomy may sometimes have to be done in cases with excessive femoral anteversion. Postoperatively patient is kept in spica cast for 6-12 weeks followed by abduction splint for 6-12 weeks.

**Between 3 to 6 Years of Age**

Children in this age group need open reduction along with an acetabular osteotomy to improve shape of the acetabular and/or coverage of the femoral head as the capacity for acetabular remodeling is diminished by this time. After 4 years of age, acetabular osteotomy is preferred to femoral osteotomy. Figure 111.10 shows the neurovascular structures to be considered while performing an acetabular osteotomy.

Most commonly performed acetabular osteotomy is Salter's osteotomy which is useful for mild to moderate acetabular dysplasia. Salter's osteotomy improves anterior (20-30°) and lateral (10-15°) coverage. Other pelvic osteotomies performed for CDH are Pemberton osteotomy, Steele (triple innominate) osteotomy, Sutherland (double innominate) osteotomy, Wagner (dial) osteotomy and Ganz osteotomy. Figures 111.11A and B show the relationship of neurovascular structures to the sites of Salter, Pemberton, Chiari and anterior Iliac (done for extrophy of bladder) osteotomies.

In older children (above 5 years) with bilateral CDH, no surgical treatment should be attempted in view of poor results. Unilateral cases, however, can be salvaged with Chiari osteotomy or acetabular augmentation by shelf procedure (Staheli) (Fig. 111.12).

**CONGENITAL AND DEVELOPMENTAL ANOMALIES OF THE KNEE**

**Bow Legs and Genu Varum**

Normally infants have symmetric bowing of the legs which starts changing to genu valgum or knock knees after the age of 1.5 years and evolves completely into knock knees by 2.5 years. The valgus then gradually reduces to physiological valgus by 4 years.

Thus, genu varum in children less than 2 years of age is physiological and needs no treatment.

Pathological conditions, which can cause genu varum and/or bow legs include internal tibial torsion, osteogenesis imperfecta, rickets, trauma, osteochondromas and Blount’s disease.
Internal Tibial Torsion

Internal tibial torsion leads to apparent bow legs or genu varum when the child walks with the knees forward and the feet rotated externally. Examination reveals internal tibial torsion. Most cases resolve by 4 years of age. Apparent bow leg deformity disappears with resolution of tibial torsion.

Blount’s Disease (Tibia Vara)

Is a disease of unknown etiology that causes progressive bowing of the leg due to a disorder of the posteromedial tibial physis. It is particularly common in blacks and hispanic, obese male children. The disease can occur as early as 2-3 years of age. The disorder can be unilateral (in adolescents; less severe
variety) or bilateral (in infants; more severe variety). Diagnosis is based on radiographs which show decreased medial tibial physeal growth with resultant metaphyseal-diaphyseal angle abnormality. Drennan’s metaphyseal-diaphyseal angle is measured between a line joining metaphyseal beaks and a line perpendicular to the long axis of the tibia. An angle more than 11° is abnormal.

Later on, radiographs show distortion of medial articular surface and fusion of the physes. A progressive angular deformity develops as the lateral growth plate continues growing while the medial side is tethered. The characteristic defect on the posteromedial part of tibial articular surface is best shown by Siffert-katz sign (rocking in flexion of knee) and also on arthrography.

Treatment of Blount's disease is based on the age and stage of the disease. Mild cases may spontaneously improve. Severe cases need tibial osteotomy to realign the extremity and reduce the load on medial tibial plateau. Osteotomy can be performed in the metaphyseal areas of tibia, intraepiphysseal or at both the sites. Physisplasty and cartilage autografting are the latest techniques being used.

**Rickets**

It may lead to bow legs due to development of soft bones, which bow with the load of weight bearing.

Children with hypophosphatemic rickets (x-linked dominant) are often short and have bilateral symmetric bowing of legs. Treatment is with phosphates and massive doses of vitamin D supplements but it has little effect on bowing. Surgical correction may be required if the bowing is severe.

**Treatment of Genu Varum** is reassurance in cases with physiological genu varum. Other cases should be investigated for underlying pathology. Bracing (Mermaid Splints) was tried in the past but has been given up now. Surgical treatment is needed if the intercondylar distance at the knee is more than 8 cm. A tibial osteotomy below the tibial tubercle with removal of lateral based wedge and fibular osteotomy is the procedure performed.

**Genu Valgum**

Children between 2-6 years age can have a valgus angle of up to 15° as a normal physiological phenomenon. Pathological genu valgum is associated with trauma, infection, renal osteodystrophy (most common cause of bilateral genu valgum), and tumors (osteochondromas). It may often be idiopathic. Apparent genu valgum may be caused by external tibial torsion though the latter condition is uncommon. Genu valgum, if severe, may be associated with recurrent dislocations of patella (due to increased Quadriceps - "Q" angle - formed between a line joining ASIS to middle of patella and another line joining middle of patella to tibial tuberosity) and flat foot.

Conservative treatment with shoe wedges (mermaid) splints and braces is ineffective. Surgery should be considered if the tibiofemoral angle (angle between the long axis of tibia and the long axis of femur) is more than 15-20° or the inter-malleolar distance is more than 10 cm. Hemiepiphysodesis or stapling of medial epiphysis can be done for severe deformities before completion of growth. A supracondylar medial close wedge femoral osteotomy...
can be done at any age to correct the deformity. Care should be taken to avoid injury to common peroneal nerve by stretching while correcting severe genu valgum deformities.

**Bowing of Tibia can be of Three Types**

**Posteromedial**

It is commonly associated with calcaneovalgus foot as both arise from abnormal uterine positioning. Spontaneous correction is the rule and tibial osteotomy is not indicated.

**Anteromedial Bowing**

It is typically caused by congenital absence of fibula with or without the absence of lateral rays. It is the most common congenital skeletal deformity in the leg. It is commonly associated with ankle instability, equino-varus foot, tarsal coalition and femoral shortening. Significant limb length discrepancy (LLD) is commonly associated with this disorder. A Syme’s amputation is often performed in these cases in view of severe LLD.

**Anterolateral Bowing of Tibia**

Commonest cause of anterolateral bowing is the congenital pseudarthrosis of the tibia. About 50% patients have associated neurofibromatosis. Dysplasia, sclerosis and cystic changes are seen in the tibia. Ipsilateral fibula is also commonly affected. Congenital pseudarthrosis is classified into 6 types of Boyd.

**Boyd Classification of Congenital Pseudarthrosis of Tibia:**

- **Type I:** Anterior bowing and defect in tibia.
- **Type II:** Anterior bowing and hourglass constriction of tibia. Fracture develops before 2 years of age.
- **Type III:** Intraosseous cyst gives rise to fracture which occasionally is seen at birth.
- **Type IV:** Sclerotic bone leads to stress fracture.
- **Type V:** Associated with dysplastic fibula.
- **Type VI:** Intraosseous neurofibroma/schwannoma.

**Clinical Features**

- Anterolateral bowing of the tibia ± fibula
- Patient presents with pseudarthrosis usually by 2 years of age (sometimes at birth)

**Fig. 111.13:** Clinical and radiological features of Type V congenital pseudarthrosis of tibia

- Limb length discrepancy (sometimes marked)
- Varus deformity of the ankle
- Characteristic location of the pseudarthrosis is at the junction of middle and lower thirds of the leg (Fig. 111.13).

All children with any variety of this disorder need treatment. If anterolateral bowing is present without fracture, protective bracing is indicated. Corrective osteotomy of anterolateral bowing should not be done because it often leads to pseudarthrosis. McFarland posterior bypass grafting may be used in high risk patients (Sclerotic bone, hourglass constriction of tibia).

Prognosis is worse in children with a fracture at a younger age, especially before 3 years. The tendency to fractures decreases with age. If the first tibial fracture occurs at or after 8 years of age, it may heal following plaster immobilization with or without bone grafting. Principles of treatment of pseudarthrosis of tibia are excision of pseudarthrosis, correction of deformity and rigid internal fixation. Autogenous bone grafting is often added to the osteosynthesis. The various procedures used include McFarland bypass grafting; Boyd’s double onlay graft, fragmentation and IM nailing and, IM nail with onlay graft.

Vascularized fibular graft (on pedicle or free) and Ilizarov methods have been used with some success in the treatment of
pseudarthrosis. However, repeated failed attempts at reconstruction and/or marked (more than 18 cms) limb length discrepancy are indications for amputation. Surgical treatment is not often successful in this condition and the parents should be counselled about the ultimate need for an amputation if necessary.

**Congenital and Habitual Dislocation of Patella**

Congenitally dislocated patella presents at birth. The primary defect lies in the vastus lateralis (muscle and fascia), vastus intermedius and the iliotibial band. These structures are contracted and result in dislocated patella. When the patella stays dislocated, the knee does not extend from the flexed position. The treatment is surgical release of iliotibial band and lateral retinaculum, mobilisation and recession of vastus lateralis from patella along with excision of any fibrotic bands in vastus lateralis or intermedius. Vastus medialis is transferred distally and laterally.

Habitual dislocation of patella is a condition where patella dislocates every time the knee is flexed and reduces with extension. Patients often present with a clicking sensation on flexion and extension of the knee. The child may keep the knee flexed and patella permanently dislocated because of the pain. Palpation of the patella, which is displaced laterally, clinches the diagnosis. An ossified patella in an older child makes the diagnosis straightforward on X-ray of the knee. In cases with severe tightness, the tibia may be subluxated laterally on X-rays.

Treatment is release of the tight lateral structures and proximal realignment of the extensor apparatus by distal and lateral advancement of vastus medialis muscle. Other procedures, which can be performed in a skeletally immature patient, are Campbell’s procedure (lateral retinacular release along with a medial capsular flap which is passed around the quadriceps tendon to pull it medially. The flap is then sutured upon itself), Galeazzi procedure (semitendinosus tendon is used to pull the patella and patellar tendon medially), and Roux-Goldthwait procedure (lateral half of patellar tendon is detached and reattached medial to the medial half). In a skeletally mature patient with an increased Q angle, distal realignment procedures (such as Hauser’s procedure-osteotomy of the tibial tuberosity and its transfer distally and medially) with or without proximal realignment procedures should be done.

**Congenital Dislocation and Subluxation of the Knee**

The spectrum of congenital dislocation and subluxation of knee includes, in the order of increasing severity, congenital hyperextension, congenital subluxation and congenital dislocation.

Hyperextension is frequently normally present at birth in breech babies but may also be present along with subluxation and dislocation.

Subluxation is more common than dislocation. Difference from dislocation can be appreciated on X-rays. The subluxated knee may have up to 20-40° of flexion. The prognosis is better than congenital dislocation.

**Congenital dislocation** is characterized by anterior displacement of tibia on femur with complete loss of contact between the two. The tibia is usually internally rotated and often laterally displaced. Associated congenital anomalies may be present in 60% of patients with congenital dislocation of the knee. Children with arthrogryposis multiplex congenita often have associated dislocation of knee.

Children with congenital hyperextension/subluxation of knee should be thoroughly evaluated for congenital dislocation of hip.

Treatment of hyperextension and subluxation should begin soon after birth and consists of manipulation (passive flexion of knee) followed by plaster cast. Casts are changed every week till 90° flexion is achieved. Splintage is continued after that to prevent recurrences.

Dislocated knee is treated by open reduction and release of contracted quadriceps and its lengthening by V-Y plasty. Anterior capsule is released and collateral ligaments are freed if required. The knee is reduced and flexed to 90° and immobilised. Prognosis of knee dislocations, which need open reduction, is not good and movements more than 90° flexion are seldom obtained.

**Osgood Schlatter’s Disease** is the osteochondritis or fatigue failure of the tibial apophysis of the tubercle in a growing child due to traction by extensor mechanism.
Clinically, it presents typically in a 10-15 year old boy. Symptoms vary from mild ache at the tubercle to severe pain. Pain is worse during climbing up or down the stairs, running or jumping. There may be a soft tissue swelling over the tibial tubercle due to the formation of a bursa. Tibial tubercle is tender on palpation.

Radiological examination shows soft tissue swelling anterior to the tubercle and thickening of the patellar tendon. Fragmentation and irregularity of the tibial tubercle apophysis is seen in older children. Often separate free fragments of bone due to heterotopic formation are seen anterior and superior to the tubercle.

Treatment in most cases is expectant, as the disease is self-limiting. Most cases resolve spontaneously around 15 years of age when fusion of the tubercle occurs.

When symptoms are severe and interfere with patient's activities, immobilization in a cylinder cast for 6-8 weeks may allow the patient to return to the normal activities. Very rarely, late excision of the separate ossicles may be required with peg grafting and therapeutic fusion of the tibial tuberosity apophysis (Bosworth procedure).

**Popliteal Cyst (Baker's Cyst)**

Popliteal cyst is a synovial cyst which arises from the semimembranosus bursa, from joint capsule or from underneath the medial head of gastrocnemius. In children it most typically arises from semimembranosus bursa, is filled with gelatinous fluid and has a lining of fibrous tissue, synovial cells and/or inflammatory cells. In children the swelling is always lateral to the semitendinosus. Popliteal cyst is usually asymptomatic but very large cysts can cause discomfort. The cyst always transilluminates unlike a vascular anomaly or a tumor. They often resolve. The treatment is expectant and the surgery is seldom required in children.

**Quadriceps Contracture**

Quadriceps contracture commonly occurs following intramuscular injections in quadriceps during childhood. The other causes of quadriceps contracture are congenital, arthrogryposis multiplex congenita, chronic osteomyelitis of femur, fracture shaft of femur and scarring due to surgery. Clinically, the patient has wasting of quadriceps and limitation of flexion and inability to squat.

Treatment in most cases should begin with physiotherapy. Resistant cases require excision of cicatrazed muscle and V-Y plasty of the quadriceps.

**CONGENITAL AND DEVELOPMENTAL DISORDERS AFFECTING FOOT**

**Clubfoot**

Clubfoot (Congenital Talipes Equino Varus: CTEV) is a congenital foot deformity, which includes components of equin. The disorder occurs in 1/1000 live births and affects males twice as commonly as females. Half the cases are bilateral. Multiple factors are implicated such as genetic (polygenic inheritance), persistence of fetal positioning, primary germ plasm defects, neuromuscular factors, mechanical factors (twins, malposition in utero) and drugs.

**Pathology**

The foot is small and the calf is hypotrophied. The equinus deformity occurs at the ankle, the inversion at the subtalar joint and adduction and supination of the forefoot occurs at the midtarsal joints. Deformities are due to underdeveloped and contracted soft tissues on the medial, posterior and plantar aspect of the foot.

The talus is most deformed and its anterior part is deviated medially and in plantar direction. Talonavicular joint is dislocated and navicular is displaced medially. Cuboid is often subluxated medially. The calcaneus is small and rotates through the subtalar joint in a medial direction and inverts (varus tilt). The talus and calcaneus are more parallel in three planes.

Clinically, the deformity is present at birth. The typical equinus, varus and adduction deformities are present in varying severity and flexibility (Fig. 111.14). It is not possible to manipulate the foot into normal position. A simple test for equinus is based on the observation that in normal newborns, the dorsum of the foot can be brought up to touch the skin. Failure to achieve this suggests the presence of the equinus deformity.

A child who starts walking on the clubfoot deformity (neglected clubfoot) develops callosities on the lateral border of the foot. Genu valgum and genu
recurvatum deformities may be associated in these patients.

Associated congenital abnormalities such as spina bifida, hip dysplasia and knee deformities should be ruled out in these patients.

Radiological examination reveals increased lateral tibiocalcaneal angle (> 120° due to equinus), decreased lateral talocalcaneal angle (< 35°; normal 35-50°) and anteroposterior talocalcaneal angle (< 20°: normal 20-40°) - both due to hindfoot varus. Talo - first metatarsal angle on AP film (normally zero) suggests talo-navicular dislocation.41

Treatment

Treatment objective of management is to correct the deformity and retain mobility. The foot should be plantigrade and have a normal weight bearing area satisfactory appearance and child should have ability to wear normal should be started immediately after diagnosis. Treatment in postnatal period consists of corrective manipulation and casting. The order of manipulation for correction of deformities is adduction, heel varus and lastly, equinus. Casts are changed every one to two weeks for 3 months.42 The corrected foot is then held in a cast or brace (Denis Browne splint) till the child starts walking when he is advised to wear CTEV shoes. The non-operative treatment advocated by Ponseti is currently very popular and good results have been shown in several series.

Surgical treatment is required if the deformity does not respond to conservative treatment or if the CTEV has been neglected (A neglected CTEV is said to exist when the child starts walking on the deformity without any prior treatment).43

The most commonly done surgery for CTEV is Postero-Medial Soft Tissue Release (PMSTR). Contracted soft tissues to the posterior, medial and plantar aspects of the foot are released to correct the deformity. It can be done as early as 4 months of age but is often recommended at 8-9 months of age because of the following reasons:

a. Release in a very small foot in a very young child is technically quite difficult, as the structures in the foot are very small.

b. A very small foot may be difficult to hold in a plaster after surgery so maintenance of correction may be difficult.

c. A child who is close to the age of standing and weight bearing at the time of surgery can start walking soon afterwards. The walking on a corrected foot stimulates the near normal growth of foot bones and soft tissues.

PMSTR can be done by a posteromedial (Turco) or Cincinnati incision.

Following structures are released:

a. Posteriorly:
   - Tendo achilles (Z - plasty)
   - Capsule of ankle joint and subtalar joint
   - Posterior talofibular and calcaneofibular ligaments

b. Medially:
   - Tendons–
     - Tibialis posterior
     - Abductor hallucis muscle
     - Sometimes FDL and FHL

c. Superficial medial release of the subtalar joint:
   - Superficial deltoid (calcaneotibial and tibio-navicular)
   - Calcaneonavicular (spring) ligament talonavicular ligament dorsally

d. Deep medial release:
   - Bifurcate ligament (Calcaneonavicular and calcaneocuboid)
   - Talocalcaneal interosseous ligament
   - Capsule of talonavicular (medial, dorsal and plantar), naviculocuneiform, cuneiform - first metatarsal and medial side of subtalar joint.
Plantar structures:
   Plantar fascia (origin)

Lateral structures:
   Lateral talonavicular capsule and dorsal calcaneocuboid joint (if required).

After surgery, the correction is maintained in a plaster for 3 months followed by CTEV shoes.
CTEV shoes are specially modified shoes for patients who have undergone correction (casting or surgery) for clubfoot. These shoes have no heel, broad toe box, straight medial border and 3/16 inch raise on the outer side of sole.

1. **Tendon transfers** are required for cases which occur or relapse due to weakness of evertor (peroneii) muscles with resultant invertor overaction. Tibialis anterior or posterior tendon is transferred to cuboid to supplement evertor action. Tendon transfers are done after 5 years of age (when the patient can comply with muscle reeducation program) in a supple foot that is otherwise corrected.

2. **Evan’s Procedure**: Evan’s procedure is done for children between 4 - 8 years of age. It comprises of shortening of lateral column of the foot by wedge resection of calcaneocuboid joint.

Salvage operations are required for resistant or residual deformities of the foot.

Forefoot adduction is treated by Heyman-Herndon tarsometatarsal joints capsulotomies in younger children and by metatarsal osteotomies when the deformity becomes rigid in older children.

Heel varus is treated by modified Dwyer’s osteotomy, which comprises of close wedge osteotomy on lateral aspect of calcaneus. However, it has the disadvantage of further reducing the size of an already small calcaneus.

Triple arthrodesis is done in skeletally mature children (>12 years of age) for neglected feet, significant residual deformity or for overcorrected planovalgus deformity. Appropriate wedges are removed from the talonavicular, calcaneocuboid and talocalcaneal joints to correct the deformities. Plaster cast immobilisation is continued after surgery for three months.

Triple arthrodesis is not done before twelve years of age because the bones are cartilaginous. A large amount of cartilage has to be removed, the growth of the foot is affected and the fusion is difficult to achieve.

Correction of rigid, recurrent, residual and/or multiply operated scarred clubfoot or clubfoot with poor overlying skin (or unstable scars) is possible by external fixator (Joshi’s External Skeletal Stabilization-JESS or Ilizarov external fixation). The principle of correction by external fixator is one of differential distraction (both sides of the deformity are distracted-concave more than convex) to correct the deformities. After correction the foot should be immobilized in corrected position for 8 -12 weeks.

### Calcaneovalgus Deformity
Calcaneovalgus deformity presents at birth with dorsiflexion and eversion of the foot. The condition is often bilateral.

This is an innocuous condition and most cases resolve spontaneously by the end of first year. Calcaneovalgus should be differentiated from congenital vertical talus. In the latter condition the calcaneum is in equinus and the hindfoot is rigid. In calcaneovalgus, the calcaneum is dorsiflexed (i.e. in calcaneus) and the hindfoot is supple. Parents can be reassured and told to gently manipulate the foot into corrected position.

### Congenital Vertical Talus (Congenital Convex Pes Valgus)
Congenital vertical talus presents with rocker bottom foot deformity at birth. The deformity is usually associated with other anomalies, syndromes (Nail-patella syndrome, multiple pterygium syndrome, Marfan’s syndrome, arthrogryposis), chromosomal abnormalities (trisomy 13-15 or 18) or with neuromuscular problems (e.g. spina bifida).

**Pathology**
Calcaneus is in equinus and rotated posterolaterally. Talus is plantarflexed and rotated medially. Head of the talus is palpable medially. Navicular is dislocated dorsolaterally. Cuboid is subluxed dorsally and laterally on calcaneus. Soft tissues on the posterior, anterior and lateral aspect of ankle are contracted.

Clinically, the patient has equinus and valgus at the hindfoot while the forefoot is dorsiflexed and abducted.

Differential diagnosis of congenital vertical talus is calcaneovalgus deformity of the foot.
Radiologically, there is increased talocalcaneal angle on AP and lateral X-rays. On lateral film, calcaneus is in equinus and talus is plantarflexed. A stress lateral view with forced plantar flexion differentiates congenital vertical talus from flexible hindfoot valgus. Talometatarsal alignment is restored in flexible deformity while it remains disturbed in congenital vertical talus as navicular remains dislocated.

**Treatment**

Treatment during the first 3-4 months is stretching of dorsolateral soft tissue by manipulation followed by casting (Plaster is applied in the position of clubfoot deformity).

Surgery is done for children over 4 months of age and consists of one stage soft tissue release in children up to 2½ years of age. Contracted posterior, anterior and lateral structures are released. Talonavicular joint and calcaneocuboid joints (if dislocated) are reduced and fixed with K-wire. Tibialis anterior is transferred to the neck of the talus if neurogenic imbalance is present.

**Other Procedures**

- Grice Green extra-articular subtalar arthrodesis can be done in children who are 4-6 years old
- Children over 3 years of age with severe deformities due to neuromuscular causes may need excision of navicular.
- Triple arthrodesis is required in patients who are over 12 years old.

**Pes Planus (Flatfoot)**

Pes planus is the condition when the longitudinal arch of the foot is low or non-existent. The foot is pronated, the navicular is prominent and the heel is in valgus. Flatfoot can be flexible or rigid. The rigid flatfoot remains flat in sitting, standing and in tiptoe standing positions of the foot. The flexible flatfoot, on the other hand, is flat only on standing. Etiology of the flatfoot is unknown but following pathologies are associated with flatfoot:
  a. Congenital
  b. Ligament laxity (Down’s syndromes, Marfan’s syndrome)

- c. Muscle imbalance (as in poliomyelitis)
- d. Tendo-Achilles contracture
- e. Residual of calcaneovalgus foot
- f. Congenital vertical talus (Rocker bottom foot)
- g. Accessory navicular (Prehallux syndrome)
- h. Tarsal coalition.

Rheumatoid arthritis and rupture of tibialis posterior tendon can lead to flat foot in later life.

**Infantile Flatfoot**

All infants have flatfoot and this is because of several reasons.

- a. Normal longitudinal arch develops usually by 3 - 5 years.
- b. Infants have ligamentous laxity thus, their arches collapse on weight bearing.
- c. Infants have baby fat in the sole, which disappears by the age of 3 - 5 years. Hence, before 3-5 years, the arch may look flat even if it does not ultimately turn out to be flat foot.

**Congenital hypermobile flatfoot** is no longer considered an abnormality but a normal variant.

This is a genetic trait and is not considered to be an indication for treatment.

**Accessory navicular syndrome** is caused by a separate ossicle in the posterior tibial tendon adjacent to the navicular. The prominence of this bone may cause symptoms. Sometimes, this accessory bone receives anomalous insertion of tibialis posterior tendon along with the flattening of the longitudinal arch — the “Prehallux Syndrome”. The treatment is by padding and foot exercises. Occasionally excision of the accessory navicular may be required.

Clinically, the patient may be asymptomatic or may present with pain. Arch pain results from foot strain in severe cases with excessive use. Tight heel cords typically cause calf pain.

The patients with flatfeet also often present with uneven wear of the shoes; the inner side of sole wears more.

Radiologically, on the weight bearing lateral view of the foot, loss of arch is seen. The sagging can be at the talonavicular or naviculocuneiform joint. On the AP view, the talocalcaneal angle is increased.

Treatment of the pes planus is required only for the symptomatic feet. Shoes with good arch support and stretching for the tendo achilles contractures are
useful measures. Medial navicular pad, Thomas heel (C and E: Crooked and Elongated Heel) consisting of medial heel wedge and longitudinal arch support is often used.\textsuperscript{44} Surgery is required for persistent pain, excessive shoe wear problems or to address specific underlying condition (such as tendon transfer for paralytic conditions, triple arthrodesis for tarsal coalition or excision of accessory navicular).\textsuperscript{45}

Surgical procedures for treatment of flatfoot can be soft tissue procedures (distal advancement of plantar calcaneonavicular ligament and posterior tibial tendon) or bony procedures (Talonavicular fusion, naviculocuneiform fusion, subtalar arthrodesis or triple arthrodesis).

\textbf{Pes Cavus}

Pes cavus is fixed equinus deformity of the forefoot on the hindfoot ("forefoot drop" for those who believe equinus can occur only at ankle) leading to accentuated longitudinal arch and contracture of the plantar soft tissues. Pes cavus is frequently associated with hindfoot varus and claw toes. Both calcaneus (calcaneocavus) and equinus (equinocavus) may be associated with pes cavus. Pes cavus can be idiopathic, familial or congenital. It can be caused by muscle imbalance (e.g. weak tibialis anterior with strong peroneus longus, paralysis of intrinsic, paralysis of triceps surae with strong long toe flexors) or by neuromuscular diseases (such as muscle dystrophy, peripheral neuropathies, myelomeningocele, diastematomyelia, Friedrich’s ataxia, etc.).

Clinically, position of hindfoot, appearance of toes, flexibility of foot and muscle imbalance should be assessed. The patient has accentuated longitudinal arch and callosities under the metatarsal heads. Toes are curled and develop callosities on the dorsal aspect due to rubbing against the shoes.

Investigations for pes cavus must include muscle power examination, EMG/NCV, X-rays of the spine and the opinion of the neurologist.

Treatment is conservative in mild cases in the form of stretching, metatarsal pads and lateral wedge for the heel varus. Surgical treatment consists of Steindler’s plantar release (release of contracted plantar fascia, muscles and ligaments), tendon transfer (long toe extensors to necks of metatarsals), dorsal wedge resection or Japa’s V osteotomy of the tarsus, osteotomy of the calcaneus (Dwyer’s lateral closing wedge) or triple arthrodesis.

\textbf{Osteochondrosis}

Osteochondritis can affect calcaneal apophysis (Sever’s), navicular (Kohler’s) or second metatarsal head (Freiberg’s).

Clinically, the patient is an adolescent who complains of pain. X-rays show irregularity and fragmentation of the epiphysis/apophysis. Treatment is conservative and symptomatic with rest, NSAIDs and plaster cast if required.

\textbf{BONE AND JOINT INFECTIONS}

\textbf{Introduction}

Osteomyelitis often occurs in growing children and especially in lower limbs. Therefore, disabling sequelae such as partial or complete epiphyseal growth arrest with resultant deformities and limb length inequalities are common.

\textbf{Acute Hematogenous Osteomyelitis}

This is the infection of the bone and the bone marrow caused by blood borne organisms. It commonly affects children. Boys are affected more often than girls. \textit{Staphylococcus aureus} (coagulase positive) is the commonest pathogen causing acute osteomyelitis. \textit{E. coli} and Group \textit{B streptococci} cause osteomyelitis in neonates. However, anaerobic infections may also be seen (\textit{Peptococcus magnus}, bacteroides). \textit{Hemophilus influenzae} commonly causes osteomyelitis in children three months to four years old.\textsuperscript{46}

Metaphysis is the initial site of infection because it presents an extremely vascular area. Branches of nutrient artery provide network of vessels for zones of endochondral ossification in this area. Most vessels do not anastomose and terminate in venous sinusoids, i.e. they are end-arteries. They have hairpin bends, which leads to vascular congestion. Venous sinusoids are ideal bed for bacterial seeding. Large calibre of metaphyseal veins in children leads to marked slowing of blood flow and thus predisposes them to post-traumatic thromboses and colonization by blood borne bacteria. Also, trauma often localises to metaphysis.
and bacteremia may infect resultant hematoma. Metastatic infection may occur in spine following genitourinary infections by gram negative rods gaining access to spine via venous plexuses (Batson’s plexuses) which lack valves and anastomose freely with segmental systemic veins and portal system.

**Pathogenesis**

Once infection occurs it spreads to adjacent cancellous bone and through cortex, via Haversian canals, to the periosteum. Periosteum reacts by forming new bone (involucrum) occasionally and may rupture. Infection leads to vascular compromise and leads to bone necrosis (sequestrum formation). Epiphyseal growth plate offers a barrier to spread of infection to the joint. However, intraarticular location of metaphysis may lead to spread of infection to joint. This is seen in hip (upper femoral), shoulder (upper humeral), elbow (radial neck) and ankle (distal fibular). Rarely, joint may be involved by pus tracking under the periosteum (outside the bone) and entering the joint.

Clinically, acute osteomyelitis is characterized by chills, fever, pain, erythema, swelling and tenderness. Empirical antibiotic treatment may mask the symptoms and delay diagnosis. The infection is most common in metaphysis of long bones, more frequently in the lower limbs. An effusion may be seen in an adjacent joint (sympathetic effusion). It is a sterile response and clinically the movements at joint are not restricted.

**Investigations**

The leukocyte count may be raised with neutrophilia. Erythrocyte sedimentation rate (ESR) and levels of C-reactive protein (CRP) are usually raised. Aspiration can help to diagnose infection, identify the organism and helps in choice of antibiotics.

Blood culture is rarely positive, often due to empirical antibiotic therapy initiated by primary physician.

**Imaging**

X-ray changes appear late and are non-specific. First 7-10 days may show muscular edema and obliteration of soft tissue (fat) planes. Periosteal reaction (elevation) is the earliest bone change and is seen at around 10 days. Demineralization of bone is seen at 10 - 14 days. Skeletal changes such as periostitis, sequestrum formation and involucrum formation take 3 - 6 weeks to appear.

**Radionucleide Scans**

Bone scans are useful in evaluating infection in the early stages of illness. Commonly used scans are:

i. $^{99m}$Tc diphosphonate scan-localizes vascularity and new bone formation.

   It may be negative in early period due to ischemia and necrosis. The scan is "Hot" in later phase.

ii. Gallium 67 citrate-shows higher localisation in inflammation and is useful for spine infections.

iii. Indium 111-labelled leukocyte scan-localises neutrophils and is useful for extremities.

Ultrasound may localise deep-seated soft tissue swellings. Magnetic Resonance Imaging (MRI) helps in diagnosis and defining the extent of the involvement.

**Differential Diagnosis**

Osteomyelitis should be considered in differential diagnosis of all orthopedic afflictions with ambiguous clinical and radiographic findings. The parents often give the history of trauma but it should not allow the orthopedist to miss the septic process. It is extremely important especially in pediatric patients to rule out neoplastic lesions especially Ewing’s sarcoma. The differential diagnosis of osteomyelitis is shown in Table 111.2.

**Treatment**

Management of infection in children is guided by several principles distinct from those, which apply, to adults. The children have greater healing potential, operative drainage is often required and the antibiotic selection is determined by the age concurrent illness and family situation (whether family is reliable).

Acute hematogenous osteomyelitis can be treated successfully with rest (splintage) and antibiotics if started early. Parenteral third generation cephalosporin or penicillinase resistant synthetic penicillin is drug of choice. Choice of intravenous antibiotics should be decided by expected sensitivity of most
likely pathogen, which may be modified if necessary, once culture report is available. The patient is monitored closely, clinically and with total and differential leukocyte counts. Intravenous antibiotics are continued till patient is afebrile. This is followed by oral antibiotics for a total of 6 weeks.

Surgical Treatment

Conservative treatment should be abandoned and patient operated when:

- The response to antibiotic is not rapid, which is evident by continuing fever, leucocytosis and severe pain;
- Patient presents late (for drainage of pus and debridement of infected tissues).

Surgery consists of drainage of abscess. If no pus is found after incising the periosteum, holes should be drilled in the cortex to localise the site of infection. A window of cortex is removed to allow free drainage. Extensive curettage of medullary cavity should not be done routinely. Wound is closed over a drain, which is removed within few days to avoid secondary bacterial contamination.

Course

Complete resolution of acute hematogenous osteomyelitis is possible with early, effective, intravenous antibiotic therapy. Long-term morbidity occurs in almost one-fourth patients where the disease leads to chronic osteomyelitis. Chronic osteomyelitis and recurrences are more common in patients who are diagnosed late.

Neonatal Osteomyelitis

This is caused by hematogenous infection. The common organisms are Group-B *streptococcus* (commonest), *Staphylococcus aureus* and *Escherichia coli*. Group-B *streptococcus* is commonly found in vagina and infection occurs during delivery and commonly involves one bone. *Staph. aureus* and *E. coli* can cause polyostotic involvement in the newborns. Immunological incompetence of the newborn may delay clinical diagnosis in some patients due to absence of systemic symptoms. Combination of penicillinase resistant synthetic penicillin and third generation cephalosporin is the primary antibiotic regimen.

Subacute Osteomyelitis

It is primarily a radiological diagnosis. The condition most often involves femur and tibia. The patient may have pain without systemic / local signs or symptoms. It occurs following partially treated acute osteomyelitis. Total leukocyte count and blood cultures are often normal in this condition. ESR, radiographs and cultures from bone may help in making the diagnosis.

Brodie's Abscess (Bone Abscess)

This is a localized form of subacute osteomyelitis. The onset is insidious and systemic manifestations are mild or absent. Radiographic features consist of localized radiolucency usually seen in the metaphysis of long bones. It is typically elongated with well-demarcated margin and surrounded by reactive sclerosis.

Sequestra are always absent. A radiolucent tract may be seen extending from the lesion into the growth
plate. (Bone abscess may cross the epiphyseal plate and extend into epiphysis unlike acute osteomyelitis). Epiphyseal osteomyelitis is caused exclusively by *Staphylococcus aureus*.

**Differential Diagnosis**

Brodie's abscess may mimic an osteoid osteoma radiologically and clinically. Presence of radiolucent tract from the lesion into the growth plate favors infection. When present in epiphysis, it should be differentiated from chondroblastoma.

**Treatment**

Treatment of Brodie’s abscess in metaphysis includes surgical curettage. Epiphyseal osteomyelitis is treated with antibiotics. Drainage is indicated if pus is present.

**Chronic Osteomyelitis**

This may arise following inappropriately treated acute hematogenous osteomyelitis or inadequate surgical debridement of necrotic bone in exogenous osteomyelitis following trauma or surgery. The necrotic bone is walled off by periosteal new bone (involucrum) and fibrous tissue. Each cavity thus formed contains a piece of dead bone surrounded by granulation tissue (sequestrum) and harbors bacteria. Skin and soft tissues are often involved and get scarred, edematous and poorly vascularized. Fistulous tracts form sequestrum/sequestra may be extruded through the sinus tract. Cavities containing sequestra may remain quiescent for variable intervals. Periods of quiescence are often followed by acute exacerbations. If drainage persists over many years, epidermoid carcinoma may develop in 1% patients (may occur 30-40 years after original infection). *Marjolin’s ulcer* is ulceration developing in epidermoid carcinoma of sinus tract. Complications of chronic osteomyelitis are enumerated in Table 111.3.

Figures 111.15A and B. show sequelae of the osteomyelitis of humerus in a child.

Chronic osteomyelitis is rare in healthy adults. It is seen in immunosuppressed hosts, in the presence of major nutritional or systemic disorder, diabetics and in patients with peripheral vascular disease and IV drug abusers.

**Diagnosis**

Diagnosis is readily made with presence of drainage and X-ray changes which include thickening and irregularity of bone, dense sequestrae surrounded by zone of lucency, cavities and radiolucent tracts in the bone and presence of involucrum (reactive periosteal new bone). Radionucleide studies may help in subtle cases without drainage. Attempt to isolate the offending organism should be made by taking cultures from deeper areas or cavity during surgery as drainage fluid has abundant contaminants. Bone scan (in the presence of implants) and Magnetic Resonance Imaging (MRI) (when implants are absent) are extremely valuable in establishing vascularity of segments of diaphysis with doubtful vascularity.
Orthopedic Problems in Children 1323

Treatment

Treatment consists of a wide range of procedures ranging from drainage of abscess and sequestrectomy to extensive debridement. The basic principles of surgical treatment of chronic osteomyelitis are:

Sequestrectomy and Saucerization

Debridement with excision of dead, necrotic, infected tissues and sequestra (sequestrectomy) till bleeding surfaces of bone and removal of the sinus tracts is done. Dense reactive bone, though not necrotic, is removed, as it is often poorly vascularized. Deroofing of the osteomyelitis cavity (saucerization) is done to facilitate drainage.

Obliteration of the Dead Space

With an attempt to increase vascularity and promote healing by:
- Cancellous bone grafts/vascularised bone grafts
- Antibiotic impregnated bone cement: Polymethylmethacrylate (PMMA or bone cement) beads impregnated with antibiotics are used to obliterate dead space and provide high local concentrations of antibiotics without systemic ill effects. Antibiotics elute from beads within 2 weeks and their local antibiotic levels are insignificant by 6 - 8 weeks and the beads should then be removed
- Surrounding muscle: When antibiotic laden PMMA beads are not available local muscle flaps can be used to obliterate dead space.

Soft Tissue Coverage

It is often required. The various methods include:
- Skin grafting
- Local myocutaneous flaps
- Fasciocutaneous flaps
- Distant free flaps.

Garre’s Chronic Sclerosing Osteomyelitis

It is an unusual form of osteomyelitis affecting diaphysis of long bones in adolescents. Anaerobes have been implicated as causative organisms. The disease is probably caused by organisms of low virulence and/or occurs in hosts with good resistance/immune response. The onset is insidious with localized pain and tenderness. Intense proliferation of periosteum occurs causing bony deposition, which is seen as dense progressive sclerosis on X-rays. Malignancy must be ruled out. Biopsy must be performed in cases where the diagnosis is doubtful. Surgery and antibiotics are ineffective in providing cure.

Sickle Cell Disease

Recurrent attacks of bone infection are common in sickle cell disease. Vascular insufficiency and bone infarcts are the underlying causes. Staphylococcus aureus is the most common causative agent, though salmonella may also be isolated. Patients with sickle cell anemia are ten times more susceptible to salmonella osteomyelitis as compared with normal population. Other diseases leading to ischemia and infection are Gaucher’s disease (after biopsy) and osteopetrosis (Jaw osteomyelitis via tooth infection).

Osteomyelitis by Unusual Organisms

Syphilitic Osteomyelitis

Syphilis is a chronic systemic infection caused by treponema palladium. Congenital Syphilis is transmitted from mother to infant. Osteochondritis, periostitis and osteitis are the typical features. Destruction at the medial aspect of the metaphysis of a long bone (Wimberger sign) is characteristic. It is most classically seen in tibia. In the late stages, involvement of tibia results in characteristic anterior bowing deformity known as “Saber-Shin” deformity.

Salmonella Osteomyelitis

It is mostly caused by serotypes other than S. typhi. It is common in sickle cell disease (but it is not the commonest organism causing osteomyelitis in sickle cell disease). It may occur in subjects without sickle cell disease. The bone affection occurs during convalescence 4 to 6 weeks after enteric fever. Diaphyseal involvement is common especially in femur. Vertebrae and ribs are also involved. Infection of tibia, fibula, humerus and clavicle has also been reported. Multiple sites of infection are commonly seen. After one to two weeks radiographs show
multiple punched out destructive lesions throughout
the metaphysis and diaphysis with extensive
subperiosteal bone formation (massive involucrum)
and irregular sclerosis.

Treatment
The treatment includes antibiotics (e.g. chloram-
phenicol, ampicillin or ciprofloxacin) for six weeks.
Response to antibiotics is poor. Abscesses should be
drained. A surprisingly good outcome may be seen
without operative drainage. Recurrences are
commonly seen.

Tubercular Osteomyelitis
Commonest involvement by tubercular osteomyelitis
is in vertebral bodies. Metacarpals and phalanges
(Tubercular dactylitis) are sometimes involved.
Multiple bones may be involved and the affected bones
become swollen and fusiform. The appearance is called
‘spina ventosa’. X-ray shows expansion of bone,
rarefaction leading to cystic appearance and periosteal
reaction. Tubercular dactylitis should be differentiated
from enchondroma, rheumatoid arthritis and syphilitic
dactylitis. In long bones, tubercular osteomyelitis
involves metaphyseal regions. New bone formation
does not occur except in vertebrae and in small bones
of hands and feet. Juxta articular metaphyseal lesions
may discharge into the adjacent joint and lead to
tubercular arthritis. Treatment consists of anti-
tubercular chemotherapy. Surgery (curettage of lesion)
is indicated for juxta articular lesion to prevent arthritis
of adjacent joint.

Infectious Arthritis

Relevant Anatomy
Orthopedic surgery is concerned mainly with synovial
joints. Other types of joints are synostosis (bony),
syndesmosis (fibrous) or synchondrosis/symphysis
(cartilage). The ends of bones in synovial joint are
covered with hyaline cartilage. Hyaline cartilage
consists of chondrocytes embedded in matrix of
collagen fibres and proteoglycans. Articular cartilage
has zones like physis and a mineralization/calcification
front at the junction between calcified
cartilage and normal articular cartilage called Tidemark.
Articular cartilage gets its nutrition by diffusion of
metabolites from synovial fluid, as the cartilage has
no neurovascular supply. The cartilage in adult cannot
grow or repair itself. Defects resulting from injury are
repaired by fibrocartilage or fibrous tissue.

Synovial membrane is a smooth, glistening
membrane, which surrounds the joint cavity and
produces synovial fluid. It has rich vascularity and
cells specialized in phagocytosis and hyaluronic acid
production. Synovial fluid is a dialysate of plasma with
the addition of hyaluronic acid produced by synovial
membrane. External to synovium, thick fibrous
capsule surrounds the joint. Capsule has special
thickenings to form ligaments of the joint. Nerve
endings in the capsule transmit proprioception, pain
and pressure sensation.

Pyogenic Arthritis

Source of Infection
Infection of the joint is most commonly caused by
Staphylococcus aureus.

The bacteria can gain entrance in to the joint by
following routes:

a. Hematogenous spread usually occurs from a
distant focus of infection. It occurs most
commonly in patients with underlying illness and
immune deficiency. Chronic illnesses such as
rheumatoid arthritis, intravenous drug abuse and
local joint trauma may predispose adults to
hematogenous infection.

b. Direct extension from adjacent focus of infection
• Infection in newborn and infants can extend
from metaphysis to the joint by transphyseal
vessels (which get obliterated after infancy).50
Infection cannot cross the physis so septic
arthritis is less common in children.

• Extension of metaphyseal osteomyelitis can
occur where metaphysis is intra-articular, most
commonly at hip. Other joints include shoulder
(upper humeral epiphysis), ankle (distal fibular
epiphysis) and elbow (radial neck).

• Contiguous soft tissue infection can extend and
cause septic arthritis.

• Umbilical vein sepsis in newborn can lead to
pyogenic arthritis.

c. Direct inoculation is seen following penetrating/
open joint injuries and following diagnostic or
therapeutic procedures (e.g. aspiration of joint...
fluid, intra-articular injections, arthroscopy). Femoral venipuncture may also lead to septic arthritis of hip in infants. Prosthetic joint surgery is another source of direct inoculation.

Pathogenesis
The presence of bacteria in the joint incites an intense local reaction. The synovial membrane becomes hyperemic, edematous and proliferates. It produces purulent fluid containing markedly increased leukocytes. Articular cartilage gets destroyed by:

a. Proteolytic enzymes released by bacteria and disintegrating inflammatory cells.
b. Pressure necrosis by raised intra-articular pressure.
c. Interference with chondrocyte nutrition and
d. Invasion of matrix and enzymatic degradation by proliferating synovium.

Infection spreads to underlying bone and can destroy the growth plate resulting in limb length discrepancies and/or angular deformities in growing children. Infected synovial membrane eventually is replaced by granulation tissue. Marked distension of joint, destruction of cartilage, capsule and ligaments and spasm of the neighboring muscles may culminate in pathological dislocation of the joint (most commonly hip). In neglected cases, multiple discharging sinuses may form. The eventual outcome of the joint depends on the virulence of the organism, age of the patient and the state at which therapeutic intervention is done.

In newborns and infants, the femoral head is mainly cartilaginous and is rapidly destroyed by the infection. Marked destruction gives rise to a hypermobile joint (Tom-Smith’s Arthritis) with exaggerated movements and marked shortening. In young children the infection results in bony ankylosis. In adolescents and adults, the joint destruction by septic process may be followed by fibrous ankylosis.

Clinical Features
Pyogenic arthritis is usually monoarticular infection and most commonly involves hip in infants and young children and knee in older children and adults. The onset is acute with constitutional symptoms and high fever. Fever may sometimes be absent in infants. The child is apprehensive, anxious and anorexic. The chief complaint is swelling, pain and limitation of motion of involved joints. Affected joint is warm, erythematous, tender, distended and has reduced range of motion with pain on attempted movements. Spasm of surrounding muscles is often quite obvious. Patient holds the joint in the position of maximum capacity to reduce intra-articular pressure and thus minimize pain.

The position of maximum intra-articular volume of various joints is given in Table 111.4.

Laboratory investigations reveal leukocytosis with shift to the left and raised ESR and C-reactive protein. Blood culture may be positive in 50% patients with hematogenous septic arthritis.

Synovial Fluid Analysis
Evaluation of synovial fluid is critical for diagnosis and treatment of septic arthritis. Aspiration of joint fluid is done following an aseptic technique. Wide bore needle is used for aspiration and as much fluid as possible is removed from the joint (to decompress the joint). Aerobic and anaerobic cultures should be taken. Tubes containing heparin or EDTA should be used for collecting fluid for cell examination. In septic arthritis, the synovial fluid shows the following abnormalities (Table 111.5). These along with positive culture clinch the diagnosis.

Imaging Studies
Early X-ray changes may be subtle and comparison with opposite (normal) joint helps to distinguish subtle changes. An effusion with distension of capsule may appear as soft tissue swelling. The earliest bony change is rarefaction of bone. This is followed by erosion of juxta-articular bone. In later stages, joint space is

Pediatric Surgery—Diagnosis and Management

Diminished due to destruction of articular cartilage. Bone scan, CT scan and MRI can help in early diagnosis in cases with ambiguous clinical signs.

**Differential Diagnosis**

Septic arthritis should be differentiated from acute osteomyelitis, hemophilia, gouty arthritis and tuberculosis.

**Treatment**

Septic arthritis should be treated as an emergency. The principles of treatment are:
1. Evaluation of pus
2. Sterilization of the joint
3. Prevention/Correction of deformity
4. Restoration of function

**Evaluation of Pus**

It is done to decompress the joint, clean it of enzymes and save the cartilage. Evaluation can be done by aspiration or arthroscopy. Hip joint is drained by posterior approach.

**Sterilization of the Joint**

Systemic antibiotics are started immediately, empirically based on suspected causative organism. They are changed if necessary after culture and sensitivity reports are available. Parenteral administration of high doses of antibiotics is continued till the constitutional symptoms subside. Once ESR comes down and the fever settles down, the oral antibiotics are started and continued for 4-6 weeks.

**Splinting the Joint**

Splinting provides rest expedites recovery and prevents/corrects the deformity.

**Restoration of Function**

The joint is mobilized to regain movement.

**Sequelae of Septic Arthritis**

1. Ankylosis of joint: fibrous or bony.
2. Instability of joint/Hypermobile joint (Tom Smith arthritis), due to destruction of cartilaginous femoral head.
3. Pathological dislocation.
4. Complication of sepsis
   - Septicemia, even death
   - Metastatic abscesses
   - Osteomyelitis
5. Soft tissue contractures.
6. Epiphyseal damage
   - Limb length discrepancies — shortening/lengthening of bone
   - Angular deformities.

**Tubercular Arthritis** is a granulomatous infection caused by human or bovine strain of mycobacterium tuberculosis. It is very common in underdeveloped and developing countries. The increased incidence of HIV has given rise to increased incidence of tuberculous infection, multidrug resistant tuberculosis and tuberculosis by atypical organisms.

**Pathology**

The infection reaches the joint either by hematogenous route or rarely by spread from adjacent bone. Disease is usually synovial initially. Synovium proliferates and
hypertrophies and gets studded with tubercles. Joint effusion follows. Tubercular granulation tissue covers articular cartilage as a pannus and destroys cartilage and subchondral bone. If untreated, necrotic material and synovial exudates perforate the capsule and form a cold abscess. Secondary pyogenic infection through the sinus tracts may further destroy the joint.

**Clinical Features**

Clinically, tuberculosis presents as monoarticular arthritis in children and young adults. Synovial thickening are readily effusion and appreciable in superficial joints such as knee. Marked muscle wasting is seen around the joint. The joint is held in position of deformity due to effusion and muscle spasm. Night cries and night sweats may be present. Fixed joint deformities develop in later stages due to destruction of cartilage and subchondral bone. Cold abscess and sinuses may be present in late stages.

**Diagnosis**

X-rays show increased joint space followed by rarefaction of bone as the earliest feature. Joint space narrowing occurs subsequently with destruction of cartilage. Reactive new bone is absent. Sequestrae are rare.

Blood examination shows anaemia and elevated erythrocyte sedimentation rate. Synovial fluid is straw coloured and has raised leukocyte count, low sugar content and forms poor mucin clot. Tubercular bacilli are rarely seen. Sometimes they can be cultured from synovial fluid. Synovial biopsy can confirm the diagnosis.

**Treatment**

Aims of treatment are eradication of disease, prevention and correction of deformities and preservation of joint functions. General measures consist of bed rest, balanced diet, pain relief and psychological support. Chemotherapy is usually started with 4 drugs HRZE (INH, Rifampicin, Pyrazinamide and Ethambutol) and if after three months, the response is good, it can be reduced to two HR. The total duration of therapy is 12-18 months. Traction in these patients relieves pain, counters spasm and prevents and corrects deformity at the joint. It also provides rest to the joint. Gentle active and passive exercises for mobilization of the joint should be started as soon as the disease activity has reduced and pain has abated. Surgical treatment may be required to confirm diagnosis, reduce disease load, improve vascularity (and hence penetration of chemotherapeutic agents), and correct deformities. Synovectomy and joint debridement are indicated when joint space is not compromised and useful range of motion is expected.

In markedly damaged and disorganized joints, arthrodesis in the functional position may be undertaken to eliminate pain, correct deformity and provide stable, functional joint.

**Hemophilic Arthropathy**

Hemophilia A is the commonest hereditary (sex linked recessive) coagulation disorder affecting 20 per 100,000 live male births and is caused by deficiency or malfunction of coagulation factor VIII. Hemophilia B (Christmas disease) is caused by lack of factor IX. Hemophilia C is a mild variety of disease caused by the deficiency of factor XI. It has autosomal dominant inheritance.

Normally very low serum levels of factor VIII are sufficient for adequate coagulation. Reduction of more than 75% in the serum levels (i.e. serum levels < 25% of normal) leads to perceptible clinical illness. The disease is graded according to the severity of factor VIII deficiency into mild (serum factor VIII levels 5-25% of normal; moderate 1-5% and severe < 1%). Bleeding can be intra-articular, intrabursa or into the soft tissues. Repeated intra-articular bleeding leads to proliferative synovitis and extensive hemosiderin deposition.

Clinically, the disease presents with recurrent episodes of bleeding, especially in the joints. The disease usually presents in early childhood with discomfort, limitation of joint movement initially followed by pain and swelling. Contractures and deformities eventually occur. Knee is the most common joint involved followed by elbow, ankle, shoulder and hip. The affected joint is swollen, warm and painful to move and often confused with septic arthritis. Bleeding into ilicus can lead to femoral nerve palsy.

"Pseudotumors" are painless masses consisting of partially clotted blood surrounded by thick fibrous
membrane resulting from juxta periosteal bleeding which mimic tumours clinically and radiologically.\textsuperscript{54} They occur in 1-2\% cases of hemophilia. They are commonly seen in lower limbs and pelvis. Pseudotumors can damage bone and muscles, can lead to infection or cause neuropathies.

**Radiologic Features**

Early stages show soft tissue swelling. This is followed by osteoporosis. Further damage to the joint is seen as bony changes (squaring of patella, widened intercondylar notch of femur and enlarged femoral condyles in the knee, formation of subchondral cysts), joint space narrowing and loss of articular cartilage. Osteophyte formation is seen.

Pseudotumors are seen as cystic expansile, lucent soft tissue swellings eroding the cortex. MRI is classical with low signal on T-1 weighted images and high signal on T-2 weighted images. Ultrasonography is useful to diagnose the intramuscular bleeds.

**Laboratory Investigations**

*Partial Thromboplastin Time (PTT)* is elevated in hemophilia. Specified factor assays should be done to determine severity of the disease. Assays for factor VIII inhibitors (antibodies) should be done, as their presence is a contra-indication to any surgical intervention.

Blood for HIV should be tested in hemophiliacs as transfusion related AIDS is a well recognized complication of hemophilia (in up to 90\% patients).

**Treatment**

Prophylaxis for hemophilia is extremely important and consists of avoidance of contact sports, physiotherapy and prophylactic administration of factor VIII whenever affordable.

Acute hemorrhage in the muscles is managed by immobilization, compression and factor VIII replacement. Medical synovectomy with radioactive phosphorus (32P) is useful for chronic hemophilic synovitis.

Surgical management of chronic hemophilic arthropathy includes synovectomy, correction of soft tissue contractures, arthrodesis and total joint replacement. Pseudotumors need excision but can be treated with radiotherapy and/or factor replacement sometimes.

**OTHER BONE AND JOINT DISORDERS**

**Legg-Calve Perthes Disease**

Perthes disease is a non-inflammatory condition leading to deformity of the weight-bearing surface of femoral head. It arises as a result of repeated vascular insults leading to avascular necrosis of the proximal femoral epiphysis.\textsuperscript{56}

The Perthes disease occurs between 4-8 years of age and is much more common in males (M:F = 4:1). Almost 10\% cases are bilateral though usually not simultaneous. Perthes disease has a higher incidence among children with older parents, children of maternal smokers during pregnancy; breech delivery, low birth weight and delayed skeletal maturation.

**Pathogenesis**

Idiopathic avascular necrosis of the femoral head occurs followed by subchondral fracture, revascularization (by creeping substitution), and healing ossification processes. The disease is divided into avascular necrotic stage, fragmentation stage and reparative stage.\textsuperscript{57} The process of necrosis and reconstitution takes about 2 years.

**Clinical Features**

Clinically, the disease varies in severity. Patient usually presents with limp with or without pain. Limping increases with activity and may be intermittent. Pain when present is usually in the groin, anterior thigh and sometimes in the knee. Sometimes the disease presents with synovitis with associated muscle spasm. Decreased range of motion is found in almost all patients and abduction and internal rotation are mainly restricted.
Orthopedic Problems in Children

Radiologically, the plain x-rays show increased joint space (because of increased cartilaginous growth) and subchondral lucency. The femoral head shows increased density, fragmentation and is deformed (Fig. 111.16).

Based on plain radiographs, the extent of involvement can be graded according to the Catterall classification:

a. **Group I:** Anterior head involvement (less than 1/2 femoral head affected) without any sequestrum or subchondral fracture.

b. **Group II:** Anterior and central half of head involved (more than 1/2 but less than 3/4th) with intact lateral margin. Sequestrum, subchondral fracture and anterolateral metaphyseal lesions are present.

c. **Group III:** Almost 3/4th of femoral head is involved including the posterior half of epiphysis - only posteromedial segment is spared. Large sequestrum forms along with subchondral fracture and diffuse metaphyseal changes.

d. **Group IV:** Entire head is involved.

Arthrogram can be used to assess containment of head and its deformity and subluxation.

Bone scan can be used to diagnose the condition early.

MRI is a non-invasive investigation, which is extremely useful for early diagnosis, and can differentiate between live and dead marrow.

**Differential Diagnosis**

Perthes disease should be differentiated from transient synovitis, septic arthritis, blood dyscrasias (especially sickle cell disease), lymphoma, trauma, tumor and rheumatic fever. Bilateral cases must be differentiated from multiple epiphyseal dysplasia, spondyloepiphyseal dysplasia, pseudoachondroplasia, sickle cell disease and hypothyroidism.

**Prognosis**

Clinical and radiological prognostic factors have been recognized.

**Clinical:** Age more than 6-8 years, obesity, decreased range of movements especially presence of adduction contracture, and female sex are associated with poor prognosis.

Radiological "Head at risk" signs are identified as calcification lateral to the epiphysis, Gage's sign (V-shaped lucent area in lateral epiphysis and adjacent metaphysis), lateral subluxation, horizontal physis and diffuse metaphyseal reaction. The presence of these signs indicates impending extensive osteonecrosis of femoral head.

Uncovering of the femoral head by > 20% is a bad prognostic indicator.

Greater the Catterall group (more extensive the femoral head involvement) worse is the prognosis.

Treatment of Perthes disease is aimed at maintaining the sphericity of the femoral head and is based on the principle that hip mobility and containment of the femoral head within the acetabulum will lead to the best healing and remodeling of the avascular femoral head. Young patients (4 to 6 years age) with involvement of less than 50% of the head (Catterall I) are observed without active treatment. Catterall II group patients less than 6 years of age are observed if they have a good range of motion. Intermittent traction and active range of motion exercises are prescribed if there is limitation of movements. Aim of treatment of Catterall III and IV groups is to achieve good range of motion and containment. This can be achieved by orthotic devices (abduction braces) or surgery. Surgery can be Salter's innominate osteotomy or a femoral osteotomy. These procedures are suitable only for those cases where there is no femoral head deformity. In group III and IV patients where the head is deformed or collapsed, no treatment is possible. Catterall V group patients older than 6 years are treated with traction and abduction bracing.

---

Fig. 111.16: Perthes' disease of right hip
Slipped Capital Femoral Epiphysis (Adolescent Coxa Vara)

Slipped capital femoral epiphysis (SCFE) is a condition wherein the femoral neck displaces through the growth plate in anterior and superior direction while the femoral head remains in the acetabulum. The condition is caused by weakness of the perichondrial ring and the zone of hypertrophy in the growing growth plate. The exact cause is unknown. Various etiologies have been suggested including hormonal dysfunction.

The incidence of SCFE is 1-3 per 100,000. Males are affected more commonly than females (2.5:1). Almost 25% are bilateral. SCFE is common during 13-16 years age in males and 11-13 years in females. There is an increased incidence in overweight as well as slender tall patients, hypothyroidism, hypopituitarism, renal osteodystrophy hypogonadism, Down’s syndrome and in the presence of a positive family history.

Classification

- An acute slip occurs suddenly.
- An acute on chronic slip presents with acute exacerbation of symptoms, which have been present for more than 3 weeks.
- A chronic slip is the one where history of symptoms is of more than 3 weeks’ duration.

Pathogenesis

Slip occurs through the zone of hypertrophy and the displacement occurs due to body weight and muscle action. Epiphysis displaces posteriorly and inferiorly while the neck displaces in anterior and superior direction. The leg rotates externally under the effect of these displacements. Progressive apparent coxa vara and shortening of the leg result.

Clinical Features

Clinically the patient, usually between the age of 10 and 16 years presents with a history of chronic or intermittent pain of insidious onset in groin, thigh or medial knee associated with a limp. Patient may also present with acute pain after an injury with a history of intermittent pain previously (acute on chronic). In the acute phase, there is significant muscle spasm and synovitis with restricted range of motion. Gait is antalgic with externally rotated foot progression angle. There is decreased internal rotation, abduction and flexion. Hip flexion produces external rotation with knee pointing towards the axilla during flexion (other causes include coxa magna and gluteus maximus contractures. Severe cases may be associated with shortening of femur.

Radiologically the earliest changes are seen only on lateral X-ray. On AP view, a line along the superior neck does not intersect any part of epiphysis (Trethowen’s sign). The medial and proximal part of femoral neck does not overlap the ischium (Capener’s Sign).

Chronic changes are seen in longstanding cases and can be widening of physis, sclerosis, and ossification at the junction of medial femoral neck. Narrowed joint space and osteopenia of femoral head are seen in chondrolysis.

Treatment in mild to moderate case is in situ pin fixation. A single pin or titanium screw is passed from close to base of neck anteriorly towards posteroinferiorly. Patient is mobilized partial weight bearing with crutches for 6 weeks. Aim of pinning in situ is to prevent further progression of slip and to achieve early closure of physis.

Attempts to reduce the physis in longstanding cases leads to avascular necrosis.

In cases of severe slip primary epiphysiodesis is described as a method of treatment.

Compensatory transcervical and basal neck osteotomies are described to correct the deformities. These procedures are technically demanding and associated with increased incidence of avascular necrosis. Contralateral hip should be closely observed till physeal closure. Prophylactic pinning is indicated only in cases with renal osteodystrophy, which are associated with increased incidence of bilateral slip.

Complications

Chondrolysis may be associated with forceful manipulation or after surgery when pin penetrates the head to enter the joint. Clinically, the patient presents with stiffness, severe pain and muscle spasm. Hemogram and other laboratory parameters are normal. Radiographs show joint space narrowing. Bone scan is positive with increased uptake in the region of acetabulum and femoral head. It may recover
Orthopedic Problems in Children

Completely in 6-12 months but may cause degeneration or ankylosis of the joint. Treatment is traction, range of motion exercises, NSAID’s and salvage operations such as arthrodesis or arthroplasty. Other complications are avascular necrosis and secondary osteoarthritis.

Transitory Synovitis of Hip (Observation Hip, Toxic Synovitis, Coxitis Fugax)

Transitory synovitis is a self-limiting condition seen in children between 3-5 years of age. Synovitis of the hip joint occurs without any obvious etiology.

The child presents with complaints of limp and pain in groin, anteromedial thigh or knee. The duration of symptoms varies from a couple of days to a fortnight. The affected hip is in attitude of flexion and external rotation. All the attempted movements are painful near the extremes. There may be history of sore throat, tonsillitis or low-grade fever. Leukocytosis and slight increase in sedimentation rate may be present. Radiographs are normal but may show soft tissue swelling in the region of gluteus medius, obturator internus and psoas. Aspiration of hip under aseptic conditions should be performed if differentiation from infective hip arthritis cannot be done.

Toxic synovitis must be differentiated from septic arthritis, tubercular arthritis, avascular necrosis of femoral epiphysis and Perthes disease.68-70

Treatment consists of bedrest and traction. Patient’s symptoms quickly abate on elimination of weight bearing. Patients are mobilized when they have regained full, painless range of motion and can ambulate without pain and limp. If pain persists or recurs, pyogenic arthritis or avascular necrosis should be suspected. Even if the child becomes asymptomatic and returns to activity, a follow-up visit at 8-12 weeks should be advised to rule out avascular necrosis clinically and radiologically.

Elbow Disorders in Children

Little Leaguer’s elbow is seen in adolescents involved in throwing activities, particularly Little League pitching in North America.

Little Leaguer’s elbow results from the compressive forces at the radiocapitellar joint and distraction forces in the medial aspect of the elbow. Articular damage to the capitellum, ligamentous laxity of medial elbow ligamentous complex and ulnar nerve neuritis leading to tardy ulnar nerve palsy may result.

Clinically, the patient may present with medial and/or lateral elbow pain. Locking of elbow may occur in severe cases by the loose bodies formed by fragmentation of the capitellum. X-rays may show resorption and fragmentation of capitellum.

Treatment consists of change in throwing activities. Elbow should be splinted for rest and comfort. Arthrotomy or arthroscopy to excise the incarcerated loose fragment may be required.

Osteochondritis dissecans of the capitellum denotes osteochondral defect resulting from repetitive microtrauma or a vascular insult. In the elbow it most commonly involves capitellum (Panner’s disease). Clinically the patient presents with pain and swelling over the lateral aspect of the elbow.

Radiologically, the plain X-rays show osteochondral fracture of the capitellum, intra-articular loose bodies and capitellar deformity. Treatment consists of rest and avoidance of throwing activities if fragment is intact and not separated.

Arthroscopic removal is indicated for intra-articular loose bodies. Drilling and bone grafting may help in selected cases.

Osteogenesis Imperfecta (Brittle Bone Disease)

This is one of the commonest heritable bone disorders (1: 20,000 births) characterized by fragility of bones but with wide variation in severity.

The disease is caused by abnormal collagen synthesis (failure of cross-linking) due to mutation in genes that produce type I collagen. Osteogenesis imperfecta is classified into four types:

- **Type I:** Mild
- **Type II:** Moderately severe
- **Type III:** Progressive deforming
- **Type IV:** Severe (often stillbirths).

Type I and II are autosomal dominant while Type III and IV are autosomal recessive.

Salient features are due to involvement of bones, teeth, ligaments or sclerae.

The condition is characterized by excessive fragility of bones, blue sclerae (Figs 111.17A and B), osteoporosis, excessive joint laxity, bowing of bones (Fig. 111.17C) and crumbling teeth or dentinogenesis imperfecta. Other features are herniae, deafness (both conductive and sensorineural), and undue ease of bruising with poor scar formation. Deformities, especially scoliosis, chest deformities, trefoil pelvis,

mebooksfree.com
biconcave vertebrae and basilar invagination may be seen. X-rays show wormian bones in suture lines, beaded ribs, osteoporosis, thinned cortices and deformities due to malunited fractures. Metaphyses appear expanded. Occasionally a cystic or popcorn appearance is seen due to irregular (curliform) ossification adjacent to the epiphyseal metaphyseal region.

Hyperplastic callus is seen sometimes after fractures. Fractures unite readily and non-union is not a problem. The tendency to fractures reduces with age. The life expectancy can be normal in mild variety whereas severely affected subjects die before reaching adulthood.

Osteogenesis imperfecta (OI) should be differentiated from child abuse (battered baby syndrome). Children with OI have wormian bones, generalised osteoporosis, expansion of metaphysis and metaphyseal fractures (cf. diaphyseal fractures in child abuse) Histologically, there is increased diameter of haversian canals and osteocytic lacunae, increased number of cells and replicated cement lines.

Management comprises of prevention of fractures and correction of deformity whenever indicated. Soffield osteotomies (sheekh kabab bone with intramedullary fixation) are sometimes required for progressive bowing of long bones.

**UPPER EXTREMITY MUSCULOSKELETAL TRAUMA**

**Injuries of the Shoulder Region**

**Clavicle Fractures**

Clavicle is the most often fractured bone in the body. Fortunately due to its intramembranous ossification origin, union is not a problem. Malunion, however, is quite common, as it is quite difficult to control the fracture fragments.

Clavicle fractures often occur in patient with other serious skeletal and extra-skeletal injuries.

**Mechanism of Injury**

Fractures of the clavicle are caused most often by an indirect injury as fall on the point of the shoulder or on the outstretched hand. However, fractures of the clavicle may also result from the direct impact on the clavicle.

**Classification**

The fractures of clavicle are classified most commonly according to the location viz. fractures of the middle third (85% - including the fractures at the junction of the middle and the lateral thirds which is the commonest location), lateral third (10%) and medial third (5%) of the clavicle. Fractures of the clavicle can also be classified as post-traumatic or pathologic (following radiation necrosis in patients with breast carcinoma); another way to classify these fractures would be displaced, undisplaced or greenstick (in children).

**Evaluation**

Patient with clavicular injuries should be assessed for vital functions and associated injuries. Usually patients with displaced fractures present with pain, deformity and shortening of the clavicle. The patient often supports the injured limb with the other hand. Patient resists any attempts to move the shoulder. Tenderness may be only elicitable sign in patients with undisplaced fractures.
Local bruising appears in cases that present a few days after the injury. A careful neurovascular examination must be done in all cases.

**Imaging**

A single anteroposterior projection of the shoulder is usually adequate imaging study in adults. However, superimposition of scapula and ribs may not allow adequate visualization of the clavicle. Cephalic angled view gets rid of the superimposition. Cephalad angulation of 15° visualizes lateral two thirds of the clavicle while the X-ray beam may have to be angulated 40° cephald to visualize the medial third of the clavicle. X-rays confirm the diagnosis and reveal the location of the fracture and the degree of displacement of the fragments. The distal fragment typically sags downwards, forwards and medially while proximal end gets elevated (due to the pull of sternocleidomastoid). Fractures of the distal (or lateral) third of the clavicle are mostly undisplaced as the coraco-clavicular (especially trapezoid) ligaments remain attached to the proximal fragment and prevent its displacement while the acromioclavicular and conoid (lateral part of coraco-clavicular ligament) ligaments remain attached to the distal fragment.

In children the fractures of the clavicle may be very subtle and are difficult to diagnose. Any kinking of the cortical contour should raise the suspicion of clavicle fracture. Including both the shoulders on one film may help in comparison with the normal side. Associated vascular injuries are rare but when present need angiography.

**Management**

Any associated injury takes precedence over clavicle fracture for management. The treatment for clavicle fracture is primarily conservative. For undisplaced fractures in children and in elderly, support is provided for the weight of the arm using a sling and these fractures unite readily.55,76 Displaced fractures are treated with a figure of 8 bandage or commercially available braces applied with the shoulders braced backwards.77,78 A triangular sling is given to the arm in addition. The aim of these methods is to reduce the overlap of fragments and anterior drift of the scapula around the chest wall as well as to relieve pain. Braces or the bandage has to be re-tightened every few days as it keeps on getting loose. Supports are discontinued as soon as the fracture site becomes non-tender.

Surgical treatment of clavicle fracture is indicated for associated vascular injuries, compound fractures or the displaced fractures of the lateral third of the clavicle with disruption of coraco-clavicular ligaments. Implants used for internal fixation of the clavicle include intramedullary pins or 3.5 mm reconstruction plate with screws.79 External fixator may be applied for compound fractures.

**Complications**

Injury to the neurovascular structures (such as brachial plexus or the subclavian vessels) may occur rarely. Vascular injuries are managed by angiography, repair of the vascular injuries and internal fixation of the clavicle fracture. Closed neural injuries are treated expectantly while open injuries need exploration and repair.

Pneumothorax, other thoracic injuries or thoracic outlet syndrome can occur.

Malunion is the commonest complication. Off-ending and excessive callus may give rise to appearance of a bump under the skin.79,80 Some remodeling occurs with time and there is no functional disability.80

Non-union is rare and reported in 1-5% cases. High-energy fractures, widely displaced fractures, open fractures and inadequate immobilization are commonly implicated caused. Only symptomatic non-unions need management with internal fixation and bone grafting. Shoulder joint stiffness may occur in the elderly. It is managed by physiotherapy to mobilize the joint.

**Epiphyseal injury** of proximal humeral epiphysis (Type II Salter Harris) occurs in adolescents (13-15 years of age) and is often displaced.81 Closed reduction is performed by abduction, flexion and external rotation of the arm (salute position).82 Open reduction and stabilization with K-wires is indicated in irreducible cases. Immobilization is continued for 4-6 weeks.

**Elbow Injuries in Children**

Elbow injuries account for 8-9% of all pediatric fractures. Elbow injuries in children are different from
adults due to several peculiar anatomic features. The distal humeral bone is mainly cancellous and undergoing remodeling in children. This fact, along with the hyperextension possible in a pediatric elbow makes supracondylar fracture a very common fracture in this age group. In fact intercondylar fractures and elbow dislocations are much less common in children. Radial neck fractures (usually epiphyseal injuries) are much more common in children than radial head fractures. Medial epicondyle and lateral condyle fractures are other common fractures in children in this region.

Several ossification centers are present around elbow and they sometimes make diagnosis of a fracture difficult. It is always helpful to take radiographs of the opposite elbow for comparison. Average age of appearance of various secondary ossification centers around the elbow is (in order of appearance) capitellum 1 year (6 months-2 years), radial head 3 years (2-4 years), medial (internal) epicondyle 5 years (4-6 years), trochlea 7 years (6-8 years), olecranon 9 years (8-10 years), and lateral (External) epicondyle 11 years (10-12 years) - CRITOE. Around 10-12 years of age the epiphyseal fuse to each other and to the metaphysis.

Supracondylar Fracture of Humerus

Supracondylar fracture of the humerus is the commonest fracture around elbow in children constituting about 69% of elbow fractures in children. Supracondylar fracture is usually a transverse fracture running just proximal to trochlea and capitellum. The fracture is common during 5-10 years of age and is rare in adults.83

Mechanism of Injury

Supracondylar fracture usually results from a fall on the outstretched hand. It can also be caused by direct injury as a fall on the point of the elbow.

Classification

Supracondylar fractures are of two types according to the mechanism of injury.

Extension type is caused by the force, which displaces the distal fragment (i.e. the lower end of the humerus) posteriorly. It is the common type and constitutes almost 97.7% of the fractures. This is the type, which results from the fall on the outstretched hand.

Flexion type is caused by a force which displaces the distal fragment anteriorly. This type of supracondylar fracture constitutes about 2.3% of fractures.

Extension type of supracondylar fracture of the humerus is further classified by Gartland according to the degree of displacement.84

I. Undisplaced.
II. Displaced with intact posterior cortex.
III. Displaced without cortical contact.

Posteromedial displacement of distal fragment with varus angulation more common.

Posterolateral displacement of the distal fragment with valgus angulation.

The characteristic displacements in a supracondylar fracture in extension are posterior shift, medial/lateral shift, anterior angulation, posterior and medial tilt, internal rotation and overriding.

Evaluation

Patients present with a history of fall following which the elbow becomes painful and swollen. There may be an obvious deformity and child is unable to move the elbow. Distal humerus is tender. The normal relationship olecranon and medial and lateral epicondyles is preserved. Dimpling of the skin over the anterior aspect of the distal arm suggests button holing of the spike of the proximal fracture fragment through the brachialis muscle and tethering the skin. Movements at the elbow are not permitted due to pain. Distal neurovascular examination must be performed in all cases.

In cases presenting late with severe swelling around the elbow, with or without encircling bandages, careful examination to rule out Volkmann’s ischemia must be performed. Tense forearm, severe pain in the forearm, impairment of two point discrimination sense and pain on passive extension of fingers all suggest Volkmann’s ischemia. It is important to note that radial pulse may still be palpable in the presence of established Volkmann’s ischemia.
Imaging

Anteroposterior and lateral views of the elbow are usually sufficient to confirm the presence of fracture, type and degree of displacement and presence of comminution.

After the reduction the lateral and anteroposterior "shoot through" X-rays (Jones view) are taken to confirm the adequacy of reduction. The following facts should be remembered.

- A "fat pad" sign suggesting hemarthrosis often is the only indication of an undisplaced fracture.
- A minimally displaced fracture is discerned by extending the anterior humeral line distally. Normally, it divides distal humeral physis into anterior one third and posterior two thirds. Subtle posterior tilt of the distal fragment will diminish the fraction of distal physis anterior to the anterior humeral line.
- Sharp spike like appearance of proximal fragment suggests rotational deformity.
- Crescent shaped overlap between the distal humeral physis and olecranon on the lateral view suggests residual medial tilt, which may result in a cubitus varus deformity.

Treatment

Conservative treatment—Undisplaced fractures are treated in above elbow plaster slab in 120° flexion at the elbow for 3 weeks.

Displaced fractures needing manipulative reduction include:

- Fracture with less than 50% bony contact
- Posterior tilt of the distal fragment by more than 15°
- Lateral or medial tilting of 10° or more
- Presence of rotational deformity
- Evidence of arterial obstruction in the presence of displacement and/or angulation of the fracture.

Technique of manipulative reduction of extension type fracture: The reduction is performed under general anesthesia. Radial pulse is palpated. Traction is applied to the forearm with the elbow in 20° of flexion while the assistant applies the counter-traction at the arm. The fracture fragments are disimpacted. The medial and lateral displacements are corrected and the elbow gently flexed to 120° with a hand on the radial pulse. Disappearance of radial pulse at any stage warrants a reduction in the flexion at the elbow till the pulse just returns. At this stage, pronating the forearm tightens the medial periosteal hinge in cases with medial tilt/lateral angulation (i.e. with varus deformity). Cases with lateral tilt/lateral angulation (i.e. with valgus deformity) are managed with the forearm supinated.

Flexion of the elbow over 90° stretches the triceps over the fracture. Triceps than acts as an internal splint and stabilizes the fracture fragments.

Technique of manipulative reduction of flexion type fracture: Flexion type of supracondylar fractures are stable in extension. To reduce these fractures, traction is applied to the elbow in the flexed position to disimpact the fracture fragments. The elbow is then gradually extended and angulation reduced. An above elbow plaster slab is applied in 10° flexion for three weeks. At this time, the slab is removed and elbow is gently flexed.

Alternatively, Sultanpur method of reduction may be used where in a plaster cuff is applied to the arm extending up to the distal end of the proximal fragment. Once this sets the distal fragment is pushed back against this cast with elbow in about 110° flexion and the cast is quickly completed. This method avoids immobilizing the elbow in the extension, thereby reducing the risk of stiffness in this position. Stiffness of the elbow in extension greatly compromises function.

- After care: The plaster immobilization is continued for 4 weeks (slightly more in older children). Lack of the tenderness at the fracture site and the X-rays suggest union. Active elbow exercises are started at this stage. A sling may be worn for a few days and discarded as early as the patient is comfortable.
- Percutaneous pinning: If image intensifies is available and during reduction, it is discovered that the reduction is achievable but unstable, percutaneous pinning may be performed. Two Kirschner-wires are used and both are introduced from the lateral side either parallel to each other or in a crossed manner. The ends of the wires are bent to avoid migration. The wires are removed after 3 weeks. Percutaneous fixation is also useful for flexion type of supracondylar fractures where it obviates the need for immobilization of the elbow in near extension.
Open reduction and pinning: is used for irreducible fractures, cases where closed reduction cannot be maintained due to inability to flex elbow above 90° (due to severe swelling and disappearance of radial pulse) and in cases with an associated vascular injury. A medial, lateral or anterior approach is used and the fracture is openly reduced and stabilized by crossed K-wires inserted from medial and lateral epicondyles (Figs 111.18A and B). K-wires are removed after 6 weeks.

Traction: Skin (Dunlop) or skeletal (olecranon pin) traction is often useful in cases where the reduction is difficult to achieve or maintain due to significant soft tissue swelling or comminution of the fracture fragments. Traction is also indicated in cases with minimal circulatory impairment, when brachial artery exploration is not indicated.

Complications

Vascular injury: Vascular injury is associated with less than 1% cases of supracondylar fractures. The vascular injury can be due to kinking over the proximal fragment, spasm of the vessel, extrinsic pressure by fracture hematoma and swelling, internal thrombus, internal tear, contusion of the vessel, partial or complete tear of the brachial artery.

Tethering of the skin overlying a prominent spike of proximal fragment in the absence of a palpable radial pulse suggests entrapment of the neurovascular bundle and is an indication for urgent exploration. Excessive swelling and bruising around elbow may suggest vascular injury. Other signs of vascular compromise should be looked for in these cases. Often the patient may present with Volkmann's ischemia or rarely frank gangrene of the fingers.

When a patient with vascular compromise is seen, all the encircling bandages are removed. Fracture is reduced by gentle manipulation and the radial pulse checked. If the radial pulse does not return the brachial artery is explored. Peroperatively, the local pressure on the vessel is relieved. The spasm of radial artery is relieved by local application of xylocaine or papaverine or by stripping the adventitia of the vessel, thus effecting sympathectomy. Spasm, which does not get relieved by these maneuvers, is possibly an intimal tear and needs expert vascular intervention. Laceration of the artery needs repair. The fracture should be openly reduced and stabilized with K-wires in all these cases. Acute Volkman's ischemia is managed by urgent fasciotomy extending right from elbow distally up to the carpal tunnel. The wound is closed secondarily after 3-5 days or skin grafted.

Established cases of Volkman's ischemic contracture are managed by physiotherapy and splintage when mild. Severe cases need excision of dead and fibrotic muscles correction of deformity (as by Maxpage flexor-pronator muscle slide or forearm/carpus shortening procedures) and restoration of function (using tendon or muscle transfers, nerve grafting).
Nerve Injury: Nerve injury may be associated with 7% cases of supracondylar fractures of the humerus. The nerve injuries are commonly due to neuropraxia or axonotmesis and recover spontaneously. Radial nerve injury is most common and is seen in posteromedial type of fracture. Median nerve is the next commonest and is involved in the posterolateral type of supracondylar fractures. Ulnar nerve is injured more commonly in flexion type of supracondylar fractures and in overhead skeletal traction. Nerve injuries are treated expectantly. However, if the recovery does not occur spontaneously, the nerve is explored.

Myositis ossificans: Myositis Ossificans is seen most commonly following massage (when fracture is set by osteopaths), repeated closed manipulations and open reduction sometimes, following open reduction. In the acute stage it presents with pain, swelling, erythema and stiffness. Serum alkaline phosphatase is often raised. On radiographs the calcific mass looks cloudy with ill-defined margins. Any intervention at this stage can aggravate the condition.

In the acute stage it presents with pain, swelling, erythema and stiffness. Serum alkaline phosphatase is often raised. On radiographs the calcific mass looks cloudy with ill-defined margins. Any intervention at this stage can aggravate the condition.

Mature myositis is quiescent clinically without attendant features mentioned above and looks well demarcated on radiographs. At this stage an excision of the myositis mass can be attempted if it is likely to improve range of motion at the elbow.

Malunion: Cubitus varus (Gunstock deformity) is the most common deformity following the supracondylar fracture of the humerus. It occurs due to a combination of malunion in the three planes-c coronal (medial tilt), sagittal (posterior tilt) and horizontal (internal rotation of the distal fragment). The carrying angle at the elbow is reduced and patient has unsightly deformity. Radiographs show crescent sign and reduced Baumann's angle (angle between the line along lateral condylar epiphysis and a line perpendicular to the long axis of the humerus). Treatment is required only for cosmetic reasons. In case the deformity is cosmetically objectionable, it should be treated by lateral closed wedge osteotomy (French osteotomy) performed at least one year after the fracture after the remodeling is complete. Cubitus valgus occurs rarely, following the posterolateral type of fracture. This deformity is not cosmetically objectionable as cubitus varus. A longstanding deformity, however, may result in tardy ulnar nerve palsy, which requires anterior transposition of the ulnar nerve.

Stiffness of the elbow: Minimal loss of flexion is common even in the well-treated supracondylar fractures. Severe stiffness may result in cases with myositis ossificans or when late open reduction is attempted (more than 5 days after injury).

Trans Condylar Fractures
These are type I epiphyseal injuries which usually occur in children less than 3 years of age. Type II epiphyseal injury may occur in older children. The displacement is usually posteromedial. The radiographs confirm the injury and displacement. Treatment is by closed reduction and immobilization in flexion and pronation. Unstable reductions or irreducible fractures are managed by percutaneous or open pinning.

Fractures of the Medial Epicondyle
Fractures of the medial epicondyle are common between 8-14 years of age. Almost 50% of fractures of the medial epicondyle are associated with elbow dislocations.

Mechanism of Injury
The medial epicondyle is fractured by a valgus pull with extension when it is avulsed by the flexor muscle mass and the ulnar collateral ligament. Due to this mechanism, ulnar nerve injury is commonly associated.

Classification
Fracture of the medial epicondyle can be undisplaced or displaced (Fig. 111.19). Displacement can sometimes be intra-articular with the fragment trapped into the joint.

Evaluation
Patient presents with the history of forcible abduction at the elbow followed by pain and tenderness, on the medial aspect of the elbow. Bruising may be present over the medial sides. Ulnar nerve should always be tested.
Imaging

Anteroposterior and lateral views of the elbow should be taken. Radiographs of the opposite elbow taken for comparison can be extremely useful X-ray confirm the fracture and its displacement. Intraarticular displacement of medial epicondylar fragment should be suspected when the medial epiphysis is not seen in AP view in a child over 6 years old, when it is seen on the lateral film, and when the medial epicondylar fragment is seen at the level of the joint line.

Treatment

Conservative treatment is adequate when the fragment is displaced less than 2 mm. Above elbow plaster slab for 3 weeks followed by active exercises is adequate for all cases. Displaced fractures are treated by open reduction and K-wire fixation.

Intra-articular displacement of the medial epicondylar fragment is managed by manipulation under anesthesia. If this method fails, medial epicondyle is retrieved surgically and fixed to its bed using K-wire or soft tissue suture. K-wire is removed after 3 weeks.

The indications for surgery in fractures of medial epicondyle humerus are:

- Displaced fracture in individuals with athletic pursuits
- Acute post-traumatic ulnar nerve palsy and
- Acute incarceration of the medial epicondyle in the elbow joint with failed attempts at closed manipulation.

The methods of closed removal of the incarcerated fragment are as follows:

- Robert’s manipulative method: extension of elbow, supination of forearm, dorsiflexion of wrist and sudden hyperextension of the fingers causing tension on the common flexor origin may help in removal of the incarcerated fragment. This is effective when done before 24 hours.
- Faradic stimulation has been used by some
- Distension of the joint by air/fluid may help in extraction.

Complications

1. Ulnar nerve injury is common in these fractures. Most ulnar nerve palsies in these injuries are lesions in continuity, i.e. neuropraxia. Recovery usually begins within 3-6 weeks. Tardy ulnar nerve palsy may also occur long after these fractures.
2. Stiffness of the elbow may occur.
3. Weakness of forearm muscle (flexor-pronator group) may occur if a significantly displaced medial epicondylar fracture is left untreated.

Fracture of the Medial Condyle

This is a rare injury in children and is often missed. Injury is seen between 8-14 years of age. It is caused by an extension and valgus stress. The fracture is classified by Milch according to anatomical location as type I (fracture line passes through the apex of trochlea) and type II (fracture line passes through the capitello-trochlear groove). Milch I is caused by impaction by radial head while Milch II is caused by impaction by olecranon. The fragment displaces anteromedially by pull of flexors and medial collateral ligament. Impacted or undisplaced fractures are treated in an above elbow cast. Displaced fractures, especially with rotation, are treated with open reduction and internal fixation. Complications include non-union with cubitus varus, delayed union and tardy ulnar nerve palsy.
Fracture of the Lateral Epicondyle

It is a very rare injury and is often missed as it is confused with the normal physeal line. The epiphysis usually appears at the age of 11 years and fuses 2-3 years later. Avulsion of the lateral epicondyle occurs following adduction stress. Comparison with radiographs of the opposite side is extremely helpful. If the displacement is less than 2 mm, the injury is treated in above elbow slab for 3 weeks. Greater displacements need open reduction and fixation with K-wire or soft tissue suture.

Fracture of the Lateral Condyle

The fracture of the lateral condyle occurs in 16.8% of elbow fractures and in 54.2% of physeal injuries around elbow. The injury is common between 4 to 8 years of age.

Mechanism of Injury

Extension and varus forces lead to avulsion of the lateral condyle. Lateral condylar fractures can also be caused by valgus stress over the elbow in which case it is fractured by shearing force.

The fragment is displaced by forearm extensors or the lateral ligament. Lateral condyle fractures are divided into two types according to Milch. In type I, the fracture line extends lateral to trochlea through the capitello-trochlear groove. It is a type IV epiphyseal injury. In type II, the fracture line extends into the apex of the trochlea. It is a type II injury.

The lateral condyle fractures can also be classified as undisplaced, displaced or rotated.

Evaluation

Child presents with history of trauma followed by pain and swelling of the elbow. Tenderness is present over lateral aspect of the elbow. Crepitus may be present over the lateral aspect. Movements of the elbow are painfully restricted.

Imaging

Plain radiographs of the elbow confirm the diagnosis and degree of displacement of the fragment. Size of the fragment as visualized on the X-ray is much smaller than the real size of the fragment when encountered during the surgery due to the large cartilaginous component of the fragment.

Treatment

Undisplaced fractures are treated in above elbow cast for 4 weeks. However, radiographs should be taken at weekly intervals to ensure that no late displacement of the fracture occurs.

For displaced fractures, especially with rotation conservative treatment is not effective. Open reduction and internal fixation with K-wires is recommended. The blood supply to the fragment enters from the posterior aspect and this aspect of the fragment should not be stripped of the soft tissues. Following surgery above elbow cast is applied for four weeks. Active exercises are started at the end of this period.

Complications

- Delayed union or non-union is common in these cases. Non-union leads to progressive cubitus valgus deformity and tardy ulnar nerve palsy. The latter is treated by anterior transposition of ulnar nerve. Supracondylar osteotomy may be indicated sometimes to correct the deformity.
- Avascular necrosis of the fragment occurs in operated cases where excessive soft tissue stripping is done
- Premature physeal growth arrest may occur
- Lateral condylar overgrowth may be seen
- Myositis ossificans may occur
- Cubitus valgus occurs due to non union and/or epiphyseal growth arrest and can be progressive.

Pulled Elbow (Nursemaids Elbow; Guyrand’s Elbow)

Pulled elbow occurs in young children (2-3 years old) due to ligamentous laxity. It is a hyperpronation injury, which leads to subluxation of radial head and partial displacement of the annular ligament. The parents give history of fall the child by holding his/her hands with forearm pronated. The child is often crying and refuses to use his upper limb, which hangs by the side of the body. Radiographs do not reveal any abnormalities and are not needed for diagnosis or treatment. Treatment consists of supination of the forearm with...
elbow flexed. The resumption of hand usage by the patient is immediate. No after care is required.

**Fracture of Radial Neck**

Fractures of radial neck occur in children. Metaphyseal compression is most common but often these injuries are type II epiphyseal injuries. These fractures may be associated with other injuries around elbow in almost half the cases.

**Mechanism of injury**

This injury is caused by fall on the outstretched hand.

**Classification**

Radial neck fractures can be undisplaced or displaced. Displaced fractures with the tilt of radial head from horizontal than 30° are treated differently from those with more than 30° tilt.

**Evaluation**

Patient presents with history of fall on the outstretched hand and pain in the elbow following that. There is tenderness over the lateral aspect of the elbow. Elbow and forearm movements are painfully restricted.

**Imaging**

Plain radiographs confirm the diagnosis and displacement of the fragment. Diagnosis is extremely difficult in a child younger than 3 years when radial head is not visualized on X-rays. High index of suspicion is required for diagnosis in these cases.

**Treatment**

Undisplaced fractures and with fractures less than 30° tilt of the radial head are treated conservatively in a plaster slab for two weeks.

Greater displacement is treated by manipulation to reduce the fracture under anesthesia. With the elbow extended a varus stress is applied to the elbow that one hand and the radial head is pushed into place with the fingers of the other hand. Failing manipulative reduction, open reduction is performed. The fracture is usually stable after reduction and is treated in a POP slab for two weeks. Transcapitellar wire into the head and neck of radius to fix the fracture has high rate of complications (breakage, migration of wire) and should be avoided.

**Forearm Fractures**

The radius and ulna are held together at the proximal and distal radio-ulnar joints, by annular ligament proximally, interosseous membrane along the length and the triangular fibrocartilage distally. These anatomical features do not allow only one forearm bone to fracture and shorten without disrupting either proximal or distal articulation between the two bones. The commonest fracture dislocation of this type is a fracture of ulna with dislocation of the radial head—the Monteggia fracture dislocation. A fracture of the shaft of radius associated with dislocation of inferior radio-ulnar joint is called Galeazzi fracture dislocation.

Fractures of the forearm bones are common in all age groups. In adults these fractures often result from the high-energy trauma, often with associated musculoskeletal and systemic injuries.

**Mechanism of injury**

Fractures of the radius and ulna can be caused by direct as well as indirect injury. Direct injury is commonly due to warding off blows, which commonly results in ulna fractures. These fractures are transverse and may be compound. Indirect injury occurs due to fall on outstretched hand and produces oblique or spiral fractures. Monteggia fracture dislocation can be the result of hyperpronation (indirect) or night stick (direct) injuries.

**Classification**

Forearm fractures are classified according to the location or configuration of the fractures. They are also characterized by the presence of dislocation of radio-ulnar or radio-humeral joints.

Monteggia fractures are classified into four types by Bado:

1. **Anterior type (Type I)** has anterior dislocation of radial head with proximal third ulna fracture angulated anteriorly. This is the commonest type (60%).
Posterior type (Type II) has posterior dislocation of radial head with proximal third ulna fracture angulated posteriorly.

Lateral type (Type III) has lateral radial head dislocation with lateral angulation of proximal ulnar fracture.

Type IV proximal third both bone forearm fractures of the forearm with anterior dislocation of the radial head.

Monteggia Variants in Children

The injuries are considered to be the equivalent of the Monteggia fracture in children:

Type I: Plastic deformation of proximal 1/3rd of ulna.

Type II: Greenstick fracture of proximal 1/3rd of ulna.

Type III: Isolated radial head dislocation.

Type IV: Fracture of both bones forearm with radial fracture proximal to ulna.

Hume’s fracture refers to the fracture of the proximal third of ulna with anterior dislocation of the radial head in children.

It should be remembered that in the proximal third fractures of the forearm bones, the proximal fragment of radius is supinated by biceps while the distal fragment is pronated by pronator teres and pronator quadratus. In the mid or distal third fractures the proximal fragment is in neutral position as the biceps and pronator teres are both attached to it.

Greenstick fractures in children are seen on X-rays as breech of only one cortex. Torus fractures caused by compression force are seen as buckling of the cortex in metaphyseal region.

Treatment

Conservative treatment is used in children, in undisplaced or minimally displaced fractures in adults, fractures in elderly and in patients in whom anesthesia or surgery is contraindicated. Manipulation under anesthesia is attempted in patients with displaced fracture, preferably under image intensifier and the forearm is immobilized in above elbow cast with elbow in 90° flexion for 12 -16 weeks. Close follow up must be done for these patients, as there is a very high incidence of redisplacement. Weekly X-rays should be taken during the first 3 weeks and plaster checked for loosenning or breakage. Undisplaced fractures can be managed by replacing the long-arm cast with a functional fracture brace with good interosseous moulding in the second week.

Monteggia fracture-dislocations are treated with open reduction and rigid internal fixation of ulna using AO 3.5 mm DCP. Radial head generally gets reduced spontaneously at this stage. Irreducible radial head is an indication for open reduction to address infolding of the annular ligament, entrapment of posterior interosseous nerve or incarceration of the radial head behind the lateral epicondyle. After surgery the limb is mobilized in above elbow cast in 110° flexion (to keep the anteriorly unstable radial head reduced) except in type II Monteggia where posteriorly dislocated head is stable in less than 90° (usually 70°) flexion after the reduction. The immobilization is discontinued after 6 weeks.

Galeazzi fracture dislocation: This consists of a fracture of the lower 1/3rd of the radius with dislocation of the distal radioulnar joint (DRUJ). It is often referred to as a fracture of necessity (c.f. lateral condylar physis injuries). This is because the fracture of distal radius are preferably immobilized in full pronation while the most common dislocation of the DRUJ is posterior which is stable only in full supination. The injury must therefore be treated with open reduction and internal fixation of radius (through an anterior approach using AO 3.5 mm DCP) and above elbow cast in supination for 6 weeks for the more common type with dorsal subluxation of ulna. Volar subluxation of ulna is treated with immobilization in pronation after internal fixation of the radius fracture.

Complications

1. Compartment syndrome may occur in patients with gunshot wounds, open fractures and fractures with vascular injury. High index of suspicion in needed for early diagnosis. Compartment pressures should be measured in doubtful cases. Early fasciotomy can preserve function.

2. Neurologic injury is otherwise uncommon in these fractures but posterior interosseous nerve palsy may complicate Monteggia fracture-dislocation.

3. Non-union is seen after conservative treatment if immobilization is ineffective or discontinued too
soon. Comminuted fractures and fractures which are not rigidly fixed at surgery are also prone to develop non-union. Treatment of non-union is autogenous bone grafting and rigid internal fixation.

4. Malunion is common with conservative treatment. It leads to deformity and restricted rotations. Severe malunion may warrant redoing the fracture followed by anatomical reduction and rigid internal fixation. Malunited Monteggia fracture-dislocations present with persistent radial head dislocation. Treatment includes ulnar osteotomy, plating after anatomic reduction and radial head excision in adults. In children, radial head should not be excised in order to avoid progressive instability at the elbow. Attempt should be made in these cases to openly reduce radial head and reconstruct the annular ligament using a fascial (Bell-Tawse procedure: fascial strip is taken from the tricipital fascia) or tendon graft.104

5. Cross union occurs in 3% cases and is common if the fractures are at the same level (most common in upper 1/3rd fractures) or are fixed by single incision allowing the fracture hematomas to communicate, if the fractures are caused by high-energy injuries, cases with infection, associated closed head injuries, if bone grafts are placed on the interosseous membrane during surgery and also following radial head excision. Cross union (proximal radio-ulnar synostosis) occurs more commonly following Monteggia fracture-dislocation.

6. Hardware related complications such as loosening, infection, breakage, etc.

7. Missed associated dislocation: Radial head dislocation is frequently missed when associated with proximal ulnar fractures. A useful clue is that normally in a lateral view of the elbow, throughout the range of flexion, a line along the longitudinal axis of the radius should always bisect capitellum.

Distal Radius Epiphyseal Injury

Distal radius epiphyseal injuries are common in adolescents. These are usually Salter Harris type II injuries and occur following fall on the outstretched hand. Diagnosis is easily made on radiographs. Anatomic reduction is mandatory for satisfactory results. Reduction should be done early. Displaced fractures are treated by manipulative reduction and below elbow Colles' plaster cast for 3 - 4 weeks. Growth disturbance is rare.

LOWER EXTREMIT Y MUSCULO SKELETAL TRAUMA

Fracture Neck Femur in Children

Fractures of femoral neck in children are treated with closed reduction and internal fixation using multiple Moore’s or Knowle’s pins. Surgery is done on the fracture table with the image intensifier. The fracture can be reduced in flexion or extension.

Reduction in Flexion

Traction is applied in the line of femur with the hip and the knee in 90° flexion and internal rotation at the hip. With the traction and internal rotation at the hip maintained, the hip is gradually extended and abducted. Reduction is checked under image intensifier/X-rays (Leadbetter technique).

Reduction in Extension

Traction is applied in the line of femur with hip and knee extended and 15-20° abduction and external rotation at the hip. The limb is firmly internally rotated fully to reduce the fracture and reduction checked under image intensifier/X-rays (Whitman technique).

Following reduction, the pins are inserted from the greater trochanter into the head of the femur. Pins should not cross the physis (Fig. 111.20).

Fig. 111.20: AP and lateral views of fracture neck femur in a child stabilized by screws
The patients should be immobilized in a one and a half hip spica for 8-12 weeks following fixation.

If a femoral neck fracture is not treated, the femoral neck starts getting resorbed by the end of four weeks and marked up riding of greater trochanter occurs. Accurate anatomical reduction becomes impossible in these cases. The following methods of treatment are available for those cases which are neglected/detected after three weeks:

In children with neglected femoral neck fracture, an intertrochanteric valgus (or abduction) osteotomy with internal fixation and or spica is the method of choice. Free fibular graft can be used across the fractures in these cases to provide fixation and enhance bone stock.

**Fractures of the Femoral Shaft**

Fractures of the femoral shaft result from severe injuries and are commonly associated with other serious injuries. The bone is enveloped by well vascularized musculature, which sustains considerable trauma in association with the shaft fracture. The compound femoral fractures are uncommon due to thick overlying soft tissue envelope. Considerable bleeding occurs from femur fracture and up to 1500-ml blood may be lost without any evidence of external bleeding.

**Mechanism of Injury**

Severe trauma, as in motor vehicular accidents, falls from height or natural calamities (as in earthquakes) leads to femoral shaft fracture. Bomb blast and gunshot wounds can lead to femoral shaft fractures along with severe injury to the soft tissues.

Pathological fractures of the femoral shaft occur commonly in association with various benign and malignant lesions located in the shaft.

Any patient with suspected femoral shaft fracture must undergo a quick assessment of vital parameters and resuscitation should be instituted immediately. Two wide bore no. 14 venflons must be used to access venous system and samples sent for blood group and cross matching, and hematocrit. Intravenous ringer lactate infusion should be started. Patient should be evaluated to rule out cranial, abdominal, thoracic and pelvic injuries.

Local examination reveals marked shortening, swelling and deformity of the thigh. The attempted movements are painful and the patient is unable to lift the leg. Any breech in the skin should be presumed to be an open fracture. Severely tense thigh should raise the suspicion of a compartment syndrome and warrants pressure measurement of the thigh compartments. A careful and detailed neurovascular examination of the extremity should be performed. Other skeletal injuries commonly associated with femoral shaft fracture should be looked for and include acetabular fractures, pelvic ring fracture, ipsilateral hip dislocation, patella fracture and ligamentous disruptions of the knee.

**Imaging**

Imaging for suspected femoral shaft fracture should include anteroposterior and lateral radiographs of the entire femur. Ipsilateral hip and knee X-rays must be taken to look for associated fractures. An anteroposterior view of pelvis must be taken in all patients with femoral shaft fractures as a screening tool for pelvic ring injury or acetabular fractures. An internal rotation view of the hip to visualize femoral neck is mandatory to rule out associated femoral neck fracture. Adduction of the proximal fracture fragment indicates associated posterior dislocation of the ipsilateral hip.

**Treatment of Femoral Shaft Fractures**

All patients with femoral shaft fracture are treated initially with resuscitation. Intravenous fluid infusion, blood transfusion and splintage. The femoral shaft fracture can be treated by both conservative as well as surgical means though surgical treatment has become the mainstay in recent times.

Conservative Treatment—Conservative treatment is the method of choice in infants and children.

**Infants younger than 2 years** are treated in the Gallow’s or Bryant’s traction. Adhesive tape is applied on bilateral legs and traction rope through the tape is attached to an overhead point so that buttocks of the infant are just off the bed. Body weight acts to align the fragments and 3 weeks in this traction are sufficient to achieve union. This type of traction is
Older children can be treated in fixed skin traction on Thomas splint or by sliding traction through an upper tibial (tensioned) Kirschner-wire with the thigh supported on a pillow. The fracture usually takes about 6 weeks to heal. Internal fixation with plating may be done in patients with polytrauma or floating knee (Figs 111.21A and B).

**Distal Femoral Epiphyseal Injury**

Separation of the distal femoral epiphysis (Type 3 Salter and Harris type) is a rare injury, which occurs in adolescents. Classically, the injury is sustained by a severe hyperextension force when the person is trying to ride on a cart while running after it. The epiphysis is displaced anteriorly and laterally and sharp spike of the proximal fragment can injure the popliteal artery. The diagnosis is evident on X-rays. The treatment is urgent closed reduction under anesthesia. The reduction may be stabilized by fixing the fragments using smooth Kirschner-wires. A long leg last is applied with knee flexed 60° for 6 weeks. The knee is mobilized at the end of this period and weight bearing started. The growth disturbance following the injury is uncommon.

### Fractures of Tibia and Fibula

Fractures of tibia and fibula are the commonest long bone fractures. The spectrum of injuries causing these fractures ranges from repetitive cyclic stress loading leading to fatigue fractures to extreme high-energy injuries leading to severe disruption and loss of soft tissue structures and bone. Close to one fourth of all the patients may present as open injuries and soft tissue management is the key factor in the management of these fractures.

#### Mechanism of Injury

The commonest cause of the both bones fracture in children is the indirect injury where the foot is caught somewhere and the twisting force causes an isolated fracture of the tibia. Other causes are road traffic accidents, fall from height and other high-energy injuries. The type of injury determines the configuration of the fracture - torsion forces produce spiral fractures while direct injury (bending force) produces a transverse fracture. High-energy torsion and combinations of bending with torsion or compression lead to comminuted fractures.

#### Classification

Tibial and fibular fractures can be classified as closed or open. Open fractures are classified by Gustilo's classification. No standardized classification for fracture pattern is available but a simple way is to classify these fractures into three types: simple (spiral, oblique or transverse), fractures with a butterfly fragment and comminuted (including segmental and crush) fractures.
Evaluation

Initial assessment includes vital function evaluation, examination for associated injuries and resuscitation. Other skeletal injuries in the affected extremity should be looked for. Local examination reveals deformity, which is readily apparent since tibia is mostly subcutaneous. The limb is shortened in cases with displaced fractures. Pain, tenderness and abnormal mobility is present at the fracture site. Soft tissues are inspected circumferentially for skin wounds, ecchymosis and any evidence of compartment syndrome. Neurovascular examination of the limb is extremely important and should be recorded.

Imaging

Anteroposterior and lateral radiographs are adequate for diagnosis and assessment of the fracture. It is imperative to include ipsilateral knee and ankle in the radiographs.

Treatment of Fractures of the Both Bones of the Leg

Treatment of fractures of the both bones of the leg is determined by the condition of soft tissues and location and configuration of the fracture and the nature of associated injuries. In treatment of fractures of both bones of the leg, fibula is ignored and treatment is planned mainly for the tibia fracture.

Conservative Treatment—Conservative treatment is the most commonly used method of treating fractures of the both bones of the leg in children. This method is applicable to closed fractures and grade I compound (skin opening < 1 cm, most likely from inside out) fractures. Rarely, fracture may have to be reduced under anesthesia. The fracture is then immobilized in an above knee plaster cast. Fractures where acceptable reduction is achieved are monitored with weekly check X-rays to detect redisplacement of the fracture. Accepted guidelines for reduction are at least 50% cortical contact, varus/valgus up to 10°, anteroposterior angulation up to 10°, less than 10° rotational malalignment and less than 1 cm shortening. The immobilization is discarded after 6 to 8 weeks, once the radiological evidence of union appears.

REFERENCES

Conjoined twins, one of the rarest congenital anomalies, have always fascinated the public, attracted intense media attention and challenged the surgeon caring for them. Even nature has pointed towards the existence of this entity in other living beings like plants and animals (Figs 112.1A and B). It is a rare opportunity for a pediatric surgeon during his or her professional career to encounter the challenge to separate conjoined twins. This chapter emphasizes the more common features of conjoined twins and their management.

HISTORICAL BACKGROUND

The earliest recorded case of conjoined twins is that of the 'Biddenden maids' born in England in 1110. Bondeson who reviewed their history, also wrote about other cases of historical interest. The first successful separation of omphalopagus conjoined twins by ligation of a small bridge of tissue at the level of the umbilicus has been attributed to Konig in 1689.3

The most famous conjoined twins were Chang and Eng, who were born in 1811 in Siam, as Thailand was previously called, giving rise to the misnomer Siamese twins. They were the first-born sons of a half-Chinese and half-Siamese mother and a Chinese father and were known in their native land as the Chinese twins. A narrow band of tissue measuring 3.5 inches across and 7.5 inches in circumference joined them at the epigastrium. Their mother noted that the junction was initially so short that the boys were always compelled to be face to face and in bed, they had to be lifted and placed in the desired position. As they grew, the union

**Figs 112.1A and B:** Conjoined twins in nature: A. Lady finger, B. Photograph of a craniopagus twins in a calf displayed during the horse and cattle show, Lahore, Pakistan
gradually stretched so that they could stand side by side, and even back to back, and to turn themselves in bed, they rolled over one another.\textsuperscript{4}

The twins emigrated to the United States and PT Barnum exhibited them in his circus shows. This resulted in conjoined twins being viewed as freaks. However, they were very popular and Chang and Eng became wealthy. They changed their family name to Bunker and married two sisters, English ladies 26 and 28 years of age, respectively. Chang and Eng retired as farmers in North Carolina and fathered 22 children between them.\textsuperscript{1,5,6} On January 12, 1874, at the age of 63, following chest infection, Chang died. Eng refused to be separated, and he died 6 hours later, probably due to exsanguination through the conjoined bridge of tissue. The band of tissue which united Chang and Eng was found to be composed of some muscle with a thin bridge of liver tissue, a situation which would have allowed easy separation during life as well as after the death of Chang.

INCIDENCE AND ETIOLOGY

The exact incidence of conjoined twinning is unknown but is estimated to be approximately 1 in 50,000 deliveries. Since two-thirds are either stillborn or die soon after birth, the incidence ranges from 1 in 100,000 to 1 in 200,000.\textsuperscript{7-10} In the Edmonds and Layde study from the United States, 40\% of conjoined twins were stillborn, 35\% survived only one day, and 25\% survived long enough to undergo surgery.\textsuperscript{10}

The etiology of conjoined twinning is unclear but is thought to be due to an aberration of the normal twinning process which occurs at about 20 days postovulation or a few days earlier.\textsuperscript{11,12} Conjoined twins are monozygotic, monochorionic twins with identical chromosome patterns.\textsuperscript{13} One theory suggests that complete separation of the inner cell mass within the chorionic vesical does not occur, and the resulting non-separated parts of the otherwise normal twins remain attached throughout development. Another theory is that the inner cell mass separate, but reunion occurs, giving rise to twins who are attached.\textsuperscript{14} The high incidence of discordant anomalies unrelated to the site of union suggests that environmental influences may also play a role.\textsuperscript{15,16}

Although the majority of conjoined twins are externally symmetrical, they can differ in size and personality, and have differences in energy metabolism.\textsuperscript{17,18} Their viscera are usually neither similar nor mirror images of each other.

CLASSIFICATION OF CONJOINED TWINS

Symmetrical conjoined twins are classified according to the dominant anatomical area of union followed by the Greek root word "pagos", meaning —that which is fixed". This classification is informative and convenient for clinical use.\textsuperscript{19} The five basic types are: thoracopagus, joined at the chest (40\%); omphalopagus or xiphopagus, joined by the anterior abdominal wall with the union extending from the xiphoid process to the umbilicus (33\%); pygopagus, joined at the buttocks (19\%); ischiopagus, joined at the single pelvis (6\%), and craniopagus, joined at the heads 2\% (Figs 112.2A to H).\textsuperscript{20} Ischiopagus twins are further grouped as ischiopagus bipus, tripus and tetrapus based on the number of lower limbs present. Recently, nomenclature based on the theoretical site of union has been proposed to facilitate identification of the pertinent anatomy of the twins.\textsuperscript{21} However, this classification has not enjoyed widespread clinical use as yet.

Thoracopagus Twins

Thoracopagus twins are the most common type. They lie face to face, sharing varying degrees of fusion of the sternum, thoracic cage, diaphragm, and the abdominal wall down to the umbilicus (Figs 112.3A and B). Seventy-five percent have conjoined hearts, 50\% have fusion of intestinal tracts, and 25\% have fusion of the biliary tree.\textsuperscript{22} Fusion of the liver is invariably present. When the hearts are joined, the abnormal union of ventricles and associated anomalies of the great arteries and veins often make surgical separation impossible. Occasionally, the esophagus and stomach are single, but the union usually starts in the distal duodenum. Joining of the biliary tree should be suspected particularly when the duodenum is single in the region of the Ampulla of Vater.

Omphalopagus or Xiphopagus Twins

Omphalopagus or xiphopagus twins also face each other, joined from the xiphisternum to the umbilicus. They usually have the least complicated union of all conjoined twins. A liver bridge is present in two-thirds of the cases. The peritoneal cavity of one may or may not communicate with that of the other. An
Figs 112.2A to H: Classification of conjoined twins

Figs 112.3A and B: A. Thoracopagus twins fused from the xiphisternum down to the umbilicus that were separated successfully B. The twins after separation
omphalocele is often present. The single umbilical cord may contain from two to seven umbilical vessels. The bladders may join via each child’s urachus in the band of tissue connecting the twins.

**Pygopagus Twins**

Pygopagus twins are joined at the sacrum and lower back; thus, they face away from each other. They may share a common spinal canal at the site of fusion, and it is common for them to have a shared lower rectum and anus, as well as fused lower genital tracts and external genitalia.

**Ischiopagus Twins**

Ischiopagus twins are united at the single bony pelvis, and the fusion begins at the level of the common umbilicus (Figs 112.4A to G). The axes of the bodies extend in opposite directions. They are mostly amenable to surgical separation since the organs, which they share, can be separated and the structures they share are not essential to sustain life. Upper gastrointestinal tracts are usually separate but often join at the distal ileum, which empties into a single colon. The rectum and anus may not empty into the perineum and may require proximal diversion soon after birth.

**Craniopagus Twins**

Craniopagus twins are rare. Joined at the heads, the union may be at the vertex, occiput or lateral parietal areas of the skull. The two brains may be connected by a bridge of neural tissue and have large intracranial vascular connections. Based on the location of the junction, the fusion of the brain tissue and the venous structures requiring interruption at operation, craniopagus twins have been reclassified.32

**Asymmetrical Conjoined Twins**

Unequal and asymmetrical conjoined twins in whom one is smaller and dependent on the other are called heteropagus conjoined twins. This type of twinning is extremely rare, occurring in about 1 or 2 per million live births.

**PRENATAL DIAGNOSIS AND EVALUATION**

Since the first report of in utero findings of conjoined twins using ultrasound in 1977 by Wilson, many cases have been reported.24-29 The diagnosis of conjoined twins can be made as early as the 12th week of gestation by ultrasonography.30,31 Either large maternal size for gestational age, or polyhydramnios, which is present in about 50% of conjoined twin pregnancies, should serve as an indication for prenatal sonographic study of the mother.

Detailed scanning during later pregnancy allows assessment of shared hearts and associated anomalies, such as an omphalocele. Echocardiography is useful in the prenatal evaluation of thoracopagus conjoined twins and the presence or absence of cardiac junction has been correctly determined in each instance.32 In utero echocardiogram is thought to be more thorough and simpler than postnatal examination since more views can be obtained, and the examination is not hampered by cardiac conjunction and associated omphalocele.32 This information allows appropriate counseling as well as planning of obstetrical and neonatal management.

Since the ability to separate thoracopagus twins and their mortality are directly related to the union of two hearts and the associated cardiac and vascular anomalies, reliable prenatal evaluation may play a significant role in deciding whether to consider termination of pregnancy. Computerized tomography (CT) and magnetic resonance imaging (MRI) have been introduced antenatally and provide additional detailed imaging.33,34

**OBSTETRICAL MANAGEMENT**

Although conventional hazardous vaginal delivery has been possible in many instances, particularly in the presence of a flexible connecting bridge, timely cesarean section in the presence of well-informed and prepared pediatricians and surgeons may improve survival.35,36 The introduction of prenatal diagnosis has led to increased delivery by cesarean section and salvage of twins who would have succumbed if delivered by vaginal delivery.37 When conjoined twin pregnancy is diagnosed, the pregnant mother should be transferred, with minimal delay and publicity to a center with special expertise or experience in
Figs 112.4A to G: Parapagus conjoined twins that were admitted at 12 hrs after birth by vaginal delivery. The combined weight was 3250 gm. There was early cyanosis in one twin that disappeared. The babies had normal feeding activity, A and B. The babies had two separate heads and upper chest, four upper limbs, lateral fusion with chest and abdomen, two vertebral columns, two legs, a single urinary outlet and a single bowel outlet. On investigation, there was a single liver with good uptake on HIDA, two hearts without any anomaly, four lungs; though compressed, two spines; each with a spinal cord, two each of stomach and duodenum but single distal colon and a normal single anus, C. Skiagram of the babies depicting two spines, D and E. On contrast study, the babies had two kidneys, 2 ureterus, but one urinary bladder and one urethra F. CT scan of the pelvis G. The parents were poor and not willing to undergo treatment. Thus the decision for separation was deferred.
separation procedures. If prenatal transfer is not possible, early postnatal transfer of the twins should be arranged.

Appropriate perinatal management of conjoined twins has been outlined by many investigators. If mothers with conjoined twins go into premature labor because of intrauterine distress, every effort should be made to stop labor in order to permit the fetuses to become as mature as possible to avoid respiratory distress syndrome. Amniocentesis with analysis of the lecithin/sphingomyelin ratio, which indicates when the fetus has achieved pulmonary maturity, is considered a useful technique for determining the timing of Cesarean delivery.

POSTNATAL EVALUATION

Following initial resuscitation and physical examination, special investigations are essential, depending on the site and extent of union. Knowledge of potential visceral and bony unions in a particular set of twins serves as a useful guide to the choice of diagnostic imaging studies. Table 112.1 summarizes the possible visceral unions in different types of conjoined twins as described by Votteler. Based on this information, appropriate diagnostic imaging studies can be performed (Table 112.2).

In thoracopagus twins, comprehensive evaluation of the cardiovascular system is mandatory. If this has not been assessed prenatally, it should be performed soon after birth since there is a possibility of an abnormality that is incompatible with life in one or both twins. The degree of separation of the two hearts is the most important prognostic factor.

Two separate pulses on physical examination and two independent QRS complexes on simultaneous electrocardiograms establish the presence of two separate hearts. A single QRS complex on electrocardiography is present when the hearts are fused. The single QRS complex often appears in one twin as a mirror image of that seen in the similar limb leads of the other twin. Other non-invasive studies include echocardiography, which has been found to be extremely useful for cardiac evaluation, and MRI. In addition, invasive angiographic studies will be necessary to delineate the intracardiac anatomy, blood flow, and anomalies of the great vessels.

Estimation of cross-circulation and admixture of the two circulatory systems is of practical importance since it allows the surgeon and the anesthetist to estimate the response to drug and anesthetics, or fluid and blood replacement. Spencer et al reported a technique of estimating the blood exchange from one twin to the other. Radionuclide cardioangiography has also been used to estimate the degree of cross-circulation. The rate of mixing due to cross-circulation is greatest in thoracopagus twins, especially in those with conjoined hearts or when there are significant vascular connections at the liver bridge or elsewhere. Failure to recognize this or to take adequate preventive measures can result in the death of one twin. The rate of cross-circulation in twins with less complicated unions is sufficiently low as to be of little clinical importance.

Thorough evaluation of hepatobiliary and pancreatic systems utilizing ultrasonography and radionuclide scans is extremely important. Instances in which the extrahepatic biliary tract is single and shared by both infants have been documented. Since the majority of thoracopagus twins share a common liver, it is essential to ascertain whether the hepatic venous outflow drains into the inferior vena cava of the same side or not. Without hepatic drainage, survival after separation is not possible. Thorough investigations must be carried out before and during separation to determine the status of the liver, extrahepatic biliary tree, pancreas and duodenum.

Depending on the level of junction, all forms of conjoined twinning except craniopagus, frequently share the gastrointestinal tract. In thoracopagus and omphalopagus twins, the junction can frequently be as high as the level of the duodenum. However, in pygopagus and ischiopagus twins, the junction is usually at the terminal ileum, in the region of the Meckel’s diverticulum. In these forms of twinning, imperforate anus may be present. The alimentary tract should, therefore, be carefully evaluated with contrast studies.

Urinary tract evaluation is particularly important in ischiopagus twins. It is done by ultrasound, intravenous urogram and cystography to obtain information on the function and number of kidneys, ureters and bladders. Further assessment of the genitourinary system is obtained with cystoscopy under anesthesia. Since most conjoined twins are female, the vagina should be assessed by ultrasound, vaginography and vaginoscopy. Whether or not the vaginas are duplex, the presence or absence of a cervix, a urogenital sinus and a hydrocolpus should be looked for. In males, proper evaluation of the penis and the scrotal contents is essential. If there is a possibility of gender change, discussion and consent of the parents must be obtained before surgery.

A thorough evaluation of the pelvis and the shared third lower limb by angiography is important in ischiopagus twins. CT and MRI are especially important to understand complicated bony unions and to visualize organ sharing in pygopagus and ischiopagus twinning. Large veins and arteries may communicate between the fused pelves in ischiopagus twins and knowledge of the blood supply to the shared limb will help in making a decision about limb salvageability and to which twin the limb should be given. Conventional radiographs, CT with 3-D reconstruction, and MRI may be needed to evaluate the pelves, vertebral columns and the pelvic structures in ischiopagus and pygopagus twins. MRI, in particular, is becoming the preferred diagnostic tool, especially in the assessment of craniopagus and pygopagus twins. Axial, coronal and sagittal views allow good assessment of neuroanatomy and pelvic floor muscles.

Conjoined twins are assessed by CT scanning, digital subtraction angiography, MRI and radionuclide scans. Electroencephalography, though often employed, does not help to determine cerebral connection but serves as a basis for future comparison.

In complex forms of twinning such as ischiopagus tripus, evaluation of skin perfusion has been described by perfusion flurometry, which utilizes a specially designed light retransmission probe and a microcomputer to integrate photometric reception. This technique allows assessment of viability of large skin flaps required to close the abdominal wall and lower extremity.

**ETHICAL CONSIDERATIONS**

Conjoined twins raise serious moral and ethical considerations. Avoidance of publicity from the time of antenatal diagnosis, delivery, postnatal period of investigations and growth, surgical separation and after discharge, is the surgeon’s responsibility. Transfer
of conjoined twins immediately after delivery to centers with experience in surgical separation is desirable. Great care must be taken to protect the twins' and family's privacy and to resist all efforts by the media to create a "media circus".

The surgeon-in-charge must develop a close relationship with the family since many difficult decisions may lie ahead in the management of the twins. A careful and thorough preoperative evaluation must be performed before detailed discussions with the parents. The welfare of the conjoined twins should be paramount in discussions of investigations and management. Legal and ethical issues must be dealt with prior to emergent or elective separation. The survival of the twins, which is of great importance, must be balanced against the expected quality of life and the wishes of the parents. Where possible, consultations with surgeons familiar with the problems of separation of conjoined twins should be conducted.

It may become apparent that only one twin can survive the separation if there are conjoined hearts, or in situations where there is only one set of hepatic veins draining the liver. In twins with conjoined hearts, the question of sacrificing one twin so that the other may live is a difficult decision for both the family and the surgeon. It is important to understand that both twins would die without separation, and with separation, at least one life may be saved. It is the inherent anatomical conjunction rather than the complexity of the operation, which usually determines the outcome of separation. The Judeo-Christian attitude towards this subject is summarized in the Hastings Center Report.52

Thorough consultation with the parents is essential before decisions can be made on allocation of organs based on the data available. When there are no medical differences between the twins, management and allocation of organs must be individualized at separation. However, when one twin is obviously mentally or physically impaired, allocation should be directed toward the healthier twin to give this child as normal a life as possible.53 Care must be taken to ensure the legal propriety of any course of action taken that may endanger the life of one twin at the expense of the other. Although life as conjoined twins would appear intolerable, there are historical as well as current examples of conjoined twins who have become relatively well-adjusted adults. Therefore, in certain situations, it may be wiser not to attempt separation.54

All discussions should take place in an atmosphere devoid of undue pressure from politicians, the curious, and the mass media that are out for sensationalism, as well as from inexperienced doctors or administrators who do not possess adequate knowledge of anticipated surgical procedures and results.

**TIMING OF SURGICAL SEPARATION**

Timing for separation should be decided on a case-by-case basis. Simple separations without life-threatening operative risks may be carried out at around three to six months of age. This allows for growth and physiological maturation of the infants, and before socialization begins. In addition, this reduces the time the parents are required to care for the conjoined twins before they grow large enough to become unwieldy and difficult to nurse as a conjoined pair of twins. For more complex separations, the timing may be delayed to around nine to twelve months. If the operation is delayed beyond one year, twins may have difficulty in developing an independent personality.

Emergency operations with or without separation of conjoined twins may be required before completion of diagnostic studies. Gans et al have proposed absolute indications for separation in the neonatal period.55 An urgent operation is indicated when one twin is stillborn or unresponsive to resuscitation; if there are severe uncorrectable anomalies or clinical situations such as severe cardiac disease or advanced necrotizing enterocolitis in one twin which threatens the survival of the other; intestinal obstruction; respiratory failure; or if there is trauma to the connecting bridge, e.g. a ruptured exomphalus.16,43,56-59 In cases of twins with significant cross-circulation, unless emergency separation is performed, the death of one twin is rapidly followed by that of the other, and is probably caused by ‘exsanguination’ of the live twin into the dead twin’s circulation.49

**PREOPERATIVE PLANNING**

It is highly desirable that a team of experienced pediatric surgical specialists and anesthesiologists perform separation of conjoined twins. The separation should be a well-planned and rehearsed procedure.
While a single team of surgeons will perform the initial separation, the surgeon-in-charge must form a separate and complete team for each child, with appropriate specialists standing by to assist if needed. A multidisciplinary team should be organized comprising of surgeons, anesthesiologists, neonatologists and pediatricians, operating room and circulating nurses, and neonatal or pediatric intensive care nurses. Hematology and biochemical laboratories, the blood bank, respiratory therapists, physiotherapists and others should be informed well ahead of the planned separation.

Preoperative discussions should include diagramming of the positions and movements of the team, a review of the placement of the various equipment including two sets each of instruments, operating tables, anesthetic machines, ventilators, fluid and blood replacement pumps and stands, cardiovascular and temperature monitors, and warming equipment. The estimates of blood volume and cross-circulation should be conveyed to the team well in advance. The importance and method of estimating blood loss for both twins together initially and individually after separation must be emphasized and planned.

Rehearsal is mandatory in order to achieve coordination of personnel and to plan placement of equipment. Infant resuscitation mannequins of approximate size or even soft toys may be used. Color-coding of all tubes, drains, equipment and monitoring leads, is helpful in order to avoid confusion during the separation. Scrubbing and draping must be carefully practiced during the rehearsals since these aspects may be totally new to all except those who have experience in the separation of conjoined twins. The need for one or two operating rooms will be dependent upon the size of operating theatres in the hospital. While others have recommended the use of two operating rooms, the author has utilized only one operating theatre on each of the four occasions where separations were performed and found it to be totally acceptable and convenient.

**ANESTHETIC MANAGEMENT**

Anesthetic management of conjoined twins has been reported by several authors. Similar to surgical teams, two experienced teams of anesthetists headed by the lead anesthetist and two complete sets of equipment are necessary for the separation. Because of the possibility of rapid cross-circulation and the anatomical configuration, the administration of anesthesia to conjoined twins may be difficult. The pharmacological effect of the drugs used will be dependent on the speed of cross-circulation and mixing between the twins and the distribution of the anesthetic agents in the tissues. Major shunting in most cases is venous. Hence, inhalation anesthetics given to one will have less effect on the other. Thiopentone, which has high tissue solubility, will also have little clinical effect on the other twin. Since succinylcholine is distributed to both vascular and extracellular compartments, its administration to one twin will produce a pharmacologic effect in the other twin as a result of cross-circulation. The degree of effect is also dependent on the dosage to weight ratio.

Body temperature of the twins must be maintained throughout transport and during surgery so as to ensure physiological stability. Hypothermia can be prevented by the use of warming mattresses and control of the room temperature. Warmed solutions for skin preparation can also be used. Adequate venous access for fluid and drug administration should be obtained before induction of anesthesia. Blood pressure, electrocardiogram, rectal temperature, chest sounds and pulse oximeter monitoring are essential. In order to prevent exsanguinating hemorrhage and hypovolemia, central venous catheters and additional venous lines will be essential in most cases for replacement of fluids, electrolytes, albumin and blood. Arterial cannulation for direct arterial blood pressure monitoring, pH and determination of blood gas, and blood chemistry should be in place when twins with complex unions are separated. Prophylactic antibiotic cover will be essential according to standard surgical principles.

Intubation may be difficult in thoracopagus and omphalopagus twins since the children face each other and have cervical hyperextension. These children will need to be intubated with the children lying sideways. Placement of one twin above the other should be avoided in order to prevent draining of blood from the upper to the lower twin. In order to avoid overdoses due to cross-circulation, the weaker twin should be anesthetized first. Short-acting inhalation anesthetics with high concentration of oxygen, or
induction by awake intubation while the other infant is maintained on preoxygenation is recommended.\textsuperscript{16,64}

When endotracheal tubes, monitoring and intravenous lines are carefully secured, the esophageal stethoscope and nasogastric tubes can be inserted. Two teams of anesthetists and nurses can lift the twins into the air so as to allow total body sterile preparation and draping. While one operating nursing team is required for the initial part of the separation, two nursing teams are required once separation is accomplished. Blood loss in the initial stages of separation will be calculated as a shared loss by both twins, and if replacement is made, each twin will receive half the volume of calculated blood loss. After separation, replacement for each twin is decided individually. The rapidity and effects of cross-circulation must always be borne in mind during all intravenous infusions of fluids, electrolytes, blood or blood products and also during correction of acid/base imbalances.

**SURGICAL CONSIDERATIONS**

The type of major structures and organs, the severity of the required division and the nature of reconstruction anticipated will determine the surgical specialty teams and instruments. It is important for the lead surgeon to be present throughout the separation procedure to integrate the efforts of all team members and for approval of any deviations from the planned procedure. Specialty surgeons will be integrated into the separation when their expertise is needed.

The surgeon-in-charge must overcome two major technical problems. The first is to separate the shared structures leaving each child with a functioning residual whenever possible. The second is the closure of skin, muscle and bony defects at the site of union. It is beyond the scope of this chapter to review all the technical details of separation of different types of conjoined twins, which have appeared in the literature\textsuperscript{16,43,65-78} Therefore, only generalizations will be made.

**Cardiovascular System**

The separation of conjoined hearts is associated with extremely high morbidity and mortality. When there is evidence of conjoined hearts, surgeons planning to separate thoracopagus twins must be prepared to employ cardiopulmonary bypass and hypothermic circulatory arrest. The hearts may be connected at the atria or ventricles or both.\textsuperscript{16,79,80} To date, there are no reports of successful separation of twins with conjoined ventricles. Though rare, successful separation in the presence of myocardial fusion at the level of atria has been reported.\textsuperscript{68} Urgent separation and corrective surgery to save a healthier twin may be necessary in the presence of severe uncorrectable cardiovascular anomalies in one twin.\textsuperscript{16,79,81}

**Hepatobiliary Pancreatic System**

Almost all forms of conjoined twinning except craniopagus and pygopagus, have a shared liver. In cases where there is a small bridge of liver as seen in some omphalopagus twins, a relatively avascular cleavage plane can be found. For division of a relatively thicker hepatic bridge, the central area of the fused livers selected for division is first dissected free circumferentially so that penrose drains can be placed as tourniquets. A double row of large mattress sutures of absorbable material can be placed between the penrose tourniquets so that the division can be performed between them by traditional means. The use of an ultrasonic dissector is a definite advantage in the division of liver parenchyma with individual ligation of larger vessels and ducts, and fulguration of smaller vessels. Tissue glue may be applied to the raw surfaces but hemostasis should not depend on this method. The use of an argon beam coagulator can be an added advantage in controlling oozing from the raw liver surface.

Whenever the duodenum is shared proximally, it is likely that there is a single biliary tree. When there is a single extrahepatic biliary tree as determined by preoperative studies, an intraoperative cholangiogram may be necessary so that the twin with the ampulla can be given the entire extrahepatic biliary system while the other is left with a single hepatic duct, which may be drained externally or into a jejunal Roux limb.\textsuperscript{63-45} If these twins share a pancreas, it is best left with the extrahepatic biliary tree. If two small pancreatic anlage are present, each infant should receive one.\textsuperscript{16}
Omphalocele

Omphalocele is often present in omphalopagus and thoracopagus twins. If the sac is intact, a conservative approach is recommended and the sac allowed to epithelialize. If the sac ruptures and the evaluation is as yet incomplete, initial closure of the defect should be attempted and formal separation delayed. However, in the hands of experienced surgeons, emergency separation is feasible. It should be emphasized that unless life-threatening complications are present, emergency separation of the twins should not be performed when repairing a ruptured omphalocele or during surgery for intestinal atresia.

Gastrointestinal System

If intestinal atresia is present, it can be resected and primary anastomosis performed. A diverting enterostomy or colostomy may be an alternative temporary measure to treat atresia.

More commonly in thoracopagus and, less so, in omphalopagus twins, the second and third parts of the duodenum may be shared; the fourth part of the duodenum and the rest of the gastrointestinal tract are separate. It is also possible that sharing of the small bowel may begin at the second part of the duodenum and continue to the region of the Meckel's diverticulum. Lleocolonic or, in rare instances, only colonic sharing may also be present. Conjoined segments of intestine without obstruction may be left intact until formal separation, or separated earlier when indicated. Fortunately, there is almost always a dual blood supply from each twin to the shared intestine. In case of colon sharing, it is preferable to give the ileocecal valve to one twin and the anus to the other twin.

Although initial correction of anorectal and genitourinary anomalies has been proposed, with the worldwide application of posterior sagittal anorectoplasty, it may be prudent to perform a diverting colostomy or enterostomy before attempting a definitive continence procedure in ischiopagus twins. The use of a muscle stimulator to identify appropriate muscle groups to preserve bowel and bladder sphincter mechanisms is strongly advocated.

Genitourinary System

In ischiopagus and pygopagus twins, complex genitourinary and lower gastrointestinal fusions are common. The tripus variety is more likely to have major arterial communication than in the more symmetrical tetrapus variety.

Although four kidneys and two ureters are usually present in ischiopagus twins, it is common to find that one ureter from each twin crosses the midline and empties into the bladder of the other. Two uteri, four ovaries and two sets of external genitalia on either side of a single anal opening are present in female ischiopagus twins. Frequently, vaginal anomalies and rectovaginal communications may be present. Halcomb et al has described the use of the urogenital sinus as a substitute bladder when the latter structure and a single bladder were present; a new vagina was also constructed.

In male twins, although four gonads may be present, fusion of the genitourinary tract distal to the bladder is common. In cases with only one phallus, one twin can be constructed as a boy while the other as a girl using the available scrotal tissue to create the labia. Penile reposition of the abnormally sited penis will also be necessary.

Depending on the anomalies, a suprapubic catheter or vesicostomy may be necessary. Staged reconstructive procedures have proven to be the most rewarding. These include bladder augmentation, vaginal and genital reconstruction, and procedures to improve continence.

Central Nervous System

Readers are referred to the excellent review by Winston and colleagues for details on this subject. The spectrum of conjunction ranges from those with extensive fusion of cerebral tissue and venous sinuses to those with a limited area of attachment of skull bones and dura only. Winston's classification is based on the deepest shared structures and is the most practical. In a review of surgically-separated twins by Hoyle, 37% of 27 craniopagus twins had a cerebral "connection" in the form of interdigitation of the two cortical surfaces or parenchymal continuity, resulting in a higher perioperative mortality as well as neurological morbidity of the survivors. Parietal fusion is most frequent and is associated with deeper union. Frontal and occipital unions have also been described. Because of the physical and mental handicaps associated with development in the conjoined state, surgical separation is considered to be justified even in high risk patients.
The presence of a superior sagittal sinus for each cerebrum is a critical factor in separation. Approaches to the venous anomalies have been developed. The use of cardiopulmonary bypass, safe division and subsequent reconstruction of the superior sagittal sinus has been described. Preoperative planning of skin flaps, mapping of vascular pedicles, and constructing models to evaluate skin cover have also been examined. Successful limitation of the growth of the area of fusion by the use of an external constricter has also been reported. Rotational flaps, skin grafts, tissue expanders, lyophilized human dural grafts and collagen sheets have been used to repair skin, skull and dura defects.

Skeletal System
Orthopedic considerations, which are substantial and important particularly in ischiopagus twins, have been reviewed by Albert et al. These considerations include three-dimensional visualization and evaluation of the problem, the separation of the pelvis, and the preservation and assignment of the shared limb to the appropriate twin. Postoperative care and procedures for the "shared" leg and the "normal" leg are essential. Other post-separation issues include deformities of the chest, congenital dislocation of the hip and knee, clubfeet, scoliosis and problems related to the shared and dystrophic limb. Some pygopagus twins require neurosurgical and orthopedic involvement due to problems arising from sharing of the sacrum.

Abdominal Wall and Thoracic Cage
Reconstruction of abdominal and chest wall defects after separation of thoracopagus and omphalopagus twins can pose difficulties. In the absence of a sternum, forceful closure of this defect results in compression of the heart and cardiac decompensation. A variety of techniques to reconstruct thoracic cage defects have been utilized. These include flaps of the chest wall and artificial implants; chest wall of the nonsurviving twin; and more recently, the use of cryopreserved syngenic thoracic cage of a twin who died after separation. To overcome the deficiencies in the skin and abdominal wall, silon chimney was used three decades ago followed by subcutaneous and intra-abdominal tissue expanders. While the use of subcutaneous tissue expanders has gained popularity, intra-abdominal use is not as popular. Tissue expanders have also been used to facilitate the separation of craniopagus twins.

RESULTS OF SURGERY
In reviewing 47 pairs of surgically-separated thoracopagus twins, in 30 pairs with completely separate hearts, 41 patients (70%) survived; in five pairs with atrial connection only, one patient (10%) survived; in nine pairs with both atrial and ventricular connections, none survived; in three pairs of unknown type, two survived. The total survival rate was 47.9%. The perioperative mortality rate for thoracopagus twins prior to 1975 was 55.6% (ignoring twins who were sacrificed to save the other). However, from 1980 to 1987, it decreased to 26%, a 32% reduction.

The results of separation of omphalopagus and xiphopagus twins are very good. In a review of 11 sets of such twins some 25 years ago, 19 of 22 children survived. However, the prognosis is worse when this type is associated with omphalocele. In 7 such sets treated between 1963 and 1981, four sets had rupture of omphalocele and one twin in three of the four sets died. Of the three sets with intact omphalocele, one twin from two of the sets also succumbed.

It is not surprising that the outlook for pygopagus twins has been good since the joined structures usually are not necessary for life. In most cases, both twins have survived the separation.

The separation of ischiopagus twins is complex since both the urinary and intestinal systems are joined. In addition, there is a single pelvic ring and often three lower limbs. In recent years, perioperative survival for ischiopagus twins has improved to about 90%; there is not much difference between tetrapus and tripus twins. Votteler reviewed 12 ischiopagus separations from 1955 to 1981 in which one or both ischiopagus twins survived. In another review of 17 sets of ischiopagus twins, 29 infants survived the separation; the remaining four died of a variety of causes.

The severity of anatomical union of brain tissue and vasculature plays a major role in the success of separation of craniopagus twins. The overall perioperative mortality for craniopagus twins has been reported to be around 50%. Votteler reporting on 22
sets of craniopagus twins, said eight of ten children with partial union lived, while only seven of twelve with total union lived. Even among survivors, about half of the children have residual neurological deficits.

Major advances in antenatal and postnatal diagnostic investigations, refinements of surgical techniques and equipments, advances in anesthetics and intensive care, nutritional and rehabilitative support, and control of infection have all been responsible for a greatly improved outcome for conjoined twins, many of whom may have succumbed if they had been born a decade or two ago.

REFERENCES

Heteropagus conjoined twinning is a rare condition accounting for a small percentage of all the conjoined twins. However, it is treated more frequently by pediatric surgeons as it is a correctable anomaly with gratifying results.

The term heteropagus twinning is synonymous with parasitic, partial, incomplete or atypical asymmetrical, unequal twinning. Heteropagus twins display unequal duplication of features with varying degrees of development in each twin. It is usually characterized by an incomplete and parasitic dependent part, usually smaller than the well formed autosite.

Conjoined twins are symmetrical and predominantly seen in females. This may be due to the fact that a female zygote once formed is more likely to remain viable as compared to the male zygote which is likely to undergo ischemic atrophy. Heteropagus twins differ in several ways from symmetrical conjoined twins, including male preponderance, and usually no major connection of vessels, bowels, or bones.

Twinning occurs in approximately 1 of every 87 live births. Monozygotic twins account for one third of twin births. Conjoined twins account for 1% of monozygotic twins. The incidence varies from 1 in 50,000 to 1 in 200,000 live births. The stillbirth rate is 40-60%. The exact incidence of heteropagus twins is not known but it is estimated that they are seen at an incidence of 2-10% of all conjoined twins.1,2 Some consider fetus in fetu to be a type of endoparasitic heteropagus twins and the external ones to be ectoparasitic Heteropagus twins.3 If these are also included then the incidence is higher. Others consider it as a distinct entity or a special case of teratoma.

More cases are being reported now because of the routine use of fetal ultrasonography. The condition is probably more commonly reported from Indian and African populations.1,4-10 Exact epidemiology across different races and nations is not known because of lack of reporting and facilities for prenatal diagnosis.

EMBRYOLOGY

Parasitic twins occur when a twin embryo begins developing in utero, but the pair does not fully separate, and one embryo maintains dominant development at the expense of the other. Unlike conjoined twins, one ceases development during gestation and is vestigial to a mostly fully-formed, otherwise healthy individual twin. The undeveloped twin is defined a parasitic, rather than conjoined, because it is incompletely formed or wholly dependent on the body functions of the complete fetus. Conjoined twins are of the same sex, thus are most probably derived from monozygous twinning. Though incomplete cleavage of the embryo at two weeks of gestation is a plausible explanation for conjoined twins, it does not seem to hold true for parasitic twins. The exact etiology is thus not known. The complexity of the defect is variable with the number of functioning organs varying from case to case.11

Some ischemic insult has been suggested as the etiology behind the selective atrophy of the body structure of the parasite at an early gestational age.1,12 The striking absence of structures other than the pelvis, lower limbs and pelvic organs except for the rudimentary hand seen in most cases of epigastric heteropagus twins may be due to the ischemic atrophy of the other structures of the body during the
Heteropagus Twinning

gestational development. Heteropagus twins thus develop when one component (autosite) is better placed so that it monopolizes the placental blood flow from the other member (parasite).

Rarely, DNA typing studies have even demonstrated dizygosity in a male parasitic twin. The unusual perpendicular orientation of the parasite to the autosite has been resembled to a mechanism observed in mares in which early fusion of two embryos is followed by resorption due to compromised embryonic polarity.\(^{13}\)

It has been inferred that the event may be occurring much after the second week of intrauterine life based on angiography performed in one of authors cases that revealed the vascular supply to the parasite to arise from the left subclavian artery.\(^{1}\) It passed under the skin bridge to supply the parasite aorta, which gave branches to all the organs of the parasite. Vasculogenesis during intrauterine life starts at 18 days, in the latter part of the third week, the intraembryonic blood vessels differentiate in situ from the angioblast cells of the intraembryonic mesoderm and establish secondary connection with the extraembryonic blood vessels.\(^{14}\) By the 29th day the seventh intersegmental artery develops which is destined to form the subclavian artery. In this case, the arterial supply to the parasite was arising from the left subclavian artery of the autosite, therefore it is believed that the intrauterine event that leads to this malformation would have occurred only after the 29th day of intrauterine life.\(^{1}\)

To date, the underlying disorder (whether genetic, metabolic or environmental) responsible for the development of this congenital malformation is not fully understood.\(^{15}\) An apparent lack of an adequate arterial blood supply to the growing embryo can contribute to the etiopathogenesis by producing a local ischemic milieu during the critical phases of embryogenesis; damaging the normal sequence of cell differentiation and morphogenesis of the various tissues composing the craniofacial complex.\(^{15}\) Impediment of the preprogrammed migration of neural crest cells to their end targets in the upper branchial arches has also been attributed to this.\(^{15}\)

An omphalopagus parasitic twin has also been produced after intracytoplasmic sperm injection.\(^{16}\)

**CLINICAL FEATURES**

In heteropagus twins, the dependent portion (parasite) is smaller than the host (autosite). Heteropagus twins are seen mostly in the males, though occasionally cases are reported in females.\(^{17-19}\) The parasite may be attached to any portion of the body. Omphalocele is also present in most of the cases.\(^{3,20}\) The most common type seen is the epigastric heteropagus twin, also known as Thoracopagus parasiticus.

In the epigastric heteropagus twinning, the parasite may have duplication of the pelvis and the pelvic organs such as complete urinary tract, external and internal genitalia.

The intestinal loops in the parasite are usually blind ending, not communicating with the autosite intestine.\(^{1}\) Rarely, a duplicated bowel has been reported in the connecting stalk that ended blindly without any connection to the intestine of the autosite.\(^{4}\) A case in which the parasite’s bowel was connected to a Meckel’s diverticulum of the autosite has been reported.\(^{17,21}\) There is usually no bony connection between the autosite and the parasite in epigastric heteropagus twinning, though exceptions are not unusual. The vascular supply to the parasite may arise from the liver, left internal mammary, epigastric, umbilical, falciform ligament, left subclavian or/and local systemic arteries.\(^{22}\) In most cases, the vascular supply to the parasite arises from the local systemic artery. Cardiac anomalies are common in autosites and should be evaluated.\(^{20}\)

There is a great diversity in the organs and tissues described in the parasitic part.

A heteropagus parasitic twin presenting as a mass in the lumbar area with an additional limb, a pair of breasts with nipples and aerola, and an anus with a blind pouch has been reported.\(^{19}\)

It is extremely rare to have bony fusions though it may be found occasionally. The pelvic bone and lower legs of the parasite were fused with the respective organs in the autosite.\(^{18}\) The variations of epigastric parasitic twinning may include with a parasite with well developed lower trunk and pelvis with rudimentary lower limbs, and well developed upper extremities without shoulder girdles and thoracic cage apart from additional accessory.\(^{6,22}\)

A rare case of epigastric heteropagus twinning in which the parasite presented with head, thorax, and a
rudimentary heart has also been reported. Rarely the parasite may have more organs. A parasite with a single lung, liver, stomach, intestine, pancreas, ovaries, a single kidney, and a bladder located in the abdominal and pelvic space of the autosite has been reported.

A rare case of craniofacial microsomia in a partially developed, malformed heteropagus conjoined twin with complex involvement of bones, cartilage, teeth, salivary glands, auditory apparatus, cerebrum, cranial nerves, ocular neuroepithelium, cervical vertebrae and appendicular long bones has been reported.

**NOMENCLATURE**

The terms endoparasitic twin has been used to describe the commonly seen external form of heteropagus twins. Endoparasitic heteropagus twin has been used to describe fetus in fetu.

A rationale nomenclature for conjoined twins has been adopted worldwide. The site of attachment of the parasite is referred to as Craniopagus (cranium); Thoracopagus (chest and upper abdomen); Omphalopagus (if heart is involved); Ischiopagus (ventral pelvis) and so forth. Additional terms suggested for identification are enumerating some parts such as di (two); tri (three); tetra, quadri (four) with brachius, pus, ophthalmia, otia and stoma referring to arms, legs, eyes, ears and mouth respectively.

The same terminology may be adapted to heteropagus twins with addition of the word parasiticus after the initial name. Thus the term epigastric heteropagus may also be called as Thoracopagus parasiticus (Figs 113.1 and 113.2). However, about 70-80% of all heteropagus twins are inserted in the epigastrium thus the term epigastric heteropagus twin has gained wide popularity. In Epigastric Heteropagus twins, the dependent twin (parasite) is attached to the right or left upper abdomen of the dominant part (autosite). Any deviation from the common form merits explanation.

Conjoined-parasitic twins united at the head are described as craniopagus or cephalopagus. Cranio-pagus occipitalis is the term for fusion in the occipital region; craniopagus parietalis is when the fusion is in the parietal region; craniopagus parasiticus is a general term for a parasitic head attached to the head of a more fully-developed fetus or infant.

The term “acardiac amorphous parasitic twin” has been used to describe a cystic umbilical swelling covered mostly by skin and partly by amnion, resembling an early embryo-like structure with facial features and limb buds. The deeper aspect was composed of large cystic and tubular structures and solid organs resembling liver and spleen.

The TRAP (twin-reversed arterial perfusion) sequence, results in an acardiac twin, a parasitic twin that fails to develop a head, arms and a heart. The resulting torso survives by leeching blood flow from the surviving normal twin by means of an umbilical cord-like structure, much like a fetus in fetu, except the acardiac twin is not enveloped inside the normal twin’s body. Because it is pumping blood for both itself and its acardiac twin, this causes extreme stress on the normal fetus’s heart. This twinning condition usually occurs very early in pregnancy.
INVESTIGATIONS

A proper evaluation at birth is necessary to establish the feasibility of separation. The separation is not an emergency and enough time may be spent in detailed investigations till all doubts are cleared.

Heteropagus twins may be suspected in the prenatal period with an ultrasonography and confirmed with a prenatal MRI.\(^{27}\)

Skilogram of the baby helps to delineate the skeleton of the baby and the presence of bony structures in the heteropagus twin (Fig. 113.3).

A contrast enhanced computerized tomography (CECT) is helpful to delineate the anatomy of the autosite and the parasite. The tissue present in the skin bridge needs to be evaluated preoperatively, so as to prepare for the separation of the tissues shared in between the twins. A functioning kidney in the parasite will also be shown with evaluation of the ureteric and bladder anatomy.

A magnetic resonance imaging is also helpful to delineate the soft tissues and plan the surgical separation of the parasite especially in cases of abdominal wall defects.\(^{25}\)

Barium Meal Follow through study may be useful to evaluate any connection between the autosite and the parasite intestines in epigastric heteropagus twins. It can be combined with the CECT scan to delineate the bowel anatomy.

Echocardiography is important to evaluate the associated congenital heart disease in the parasitic twins. Common associated anomalies are patent ductus arteriosus (PDA), ventricular septal defect (VSD) and atrial septal defects (ASD) and single ventricle.\(^{20}\)

Chromosomal analysis may be performed to establish the karyotype of the twins. It will be helpful in understanding the embryopathy of the parasitic twinning.

Angiography is helpful in the exact delineation of the vascular anatomy of the autosite and the feeder vessel to the parasite. It helps establishing the anatomy and helps in the understanding of the embryopathy of this condition.

MANAGEMENT

Inspite of monstrous appearance, the parasite component of epigastric heteropagus can be separated successfully with minor surgery. This fact should be kept in mind during the intrauterine evaluation of these type of anomalies in order to avoid needless terminations.\(^{22}\) Surgical excision of the parasite and repair of the abdominal wall defect in cases of omphalocele are usually successful.\(^{20}\) If the skin cover is good, there is no urgency for the separation (Fig. 113.4). A proper evaluation leads to successful...
separation of the parasite from the autosite (Figs 113.5A to I). In the presence of an omphalocele with a thin sac, separation is expedited once the cardiac evaluation has been completed. The skin bridge should be carefully dissected, preserving all the vital tissues and securing the feeder vessel. Rarely, the autosite liver may be the content of the sac. The abdominal wall defect can be closed primarily wherever feasible, without any postoperative ventral hernia or else a silo or a ventral hernia is created. The omphalocele may also be managed conservatively by mercurochrome application after excision of the parasite.6

**PROGNOSIS**

The survival of the patient is adversely influenced by associated cardiac anomalies. Without a severe cardiac condition, the result is usually excellent.

---

**Figs 113.5A to I:** A-C. A two days old parasitic epigastric twin presented with sepsis and palor. The parasitic twin had both lower limbs, one upper limb with three digits, external genitalia and used to pass urine occasionally. D. The CT scan demonstrated presence of bowel, kidney and bladder in the parasitic twin. Echocardiography showed double outlet right ventricle. DTPA scan demonstrated a functional kidney in the twin. E. Surgical excision was planned. The incision was given all around the junction. The distended bladder can be seen. F. The main vessels have been held in slings. G. The main part of the twin has been excised. The remaining upper limb can be seen with its vascular supply. Mass excised and defect repaired primarily. H. Parts of the excised parasitic twin including a large urinary bladder (UB) and gut. I. The split kidney of the parasitic twin can be seen (arrow).
Proper evaluation of the associated cardiac anomaly and its treatment is important for the successful outcome of the autosite. Cardiopulmonary failure has been reported as a cause of mortality. There are not much reports on follow-up. A follow-up at 34 months has been reported with a healthy autosite.

REFERENCES

The gynecological disorders of children, especially prior to puberty merit special consideration as these are far more difficult to diagnose and treat than in the adults. A knowledge of some of these disorders and their management is important as parents are frequently deeply alarmed by the diseases of sexual organs in children and some of these may have serious repercussions in later life. Adolescent and pediatric gynecology is now gaining importance with the awareness of the special issues involved pertaining to children. Certain emergency situations may arise in adolescents like ectopic pregnancy and pelvic inflammatory disease. A pediatric surgeon is required to understand these problems, though surgical intervention is only infrequently needed.

EMBRYOLOGY

Understanding the developmental anatomy is important as aberrations can result in several reproductive problems. Sex of the embryo is genetically determined at the time of fertilization. The development of gonads, internal genitalia and external genitalia takes place under the influence of Y chromosome and hormones. The gonads acquire male or female morphology from 7th week of development (Fig. 114.1).

The gonads develop from genital ridges formed by proliferation of the coelomic epithelium and condensation of the underlying mesenchyme. Primordial germ cells are derived from endoderm cells in the wall of yolk sac. These migrate along the dorsal mesentery of the hindgut and invade the genital ridges in the 6th week of development. Depending on the sex chromosome the gonads develop into either testis (XY) or ovary (XX).

Internal genitalia develop from two pairs of the duct systems, which mature under the hormonal influence in the fetus. Both male and female embryos initially have both the genital ducts-the mesonephric and the paramesonephric ducts. Fetal testis produces an inducer substance, which causes differentiation and growth of the mesonephric ducts and inhibits the development of the paramesonephric ducts. Androgens stimulate the development of male genital organs. While in the absence of androgens the development takes place along female line. The mullerian inhibiting substance from fetal testes also plays an important role in genital differentiation. In the female embryo, the paramesonephric or mullerian ducts grow and develop into the internal genital organs in response to maternal and placental estrogens circulating in the fetus.

In the absence of male inducer substance and androgens the mesonephric duct system regresses. The paramesonephric ducts lie lateral to the mesonephric ducts (Fig. 114.2). The cranial part opens into the coelomic cavity, the middle part crosses horizontally the mesonephric ducts and the caudal part lies
vertically alongside the duct from the other side. The two ducts fuse in the middle to form uterus, cervix and upper 2/3rd of vagina. The first two parts of paramesonephric ducts develop into the fallopian tubes. The lower 1/3rd of vagina is derived from the urogenital sinus (Fig. 114.3). Sinovaginal bulbs at the tip of paramesonephric ducts invade the urogenital sinus. The proliferation continues at the cranial end of the plate, thus increasing the distance between uterus and urogenital sinus. Lumen of vagina remains separated from that of the urogenital sinus by a thin tissue plate, the hymen.

Development of external genitalia takes place simultaneously. In the third week of development mesenchyme cells in the region of the primitive streak migrate to form cloacal folds around the cloacal membrane. Directly cranial to the cloacal membrane the folds unite to form the genital tubercle. In the sixth week, the cloacal membrane is subdivided into the urogenital and anal membranes. Genital swellings appear as elevations on either side of the urethral folds, forming scrotal swelling in the male and labia majora in the female. Genital tubercle elongates to form phallus in male fetus under androgenic influence. The external genitalia of the female forms under estrogenic influence. The genital tubercle elongates slightly to form the clitoris, the urethral folds remain unfused to form the labia minora and genital swellings enlarge to form the labia majora.
Clinical Anatomy

The genitalia in a newborn undergo relatively few changes during the years of early childhood. The effects of maternal hormones on the genitalia of the newborn soon recede. The vulvar vestibule in the newborn infant is deeper and more anteriorly placed than in an adult. The labia majora do not actually develop as distinctive structures until late childhood. The perineal body is a thick, wedge-shaped mass of connective tissue between the anus and the vestibule. The mons pubis is a fatty pad over the symphysis, but does not acquire a rounded contour until late childhood. The labia minora which develop from the unfused urethral folds of the embryo, are relatively larger and thicker at birth and for several weeks thereafter, than in the older child or adult. The clitoris formed from the genital tubercle is also disproportionately larger and thicker at birth and for several weeks thereafter.

Separation of the labia minora exposes the urethral meatus and the hymen. In some infants a shallow urethral groove will be seen extending from the anterior margin of the urethral meatus to the base of the clitoris. The hymen is a thin membranous diaphragm, which, except for a central aperture of about 0.4-0.5 cm covers the opening of the vaginal canal. The thickness and succulence of the hymen reduces with the withdrawal of hormonal stimulation from the mother. Regressive changes in genitalia begin at birth and are usually complete by about two weeks. The resting phase of the genital growth usually lasts until the child is approximately seven years of age. The phase for the gradual growth of genitalia starts for most girls between 7 to 9 years of age.

Adolescence is characterized by maturation from a child to adult with an insidious beginning and end. All parts of biological system do not mature simultaneously; thus the process spans over a time period with puberty (anatomical change), menarche (functional change) and ovulation (endocrine change) occurring in a harmonious succession.

In recent years a precocious maturation of children is being noticed largely influenced by mass media exposure. This is more in terms of psychosocial maturation and may not be associated with proportionate physical maturation.

Gynecological Examination of the Newborn

Major anomalies of the external genitalia can be detected at birth. The baby should be placed on its back and having an assistant flex its thighs on its abdomen helps in exposing the genitalia.

The hymen, vulvar tissues, labia majora and minora, clitoris and urethra will be visible. Anomalies of the hymen, particularly imperforate hymen, can be discovered at birth. The opening is evident when the labia minora are separated and pulled gently posteriorly. If not evident as an orifice, the examiner can search by gently probing between the labia with the tip of no.14 French catheter. If the opening is not found it has to be differentiated whether it is an imperforate hymen - a thin shiny membrane or vaginal agenesis-vestibular tissues are thick and unyielding and there is a ‘dimple’ surrounded by an imperfectly formed hymen. Doubling of vagina is suspected if the hymenal orifice is centrally divided by an antero-posterior band of tissue.

Clitoral enlargement in a newborn signifies congenital adrenal hyperplasia, excess of androgenic hormone treatment in the mother or intersex.

Digital palpation of the anorectal canal is part of the examination of a newborn.

Turning the baby onto its face and putting it in a knee-chest position makes it easier. If the child does not pass meconium the patency of the rectal canal is determined by gently inserting a soft rubber catheter to a point above that reached by the examiner’s finger. Pelvic tumors are rare in newborn babies, but enough...
cases have been reported to warrant making rectoabdominal palpation a part of the newborn female examination.

EXAMINATION OF THE PREMENARCHIAL CHILD

In premenarchial age group the girls may present with complaints of discharge, redness or eruptions on the perineum and vulva, abdominal lump, vaginal bleeding, precocious development, urinary or rectal symptoms, etc.

Gynecologic examination of the premenarchial child is seldom difficult. Informed consent of the guardian is obtained as well as the child is explained about the examination. Cooperation of the child is important for satisfactory examination. For uncooperative children or children having perineal injury, it is better to conduct the examination under anesthesia. Habitus, built, gross congenital anomalies and hygiene are noted. Presence of secondary sexual characters—breast development, pubic and axillary hair is recorded. Having the child flex her thighs acutely on her abdomen offers better exposure. Examination can also be done in the Sim’s or knee-chest position. Inspection is done after gently separating the labia and hygiene, excoriations, rashes or lesions are looked for and the patency of the hymen checked.

Vaginoscopy may be required to examine condition of vagina and cervix or to detect the presence of foreign body in the vagina. Proper inspection is important in girls with injury. Use of Huffman vaginoscope helps in visualization. A nasal speculum can also be used. Rectal and rectoabdominal palpation establishes the normalcy of the rectal canal and rectovaginal septum. Pelvic tumors or collections of blood or fluid can be detected on bimanual palpation.

EXAMINATION OF THE ADOLESCENT

Gynecological examination of an adolescent is no different than an adult, except that informed consent is a must. Adolescents are more uncooperative and shy than children are and proper explanation before examination is important. Special attention is paid to secondary sex characters, as well as any abnormality in puberty maturation. History of sexual activity may not be always forthcoming, but this opportunity can be utilized to educate the sexually active as well as other girls about sexual and reproductive health. This should include information about prevention of reproductive tract infections, including HIV/AIDS and contraception. It may be necessary to obtain specimen of discharge for microscopic examination and culture.

COMMON GYNECOLOGICAL PROBLEMS IN CHILDREN

Some of the commonly presenting gynecological disorders are discussed here.

The various gynecologic disorders in pediatric age group can be grouped as:
- I. Congenital
- II. Inflammatory
- III. Traumatic
- IV. Neoplastic
- V. Endocrine
- VI. Psychosomatic disorders

Congenital Disorders

Congenital Disorders Diagnosed in Utero

Conditions of the fetus requiring pediatric surgical consultation: With the use of routine screening by ultrasonography in pregnancy a majority of congenital malformations can be diagnosed during the prenatal period and require to be managed in consultation with pediatric surgeon to plan safe delivery and improve the neonatal outcome.

Ventriculomegaly is one of the conditions diagnosed on basis of measurement of ventricular-hemispheric ratio and cortical mantle width. In a fetus with hydrocephalus intrauterine infections and chromosomal anomalies such as trisomy 13,18 and Turner’s syndrome need to be ruled out. Based on the severity of affection termination or fetal surgery or early neonatal surgery is planned in consultation with the pediatric surgeon.

Urinary tract obstruction is found in one in 500-1000 pregnancy. Ultrasound helps in identifying unilateral/bilateral obstruction, bladder thickening/dilatation, renal echogenicity, ureteric dilatation, sex of fetus, other associated anomalies and amniotic fluid volume. The fetus is at a risk of pulmonary hypoplasia with bilateral obstructive nephropathy and oligohydramnios. Karyotype by cordocentesis helps to decide termination for abnormal fetuses. In utero treatment in early gestation with urethral obstruction has been tried by placing double pigtail vesico-
amniotic shunt. If diagnosed late, most fetuses with significant nephropathy can be successfully managed after birth in collaboration with a pediatric surgeon and safe neonatal outcome achieved. Congenital diaphragmatic hernia is rare but appropriate management in the prenatal period and at birth can be life saving for the baby. In utero surgery to reduce development of pulmonary hypoplasia has been tried.

In gastroesophageal atresia and duodenal atresia diagnosed by ultrasound, pediatric surgeon’s opinion is required and surgery in early neonatal period planned. Care after safe hospital delivery in a tertiary care center and practice of keeping the neonate on intravenous therapy, no feeding and nasogastric tube is important to prevent complications like aspiration and fluid-electrolyte imbalance.

Abdominal wall defects-gastrochiasis and omphalocele also require delivery to be planned after pediatric surgical consultation. Fetal karyotyping is essential in omphalocele where the association with chromosomal anomalies is as high as 60%. Labor induction, avoidance of emergency operation and quick transfer to the pediatric surgical unit for appropriate timing of neonatal surgery are important.

**Congenital Disorders Detected after Birth**

Anomalies of the hymen: Variations in size and number of fenestra and in thickness of the hymen are common. The hymen may be imperforate, cribriform, anteriorly displaced and septate. Two orifices in hymen may be associated with duplication of internal genitalia. Hymeneal anomalies are clinically important and require surgical correction, if they block the escape of vaginal discharge or menstrual fluid or cause coital problems.

*Imperforate hymen* may produce a mucocolpos in infancy and if not corrected before menarche, will cause a hematocolpos and hematometra when the girl starts to menstruate. Symptoms are those related to pressure on the urinary tract, abdominal or pelvic lump and cyclical pain abdomen with failure to attain menarche. The girl may be brought to casualty with acute urinary retention. Inspection of the vulva reveals a bulging tense bluish membrane.

In a neonate this membrane may rupture spontaneously or may be incised to drain collected discharge and edges may be sutured with absorbable suture. In an adolescent girl a cruciate incision is given in the bulging membrane under general anesthesia and collected blood is sucked out. The child is nursed in Fowler’s position to facilitate drainage and vaginal examination is deferred to a later date.

Anomalies of the vagina

Anomalies of the vagina do not cause symptoms during infancy and childhood. They present later when there is interference with menstruation. Double vagina and septate vagina are reported. Transverse vaginal septum occurs at any level above the hymen and needs surgical correction to widen the vagina and allow normal menstruation and coitus. To prevent stenosis of vagina, complete excision of septum is important and use of vaginal dilators may be required. In case of a high septum, vaginal advancement surgery is done to prevent restenosis. Longitudinal vaginal septum does not interfere with menstrual flow, thus usually present later with dyspareunia or obstruction during labor. With uterine duplication, one side may be obstructed, and girl complains of severe pain during period due to hematometra on the obstructed side. Though uncommon, this condition has often been misdiagnosed and mistreated, as menstruation occurs regularly from the normal side and girls continue to be treated for primary dysmenorrhoea. Endometriosis can occur due to retrograde menstruation.

Vaginal atresia due to complete or partial failure of canalization of the vaginal plate will also lead to hematometra and hematocolpos when the girl attains puberty. Vaginoplasty with amnion or split thickness skin graft is the treatment.

Mullerian agenesis is total agenesis of the uterus, vagina and cervix and vaginoplasty can help for coital function but these patients cannot menstruate or conceive. Most of these girls present with primary amenorrhoea. Some may get married young and report with apareunia.

Congenital vaginal cysts usually develop from occluded persistent fragments of the mesonephric ducts, from unfused portions of the paramesonephric ducts or from obstructed paraurethral ducts. Small cysts require no treatment; however, larger ones need to be excised.

**Uterine Anomalies**

These anomalies rarely cause problem in infancy and childhood. Bicornuate, septate, unicorneate uterus
with rudimentary horn, uterus diadelphys, etc. all are associated with problems of conception and pregnancy complications (Fig. 114.4). Mullerian agenesis with congenital absence of vagina and uterus (Mayer Rokitansky Kustner Hauser Syndrome) manifests early with failure to menstruate. Approximately, 40% of these girls have associated urinary tract anomalies and 12% musculo-skeletal malformations. Endocrine and ovarian function as well as karyotype is normal. Ultrasound and laparoscopy are useful to differentiate this condition from isolated vaginal malformation.

A complex surgical procedure is required to create a new vagina in these girls. Vaginoplasty is usually carried out only when sexual function is desired, i.e. after the marriage has been fixed. Proper counseling is important and full co-operation of girl is essential to maintain the patency of neovagina by repeated use of vaginal dilators. Several tissues have been used for vaginal graft including split thickness skin graft from thigh, amnion, perineal skin, sigmoid loop, gracilis musculo-cutaneous flap or pelvic peritoneum William’s vulvoplasty may be done in selected cases to create a coital pouch.

**Intersex**

Intersexuality is the condition of imperfect sexual differentiation. Sex is Primarily determined by the sex chromosome supplied by the spermatozoa. The Y-chromosome gives the positive drive towards male sex differentiation and determines the gonadal development into a testis. In the absence of Y chromosome the gonad matures as ovary. If the chromosomal direction to the gonad is confused, ovotestes develop. When the chromosomal drive to the gonad is weak, hypoplasia of the gonad is likely, resulting in gonadal aplasia, hypoplasia or streak gonad.

Turner’s syndrome is the classical syndrome associated with streak gonads, with a karyotype of 45 X0 or a mosaic. The primary cause is non-disjunction of the sex chromosomes. Triple X (47XXX) syndrome also results from non-disjunction and leads to problems of oligomenorrhea, secondary amenorrhea, infertility, genital hypoplasia and mental retardation. Klinefelter’s syndrome (47XXY) is characterized by a tall eunuchoid figure with testicular and genital hypoplasia.

Maternal hormones during pregnancy cross the placenta but do not influence the sexual differentiation. If, however, the mother suffers from an androgenic tumor of the adrenal or ovary, congenital adrenal hyperplasia or she takes exogenous androgens the external genitalia of the female fetus can get virilized, the degree depending on the timing and strength of the influence. Progesterone is also weakly androgenic and synthetic progestogens when given to the mother for pregnancy support can sometimes virilize the female fetus.

Intrauterine adrenogenital syndrome is a familial disease transmitted by a recessive gene leading to inherent error in the biosynthetic process in the adrenal cortex, and elevated levels of androgenic hormones. Deficiency of adrenal cortical hormones further increases the output of ACTH causing bilateral adrenal hyperplasia. There is anomalous sexual differentiation of external genitalia in the female fetus including labial fusion, hypospadias and phallic enlargement. Congenital variety presents as ambiguous genitalia at birth, the acquired syndrome presents as stunted height, hirsutism, infertility, amenorrhea, voice change and clitoral hypertrophy at a later age. Diagnosis is based on elevated 17-hydroxy progesterone levels and testosterone with 46XX karyotype. Treatment is by dexamethasone to suppress adrenal hypertrophy and later in life correction of genital ambiguity and treatment for amenorrhea, hirsutism and infertility.

Intersex states can also result from androgen insensitivity leading to testicular feminization syndrome. This is an apparent female, with breast...
development, normal vulva and hairless skin, but the gonads are testes and karyotype is 46XY.

Of all these intersex disorders, the most significant is detection of ambiguous genitalia at birth. This requires immediate attention, as parents are keen to know the sex of the child. They should be counseled and sex assignment is delayed till complete evaluation is done.

Evaluation includes a history of similar disorder in family, maternal virilization and maternal drug intake. On labioscrotal and rectal palpation the presence of testes and uterus is determined respectively. Ultrasonography is also useful. Blood tests include measuring serum aldosterone, cortisol, hydroxy-progesterone, LH and FSH levels and determining the karyotype. Electrolytes are also monitored till the diagnosis is established and treatment initiated. Sex assignment is not solely based on karyotype or gonad type but on what can be achieved subsequently. Female pseudohermaphrodites due to congenital adrenal hyperplasia are reared as females despite marked virilization, as it is possible to create a functional vagina, do clitoroplasty and even restore fertility in these girls. Male pseudohermaphrodites respond very well to androgen treatment, thus even when the testes is undescended and there is marked hypospadias, these children are brought up as males and surgical correction is done at a later age. Males with androgen resistance do not respond to androgen treatment, thus should be brought up as females despite XY karyotype and with gonadectomy is done as soon as pubertal growth spert has taken place. Vaginoplasty is carried out as and when, the sexual function is desired.

**Inflammatory Disorders**

Inflammations and infections of perineal and vulvar skin is the most common problem that brings little girls to physicians.

**Diaper Rash**

Excess moisture, heat and poor hygiene can lead to infections due to fecal bacteria and urinary contamination in infants. Ammonia dermatitis is a major factor in causing diaper rash. Proper cleanliness, bathing and drying before applying talc helps in the treatment. Calamine ointment containing 1% erythromycin can be applied to the affected area. Diapers are sterilized by boiling and thoroughly rinsed and dried before use.

**Perineal Dermatitis**

This is often an acute inflammatory process in slightly older girls with a secondary pyogenic infection.

Nutritional disturbance, allergy or drug reaction can also lead to perineal dermatitis. Symptoms vary from itching, burning or pain on micturation. Perineal hygiene, keeping the affected area dry and topical antimicrobial ointment are the treatment.

**Intertrigo**

Intertrigo is an inflammatory disorder of skin, which occurs when skin surfaces of the vulva, buttocks and thighs are in apposition for a prolonged period. This can affect girls of all ages, but obese and diabetic are more prone to it. Friction produces erythema, maceration and inflammation. Secondary infection with bacteria or fungus may take place. Proper perineal hygiene, cleanliness in the crevices, talc application and topical antibiotic ointments is used. Sitz’ bath and ointments with topical steroids also help.

**Premenarchial Vulvovaginitis**

Vulvovaginal inflammation with vaginal discharge is one of the most frequent disorders treated in a pediatric gynecologic clinic.

At birth babies have excess physiologic vaginal fluid and later it becomes blood—stained due to the withdrawal of maternal hormones. Discharge and bleeding disappear within 7-10 days and do not require any treatment.

Premenarchial girls are particularly susceptible to Vulvovaginitis due to thin vaginal lining and neutral pH. It is caused by bacterial, trichomonal, mycotic (candida) or viral infections and as reaction to medications, bubble baths or nylon undergarments, etc. Nonspecific vulvovaginitis is an infection of the vulvar and vaginal epithelium by pyogenic organisms secondary to poor hygiene, skin or urinary tract infections, foreign bodies in the vagina or sexual abuse. Discomfort, itching and discharge are usual presenting complaints. Burning sensation or irritation after voiding, stain on panties or vulvar redness may also bring the child for consultation. A sample of vaginal discharge is collected for wet smear, gram-stain and
culture. For vaginal secretion sampling, compliance of the young patients has been studied and reported best with the otologic cotton swab.\textsuperscript{5}

Proper perineal hygiene is the key factor in treatment along with treatment for the primary infection. Specific vulvovaginitis due to gonorrhea, chlamydia, hemolytic \textit{streptococci}, hemophilus vaginalis, diplococcus pneumoniae, etc. need specific treatment. Trichomoniasis needs to be treated with metronidazole and candidal infection with clotrimazole or miconazole. Threadworm infections usually respond well to deworming by piperazine preparation or mebendazole suspension.

\textbf{Labial Adhesions}

Adherent or fused labia minora is a common pediatric gynecologic problem. They occur most often in children between 1-6 years of age. Poor hygiene and inflammation lead to adhesions between the two labial surfaces due to the eroded epithelium. Lack of estrogen helps in adhesion formation. Labial adhesions are never present in a neonate, as maternal estrogen is protective. Sometimes parents bring the young girls suspecting that the sex of the child is changing. If labia are fused at birth the neonate should be evaluated for intersex problems. The treatment options available are:

a. Maintaining careful local hygiene and application of an estrogen ointment at bedtime for 14 days can separate the labial agglutination. Topical estrogen therapy has been found to be effective in treating persistent or recurrent labial agglutination.\textsuperscript{6}

b. Gentle manual separation can be done easily as an outpatient procedure. It is to be followed by local application of a soothing antibiotic cream to avoid adhesions

c. Surgical separation may be needed occasionally for dense adhesions recur. The mother should be instructed to maintain the genitalia clean and dry.

\textbf{Traumatic Disorders}

\textit{Injuries to the Genitalia during Childhood}

Injuries usually occur as a result of fall on sharp or penetrating objects. Many injuries are trifling in character, but few are life-threatening and require extensive reconstructive surgery. Physical or sexual assault may also lead to injuries. Most of the extensive hematomas or lacerations of vulva, vagina and urethra in young girls require proper resuscitation, examination under anesthesia, evacuation of hematoma and proper reconstructive surgery. However, we have noticed that healing in young girls with perineal injuries is very good even following extensive tissue damage. Repair needs to be done very patiently using atraumatic sutures, as the vaginal mucosa is very thin. Proper exploration for concomitant bladder and anorectal injury should be done. In very extensive cases prolonged bladder drainage or colostomy may be required. Maintenance of proper vulvar hygiene and use of broad-spectrum antibiotics is important for successful outcome.

For victims of sexual abuse screening for sexually transmitted infections including HIV is important. Postmenarchial girls should also be given emergency contraception.

\textbf{Vaginal Foreign Bodies}

Foreign bodies in the vagina although almost always considered a possibility in young girls presenting with mucopurulent foul smelling or blood stained discharge, but are relatively uncommon. Bits of cloth, toilet tissue, pieces of toys are the common ones, which need to be removed at vaginoscopy. Profuse discharge and pain may necessitate removal under sedation or anesthesia. Antibiotics are given to take care of superadded infection. Hypercalciuria with microcrystals and urethral irritation has also been reported to cause genital bleeding in girls.\textsuperscript{7}

\textbf{Neoplastic Disorders}

\textit{Benign Tumors of the Vulva and Vagina}

Benign genital neoplasms occur very rarely in human females under 16 years of age. Epithelial inclusion cysts and paraurethral cysts are uncommon but can be found in any age group. Labial papillomas (skin tags) are asymptomatic and usually do not need surgical removal. Vulvar hydrocele or cyst of the canal of Nuck occurs as a cystic swelling of the distal closed end of a remnant of the processus vaginalis that extends into the labium majus. It requires surgical excision. Capillary hemangiomas of the vulva do not cause symptoms and do not require treatment. Many of them regress spontaneously over a period of 5-6 years due
to thrombosis and fibrosis. Cavernous hemangiomas are however hazardous and require surgical ligation of the feeding blood vessel. Lipomas, myoblastomas and teratomas of perineum are extremely rare.

Vaginal benign tumors include vaginal polyps, mulleirian duct cysts and Gartner’s cysts.

**Malignant Tumors of the Vulva and Vagina**

Most common tumors reported are mixed mesodermal tumors of the vagina. These malignancies are extremely rare in children and adolescents but are associated with a high malignant potential. Vaginal adenosis and adenocarcinoma occur in young girls with history of exposure to diethyl-stilbestrol (DES) in utero.

The most serious tumor in pediatric age group is embryonal rhabdomyosarcoma, which progresses rapidly. Five-year survival has improved with combination chemotherapy—utilizing vincristine, actinomycin and cyclophosphamide.

**Tumors of the Uterus, Tubes and Broad Ligaments**

Benign tumors of the cervix include cervical papillomas and myomas. Uterine leiomyomas have also been reported in young girls.

Carcinoma of the cervix has been rarely reported in girls below 16 years of age. Adenocarcinoma of the uterine corpus and mixed mesodermal tumors of the uterine corpus though extremely rare, have been reported in young girls. Management is similar to adults.

**Ovarian Tumors in Children and Adolescents**

Ovarian tumors constitute about 1% of all new growths in girls under 16 years of age. Despite their rarity, germ cell tumors of the ovary are the most frequent genital neoplasms during childhood and adolescence. Approximately 30% of all ovarian tumors in children and adolescents are benign cystic teratomas or dermoids. Simple cysts of follicular type may be found especially in the newborn and a very young child. Multicystic ovaries, polycystic ovarian disease, corpus luteal cysts and theca lutein cysts are the benign lesions in the ovary.

Malignant tumors include dysgerminomas, malignant teratomas, embryonal carcinomas and sex cord stromal tumors.

Dysgerminoma is relatively commoner in younger age than in the adult. Ten percent of all solid carcinomas of the ovary develop during the first two decades of life. The patient presents with pain and lump abdomen, anorexia, weight loss and abdominal distension due to ascites, etc. Estrogen producing tumors may cause precocious puberty, while, androgenic hormones may produce irregularity of menses, voice changes, hirsutism and clitoromegaly.

Treatment comprises of surgery, radiation and chemotherapy depending on the stage and type of malignancy. Fertility conservation is an important consideration in benign tumors and early stage cancers of the ovary. In tumors confined to one ovary, unilateral ovariotomy and wedge resection with biopsy from contralateral ovary is done. This is followed by radiation or chemotherapy depending on the stage.

**Gynecological Consequences of Cancer Therapy in Children**

A number of children with cancers like leukemia, lymphomas, CNS tumors and neuroblastoma are treated with surgery, radiation and/or chemotherapy that can affect their reproductive potential.

Surgery for CNS tumors can affect pubertal maturation. Resection of pituitary tumors can lead to endocrine dysfunction. Pelvic surgery for bladder or other tumors can also devitalize uterus or ovaries.

Ovaries in children are more resistant to radiation or chemotherapy than adolescents and adults, nevertheless, children receiving 3000 rads pelvic radiation can have permanent ovarian failure. In such children laparoscopic oophoropexy (fixing ovary out of radiation field) is currently being done routinely.

Ovarian suppression with long acting GnRH analogue has also been tried to reduce radiotoxicity. Radiation to head can also affect pituitary hormones and result in gonadal failure. Most children surviving after acute lymphocytic leukemia suffer from growth failure.

Chemotherapy alone has very little effect on prepubertal ovary, thus most girls treated with combination chemotherapy have normal puberty.
Endocrine Disorders

The hormonal control of pubertal development begins in the hypothalamus by producing gonadotrophin-releasing hormone, which passes down the pituitary portal system to the anterior pituitary where follicle-stimulating hormone (FSH) is produced. This stimulates the development of Graffian follicles in the ovary, one of which ovulates as a result of luteinizing hormone (LH) surge at the appropriate stage of follicle development. These cyclical hormonal changes produce varying levels of oestrogen and progesterone leading to cyclical phases of the endometrial menstrual cycle.

The first sign of pubertal development is usually thelarche (breast growth) between the ages of 8 and 13 years. Growth in height occurs about the same time. Adrenarche (pubic hair development) usually follows next, and later the appearance of axillary hair and onset of menstruation (menarche).

Precocious Sexual Development

Sexual development must be considered precocious if there is breast and pubic hair growth before the age or 8 years and menstrual period before the age of 10 years.

The most common cause for this is constitutional precocious puberty, without any organic lesion being found. The signs of puberty usually appear in their correct order and the bone-age as well as the child’s height are several years in advance of the chronological age.

Before labeling the condition as constitutional precocious puberty, the organic causes must be excluded. These include intracranial lesions, such as meningitis, encephalitis, cerebral tumours, third ventricle hamartoma or Albright’s syndrome. MRI helps in detecting the CNS pathology. Less common is premature sexual development due to a feminizing tumor of the ovary. Treatment of cause, e.g. oophorectomy cures the girl. It may sometimes be partial precocious puberty with isolated breast development (excess estrogen only) or early pubic hair growth (adrenarche-with excess androgen alone). These usually require no treatment. Constitutional precocious puberty is treated with cyclic GnRH analogue injection 3.6 mg every 4 weeks., cyproterone acetate 70-150 mg/m² orally or medroxy progesterone acetate 100-200 mg intramuscularly every 2-4 weeks.

Delayed Puberty

Absence of sexual maturation till 14 years of age is delayed puberty and absence of menstruation till 16 years is considered as primary amenorrhoea in a young girl.

Delayed puberty is commonly constitutional. Usually there is a family history of similar delay. Only reassurance and observation is required if investigations reveal no abnormality.

Delay in maturation may be due to primary gonadal failure (hypergonadotrophic hypogonadism) or hypothalamic-pituitary failure (hypogonadotrophic hypogonadism). In primary hypogonadism, estrogen level is low with high FSH and LH. This is seen in girls with gonadal dysgenesis, Turner’s syndrome or following surgical removal of gonads. Hypogonadotrophic hypogonadism may occur secondary to CNS tumors, radiation or congenital hypothalamic defect. Anorexia nervosa and chronic illness can also delay the normal maturation. In both hypo and hypogonadotrophic hypogonadism cyclic estrogen replacement results in sexual maturation and withdrawal bleeds. Fertility is possible in hypogonadotrophic states, by ovulation induction using high doses of gonadotrophins.

Dysfunctional Uterine Bleeding

Early menstrual cycles are often irregular in their duration and amount of blood loss for some months after the onset of menarche, due to irregular ovulation. Such variation is within physiological limits, thus investigation and treatment are unnecessary. In girls presenting with excessive and irregular menstrual bleeding complications of early pregnancy and irregular oral contraceptive pill use should be excluded by careful history.

Reassurance and maintenance of menstrual chart along with mefenamic acid (500 mg TID) during menses is sufficient in majority. Puberty menorrhagia with heavy bleeding may necessitate hormonal therapy in some cases. Norethisterone (5 mg TID or QID) stops bleeding in few days. Subsequently cyclic treatment is given with combined pills for 2-3 cycles. Tuberculosis and blood coagulation disorders should be excluded as these may present as puberty menorrhagia. Iron therapy and dietary advice must also be given.
Irregular menstruation and oligomenorrhea or hypomenorrhea often result due to anxiety or stress of examination and emotional factors. These usually do not need any treatment except for protracted cases where tuberculosis should be ruled out. Thyroid disorders may also present as menstrual disturbances.

**Dysmenorrhea**

Anovular menstruation seldom causes pain. Dysmenorrhea is more common when regular ovulation is established. Some young girls take little discomfort at the time of periods in stride, while others feel extremely incapacitated by it. A significant number miss school due to pain. Exercise should be encouraged and the patient reassured. NSAIDS and mefenamic acid tablets (500 mg TID) are very helpful. Severe cases may require oral contraceptive pills to inhibit ovulation. An ultrasonographic scan of the uterus and ovaries should be done to exclude any organic pathology specially endometriosis or genital tract anomalies.

**Amenorrhea and Hirsutism**

The symptoms of secondary amenorrhea and hirsutism are both related to disorders in hormonal balance or due to specific organic cause. Primary amenorrhea needs to be evaluated if the girl has reached the age of 16 years without menarche or if secondary sexual development has not begun by age of 14 years. Secondary amenorrhea is the absence of menstruation for 6 months or longer in a girl who has previously had normal menstruation. These need detail gynecological and endocrinological investigation and management. Peripubertal polycystic ovary syndrome commonly manifests with oligomenorrhea, acne and hirsutism. Early identification and treatment is important to prevent long-term consequences.

**Premenstrual Syndrome (PMS)**

The premenstrual syndrome has been defined as menstrual related mood disorder that includes the cyclic occurrence of symptoms that are of sufficient severity to interfere with some aspects of life. Symptoms vary from tension, anxiety, anger, altered appetite, abdominal pain and bloating, weight gain, nausea, diarrhea, etc. Counseling, tranquilizers, pyridoxine and progesterone are used in the treatment.

**Psychosomatic Disorders**

**Anorexia Nervosa and Bulimia Nervosa**

This is a significant problem in affluent classes. The social climate as well as genetic, physiological or psychological vulnerability is there. In anorexia nervosa there is extreme weight loss which may lead to stoppage of menstruation. Bulimia is episodic binge eating of variable duration, which may be followed by a phase of anorexia nervosa. In anorexia there is loss of at least 25% of original body weight, while bulimia is usually associated with obesity. These disorders can be cured if treated early. Identification and correction of predisposing factors is important. Psychotherapy and reinforcement is often required.

**CONCLUSION**

Children and adolescents can present with a myriad of gynecological disorders. A knowledge of these is essential to prevent misdiagnosis and ensure proper management.

**REFERENCES**

Ovarian cysts in the pediatric age group are seen at two different peaks of age group, in the neonatal period and in the adolescent age. The cyst usually develops as a result of change in the hormonal milieu.

**FETAL AND NEONATAL OVARIAN CYSTS**

Ovarian cysts are most frequently diagnosed during the prenatal period due to routine antenatal ultrasonography. In the neonates, the ovarian cysts are rarely symptomatic. In absence of an antenatal ultrasonography, most of these cases would have passed unnoticed. More than 250 cases of antenatally diagnosed ovarian cyst had been reported till 1990. Though not all cases are reported yet, their number is increasing each year.1,2

The ovarian cysts in the fetus and the newborn develop due to the high level of fetal circulating gonadotropins, due to maternal estrogens and placental chorionic gonadotropins (HCG).3 The HCG levels may be high in mothers with diabetes, Rh-immunization and Toxemia.4

An immature hypothalamus-pituitary-ovarian feedback is thought to be responsible for gonadal hyperstimulation in severely premature fetuses. At birth, maturation of the central nervous system and regulation of anterior pituitary function lead to a negative-biofeedback mechanism decreasing hormonal stimulation and arrest of follicular maturation, and development.4

After birth the hormonal stimulation is withdrawn and the ovarian cysts that are small in size disappear spontaneously. However, the cysts that are larger (more than 4 cm. in size) do not disappear and are more likely to undergo complications.5 The etiology of ovarian cysts varies with the developmental stage and hormonal milieu of the patient.6

**CLINICAL FEATURES**

Most ovarian cysts are unilateral, only rarely are they bilateral. Most of the Fetal and neonatal ovarian cysts are asymptomatic and are diagnosed in the antenatal period.

Rarely, the cyst may present as an abdominal lump. The newborn is usually asymptomatic despite the fact that the cyst may have already undergone complications like torsion, hemorrhage and adhesions with formation of bands.3 A moderately sized cyst, especially with long pedicles is freely mobile in the abdomen and can reach up to the umbilicus, or even higher up without any difficulty. Occasionally the cyst may enlarge grossly, causing respiratory embarrassment, pressure over the inferior vena cava, bladder and the intestine and may simulate neonatal ascites.

**COMPLICATIONS**

1. Fetal ovarian cyst–Dystocia during delivery
2. Torsion of the cysts around the ovarian pedicle
3. Infarction
4. Autoamputation which may present as a wandering mass in the abdomen.7
5. Rupture. It may present as complicated ascites and a collapsed cystic structure in the abdomen.
6. Ascites
7. Hemorrhage
8. Infection
9. Respiratory embarrassment.8
10. Infertility in bilateral cases.
11. Compression of other viscera.
12. Edema of the labia.

Most of fetal and neonatal cysts are simple cysts that involute during pregnancy or in the first months of life. Torsion is the most common (50-78%) complication because the newborn ovary has a long pedicle and it is more common in cysts > 5 cm in diameter.

Spontaneous hemorrhage into a fetal ovarian cyst is a serious complication and should be followed by serial ultrasound and Doppler assessments to reveal the development of fetal anemia, which should be managed by intrauterine blood transfusion.

INVESTIGATIONS

Ultrasonography is the most useful and solely sufficient diagnostic modality for an ovarian cyst. Aspiration of the fluid in the cyst under ultrasonic guidance and analysis for high hormones levels (estrogens, progestins) is diagnostic. Ultrasonicographic evidence of torsion is described as an intracystic flocculation which typically is deposited on the sloping part of the cyst, and gives a characteristic liquid interface. Antenatal ultrasonography reveals an echo-rare or echo-free area in the fetal abdomen.

Computerized tomography is indicated only if the diagnosis is in doubt, or a solid component is seen on ultrasonography.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes the following:
1. Solid tumors with large cystic components. Granulosa cell tumor and cystadenoma have been reported as cystic lumps in the newborn. A fetal juvenile granulosa cell tumor has been diagnosed as a complicated ovarian cyst in the 32nd week of pregnancy.
2. Duplication bowel cyst (spherical type). The duplication cyst tends to have some intestinal symptoms. Most cystic duplication cysts are in relation to the small bowel and rarely with the left colon.
3. Urachal cyst. Mobility is very much limited.
4. Cyst of the renal origin. These can be easily differentiated on ultrasonography.
5. A small omental and the mesenteric cyst may be quite difficult to differentiate from an uncomplicated ovarian cyst.
6. Hydrometrocolpos presenting, as an abdominal mass is present in the midline, and extends deep into the pelvis. There may also be a single opening in the perineum and the symptoms of urinary obstruction may be present.
7. Occasionally, a duplex kidney with megaureter has also been mistaken for an ovarian cyst.

MANAGEMENT

The management of fetal ovarian cysts is still controversial. Some studies suggest an aggressive management, while others opt for a conservative one. In general, most ovarian cysts are functional in nature and usually resolve without treatment, if small in size.

Indications for Surgical Intervention

1. Patient is symptomatic.
2. If the diagnosis is in doubt.
3. Complex or functional cysts.
4. Cysts larger than 4 cm in the prenatal or newborn period and larger than 5 cm till one year of age.
5. The cyst persists longer than one year.

All surgical procedures for ovarian cysts should spare functional ovary as much as is technically possible. Simple cysts should be fenestrated. Complex or functional cysts should be excised, with preservation of the remaining ovary.

The ovarian cyst, which is really small, can be left and observed regularly by serial ultrasonography. The cut off size for conservative management with observation and reassessment by serial ultrasonography is taken by some as 4 cms and by others as 5 cm. Involution of neonatal ovarian cysts occurs usually by 12 months. Persisting cysts larger than 4 cm are prone to torsion.

As the cyst involves almost whole of the ovarian stoma, oophrectomy is the procedure often required in most of the complicated cysts. Occasionally, if the ovarian stroma is seen uninvolved or found stretched over the cyst, a cystectomy or deroofing can be performed, preserving the remaining functional ovarian tissue (Fig. 115.1). In-patients with bilateral ovarian cyst or bilateral ovarian disease, every attempt
should be made to preserve whatever ovarian tissue can be salvaged (Fig 115.2). Failure to achieve this, would require a life long hormonal support.

Intrauterine intervention (needle aspiration) decompresses the cyst and is known thus to prevent complications and preserve ovarian functions.\(^\text{12}\) Large cysts can also be decompressed if uncomplicated.\(^\text{17}\) US-guided aspiration has been found quite safe and effective. The aspirations can be repeated also if the need be, for the salvage or decompression if the intrauterine ovarian torsion occurs.\(^\text{16}\) Surgery should be reserved for patients with acute torsion, intestinal obstruction due to bands, adhesions and intestinal volvulus.\(^\text{16}\)

In earlier reports, more liberal surgical intervention was advocated to prevent complication.\(^\text{18}\) Neonatal cystic lesions may not always require therapy.\(^\text{19}\) Nowadays surgical intervention is warranted in only about 50% of the cases. The most appropriate clinical approach in the management of benign feto-neonatal ovarian cysts is to adopt a wait-and-see policy, assessing the course of the condition by means of periodic ultrasound monitoring and intervene if the diagnosis remained in doubt.

In the authors experience most of the ovarian cysts seen during the neonatal period have presented with asymptomatic abdominal lumps. Most of these (60%) were found to have already undergone torsion, infarction, hemorrhage, or even auto-amputation, completely destroying the ovarian tissue.\(^\text{3}\) The ovarian cysts were also found to have exudates and fibrotic bands attaching the same with the intestine loops. The bands can not be appreciated on ultrasonography. This may result in a serious complication in the form of intestinal herniation and volvulus, if the conservative treatment is followed. Thus, not only the large and complicated cysts, but all ovarian cysts, irrespective of their size, are best managed by surgery.

Laparoscopy has now become quite popular to treat ovarian cysts and the approach is favored by most pediatric surgeons who are in this field.\(^\text{6}\) Aspiration, deroofing, cystectomy and salpingo-ophrectomy can all be performed, including the neonates, by laparoscope.\(^\text{20}\) A complex ovarian cyst in a neonate has been successfully treated by laparoscopic-assisted transumbilical ovarian cystectomy procedure.\(^\text{21}\)
Prenatally diagnosed complex ovarian cysts are most often managed surgically in an attempt to save the ovary. Nevertheless, published surgical results show that most patients undergo oophorectomy or salpingo-oophorectomy. Histologic analysis has suggested gonad maldevelopment as the origin of complex neonatal ovarian cysts. Needle aspiration during the antenatal period, can help in regression of the large number of cysts, even those larger than 5 cm in diameter. In the meta-analysis of 420 cases, reported by Slodki et al, 89% cysts (25 out of 28) resolved with prenatal needle aspiration.

**PROGNOSIS**

The prognosis of the majority of congenital ovarian cysts is good since they have a benign origin. In about 50% cases, in which the cyst diameter was less than 4 cm, periodic ultrasound examinations have revealed a tendency towards spontaneous regression of the cysts. In the other 50% cases, with a cyst diameter more than 4 cm, cystectomy is necessary due to subsequent complications (torsion, intracystic hemorrhage). In a series reported by Foiley et al, 8 out of 11 ovarian cysts which were simple at recognition, became complex by the time at birth, with an ovarian tissue loss in 54% cases.

The meta-analysis of 420 fetuses with ovarian cyst reported by Slodki et al, showed that the majority of the ovarian cysts regressed (n=209, 50%) spontaneously and 98% of these were less than 5 cm in diameter. Surgical treatment was performed in 174 cases (41%) and 93% of these had ovarian cysts larger than 5 cm in diameter. Also, 145 cases (35%) cysts got complicated by torsion and intracystic hemorrhage requiring surgery.

**PERIPUBERTAL OVARIAN CYSTS**

Ovarian cysts develop usually after puberty from the mature follicles when the ovaries become hormonally active. Most of these cysts are asymptomatic. Due to the widespread use of sophisticated and detailed diagnostic imaging, pediatric surgeons may encounter incidental ovarian masses on preoperative imaging obtained for abdominal pain, trauma or other indications, or at laparotomy or laparoscopy.

Polycystic ovary syndrome (PCOS) appears to arise as a complex trait with contributions from both heritable and nonheritable factors. Polycystic ovary syndrome is the most common endocrine disorder causing female infertility.

Polygenic influences appear to account for about 70% of the variance in pathogenesis. Congenital virilizing disorders; above average or low birth weight for gestational age; premature adrenarche, particularly exaggerated adrenarche; atypical sexual precocity; or intractable obesity with acanthosis nigricans, metabolic syndrome, and pseudo-Cushing syndrome or pseudo-acromegaly in early childhood have been identified as independent prepubertal risk factors for the development of PCOS. During adolescence, PCOS may masquerade as physiological adolescent anovulation. Intractable prepubertal obesity was recognized to culminate in early childhood pseudo-Cushing’s syndrome or pseudo-acromegaly, which are manifestations of insulin-resistant hyperinsulinism, and to herald adolescent PCOS. Functional ovarian hyperandrogenism is considered to be a form of polycystic ovary syndrome at adolescence. One of the earliest manifestations of PCOS is premature pubarche. Prepubertal girls with obesity or insulin resistance are also at risk to develop the full PCOS phenotype after puberty. In prepubertal girls who carry risk factors, including genetic polymorphisms and/or particular environmental factors, Functional ovarian hyperandrogenism or polycystic ovary syndrome could develop at a high rate. Children with primary hypothyroidism generally have delayed sexual maturation and delayed puberty. Ovarian cysts have been reported in girls with longstanding uncompensated primary hypothyroidism.

Anti-Müllerian hormone (AMH) is produced by the granulosa cells and reflects follicular development. Adult women with polycystic ovary syndrome (PCOS) have increased levels of AMH associated with an excessive number of growing follicles. Serum AMH concentrations are increased in prepubertal and peripubertal daughters of PCOS women, suggesting that these girls appear to show evidence of an altered follicular development during infancy and childhood. An increased follicular mass is observed in these children that is established during early development, and persists during puberty.

The phenotypes of the polycystic ovarian syndrome (PCOS) and congenital adrenal hyperplasia syndrome (CAHS) present a number of similarities.
The main symptoms of PCOS are obesity, menstrual disorders, hirsutism, and low fertility in which the pituitary and adrenal glands are spared. The CAHS is a group of various entities all characterised by different degrees of malfunction of the 21-hydroxylase (CYP21) enzyme that result in decreased levels of aldosterone and cortisol, and the hyperproduction of adrenal androgen hormones. Metformin is an attractive option for induction of ovulation in PCOS patients, there is a need for more evidence related to its safety during pregnancy.33

**McCUNE-ALBRIGHT SYNDROME**

McCune-Albright syndrome (MAS) is characterized by gonadotropin-independent precocious puberty, café-au-lait spots on the skin and polyostotic fibrous dysplasia of bones. Ovarian cysts are common in peripheral precocious puberty in this Syndrome.54 Gonadal hyperfunction is the most frequent endocrine dysfunction in females with McCune-Albright syndrome. Peripheral precocious puberty is usually the first MAS manifestation in children, characterized by episodes of hypersecretion of estrogens with a consequent reduction in gonadotropin secretion.

High estradiol level and low gonadotropins concentration as well as their level after GnRH administration suggest ovarian autonomy.35,36 Scintigraphy, radiography and computed tomography scans may be helpful to delineate fibrous dysplastic bones.35

The clinical course of ovarian cysts is unpredictable due to episodes of hyperestrogenism typical of MAS ovarian hyperfunction. In persistent and recurrent large ovarian cysts with sustained estrogen hypersecretion and relevant clinical disturbances (increased linear growth and bone age maturation, vaginal bleeding and psychological disturbances) treatment is mandatory. Treatment of precocious puberty in MAS should be considered in patients with poor predicted adult height. Treatment of gonadotropin-independent precocious puberty in MAS with ketoconazole, cyproterone acetate or testolactone, an aromatase inhibitor, does not appear to be always effective in slowing bone maturation.37 Tamoxifen, a selective estrogen receptor modulator has also been used with success for the management of advanced puberty and rapid bone maturation.37

Experimental courses of estrogen-blocking drugs may have insufficient or no therapeutic effects. In these cases and when molecular analysis is required to obtain MAS diagnosis as in isolated peripheral precocious puberty, surgery is the option.34 Laparoscopy minimizes surgical intervention and facilitates obtaining tissue samples for molecular analysis, and sometimes relieves hyperestrogenism with the excision of hyperactive ovarian areas.34

**TREATMENT OF PUBERTAL OVARIAN CYSTS**

These cysts can be treated easily if the etiology is recognized. Identification of hypothyroidism in these girls obviates the need for extensive investigations.29 The restoration of euthyroid state with thyroid hormone replacement has been associated with resolution of these cysts.

Autonomous functional ovarian follicle cyst is the most often cause of isosexual pseudoprecocious puberty.38 Short period of observation is suggested because these cysts can resolve spontaneously.38

However, there are few cysts that require operative intervention that differs based on the size, type of lesion (cystic, solid or mixed) as well as the age of the child.19 A solid ovarian mass in an adolescent requires appropriate evaluation to differentiate benign from malignant disease.19 Pediatric dermoid cysts, adnexal torsion, ruptured lutein cysts, paraovarian cyst and serous cystadenoma require surgical intervention, though all these can be managed laparoscopically also.39 Even the giant ovarian cysts can be treated successfully with the laparoscopic procedure.40

**REFERENCES**

Vaginal anomalies can be present as a separate entity or may be associated with other anomalies like anorectal malformations. Misdiagnosis of vaginal anomalies is a common occurrence especially when present as separate entity. It may be diagnosed as late as puberty or may present as infertility in older girls. Adequate knowledge of the anatomical defect is essential for proper planning and reconstruction of the defect. Psychological counselling is also important in cases of absence of vagina. A good reconstruction at an early age with proper documentation of the defect is essential to prevent any gynecological mishap later in life.

The crux of treatment lies in a good follow-up and collaboration with a gynecologist at an early stage to help implement proper counselling that is required at the different stages of life. Bowel vaginoplasty has now been used by various surgeons and has stood the test of time. For vaginal agenesis, a sigmoid vaginoplasty provides a functional self-lubricating neovagina. Some authors have recommended reconstruction for absent vagina during adolescence because the local conditions are excellent and it allows adaptation of the anatomy to physical development.

Frank’s autodilatation, a nonsurgical method of creating a neovagina by recurrent dilatations requires long and often embarrassing self-catheterization which is often painful, and yields a vagina with limited length. Surgical options are better accepted.

Laparoscopy sigmoid vaginoplasty for reconstruction of a vagina in patients with the Mayer-Rokitansky-Küster-Hauser syndrome has been reported. For cases with associated anomalies, an early reconstruction during the definitive surgery is always preferred. It is extremely important to establish an accurate neonatal diagnosis especially in cases of cloaca, drain the hydrocolpos when present, and avoid a persistent urogenital sinus.

Patients born with persistent cloaca have a high incidence of gynecological problems at the onset of menses and in early adult life. Therefore, it is necessary to reassess these girls at early puberty by ultrasound/magnetic resonance imaging and vaginoscopy. Additional surgery may then be necessary to create a vagina for menstruation and sexual intercourse.

Besides congenital anomalies, vaginal reconstruction may be required for, vaginal stenosis after treatment of pelvic tumors, severe vaginal scarring secondary to chronic inflammatory disease or as a secondary corrective surgery after failure gender surgery.

However, as each case is different, there is always scope for new innovations and experiments in the formation of a neovagina still continue.

**CLASSIFICATION OF VAGINAL ANOMALIES**

A classification of vaginal anomalies has been derived, which permits logical operative decisions. This tool allows the assignment of increasingly involved reconstructive operations to progressively more complex vaginal. Powell et al, categorize the vaginal anomalies as follows:

- **Type A.** Simple labial fusion
- **Type B.** Distal urogenital sinus formation.
- **Type C.** Distal vaginal atresia with proximal urethrovaginal fistula
- **Type D.** Complete absence of the vagina

Based on the following anatomic classification, the following approaches to reconstruction can be
recommended. For Type A (simple labial fusion), a midline division of the labia shows a normal hymenal ring and a normal or near normal urethral meatus. After division of the labia, the skin and mucosal layers are approximated to assure that the introitus remains open, creating a normal appearance. For Type B (distal urogenital sinus formation), a more extensive separation of the fused tissue is required. It is necessary to develop a posterior pedicle flap from the labioscrotal tissue, which then is sutured to the vagina, creating a satisfactory opening for the urinary and genital orifices. In those patients with Type C anomaly (distal vaginal atresia with proximal urethrovaginal fistula), a vaginal pull-through using a perineal approach is performed. Patients with Type D (complete absence of vagina), are rarely encountered. These patients will require a vaginal substitution of some kind discussed later.

The choice for and timing of vaginal reconstruction rests on precise anatomic evaluation. The complexity of vaginal reconstruction in the growing child and the essentiality of psychosocial adjustment to appropriate sexual identity and function mandate long-term comprehensive follow-up. Optimal care for each patient requires experience and continuity to take the child through diagnosis, surgical reconstruction, stressful adolescence, and into adulthood with full attention to anatomic, physiological, and psychological support.

**Vaginal Agenesis**

The female reproductive system is derived primarily from the müllerian or the paramesonephric ducts. In the absence of a fetal testis there is no production of androgen or müllerian inhibiting substance (MIS), and consequently the wolffian system regresses and the müllerian system is free to differentiate. Between the sixth and eight weeks of gestation, the paired müllerian ducts develop lateral to the wolffian ducts and then cross medially to fuse in midline. These fused müllerian ducts join the urogenital sinus at the müllerian tubercle. By the tenth week of gestation, the ducts form a single midline tubular structure called the uterovaginal canal. The lateral aspect of the müllerian ducts, which remain separate, ultimately become the fallopian tubes. The fused portion of these ducts, which thicken, become the fundus, body and cervix of the uterus. Complete absence or agenesis of the vagina, also known as Mayer-Rokitansky syndrome results from a disorder of the ureterovaginal canal or the vaginal plate. In 1829 Mayer and in 1838 Rokitansky first described autopsy specimens of müllerian dysgenesis in female subjects.11,12 Subsequently Hauser et al described the frequent association of renal and skeletal anomalies.13 The incidence of vaginal agenesis has been reported to vary from 1 in 4000 to 1 in 5000 live births. The patients are typically 46XX females with normal secondary sex characters who present with anconorrhea. The association of congenital absence of vagina and anomalies of urinary system is very common.14,15 Most common renal anomaly is agenesis of one kidney or ectopia of one or both kidneys. Fusion anomalies, such as horseshoe kidney and crossed renal ectopia, are also very common. The ureter may be defective, because of lack of wolffian duct, or because of inhibition, debilitation or duplication of the bud. Griffin et al have reported skeletal anomalies in approximately 12% of these patients.15 Two-thirds of these patients have anomalies of spine, limb or rib. Six percent of skeletal malformations were of Klippel-Feil type. Duncan et al have suggested that this combination of malformations be called MURS association (müllerian duct aplasia, renal aplasia, and cervicothoracic somite association).16

**SURGICAL PRINCIPLES FOR VAGINOPLASTY**

Vaginal reconstruction is an extremely complex discipline due to wide diversity in vaginal anatomy and the commonly associated anatomical and functional abnormalities or the urogenital tract. Consequently no single reconstruction approach or combination of approaches can be applied empirically. Only an individualized approach can be expected to achieve the best possible outcome. This requires careful preoperative anatomical and functional evaluation, followed by extensive surgical planning based on the relative merits of surgical options. For a successful outcome of vaginal reconstruction in the setting of complex associated anomalies, adherence to several surgical principles is of paramount importance. The first principle is that all anticipated perineal reconstruction, including urethral, vaginal, and anorectal, should be done in a single stage.17,18 To achieve single stage perineal reconstruction complete
anatomical delineation is necessary before surgery, including ultrasound, a voiding cystourethrogram and endoscopy. Some patients may benefit from computerized tomography or magnetic resonance imaging of the pelvis to delineate further anatomy, although these evaluations are not performed routinely. Patients suspected of having neurovesical dysfunction require urodynamic studies because the resulting functional deficiency may significantly alter the surgical approach to reconstruction. The association of spinal cord disease must be carefully excluded. All children with associated anorectal or urogenital sinus anomaly should be screened by spinal ultrasound during infancy. After about the age of 6 months such children require magnetic resonance imaging, since vertebral calcifications preclude ultrasound transmission.

The second principle involves access for urethral catheterization. Since more than 50% of the patients require intermittent catheterization for neurovesical dysfunction, reconstruction must be performed to anticipate easy access. Accurate neourethral reconstruction is mandatory. The neourethra must have a smooth course and be well exteriorized to facilitate adequate intermittent catheterization. When the native urethra cannot be made to fulfill these criteria, the construction of a Mitrafanoff neourethra offers an excellent alternative.

The third principle is that urinary tract reconstruction has a major role in cases of vaginal abnormalities. Ureteric reimplantation is frequently necessary.

Of critical importance is the fourth principle of avoidance of overlapping suture lines, since they may result in fistula formation. Vaginal inlay flaps are especially important in the surgical correction of urogenital sinus, as demonstrated. Inlay flaps may be obtained from perineum, prepuce, or labia and all give excellent functional results. When vaginal reconstruction for cloacal anomalies is performed, the potential for overlapping suture lines with a neourethra is extremely high and can be readily avoided by rotating the neovagina 90°. Since vaginal reconstruction of this type is performed early in childhood, one must take every measure to ensure maximum growth potential of the neovagina, which is the fifth principle. Free grafts are to be avoided whenever possible. Vaginal inlay procedure (especially scrotum) and visceral substitution (usually colon or small bowel but occasionally bladder) are preferred for total creation of a neo vagina. Vaginal substitution is a complex undertaking. The colon is commonly recognized as the intestinal segment of choice due to the low incidence of stenosis on long-term follow-up. However, ileum has an important role when the colon is unavailable, as in genetically male infants with cloacal extrophy who undergo reconstruction to female gender. Ileum is also useful in cases of imperforate, when isolation of a colonic segment may devascularize the distal rectum by interrupting mesenteric collaterals. An alternate approach is the use of the distal end of rectum for vaginal replacement. Bladder substitution is an excellent substitute in some cases.

Meticulous follow-up is necessary to avoid stenosis and to ensure progressive enlargement of the vaginal vault to a degree appropriate with age. Routine dilatation, the sixth principle, is required to avoid stenosis. Patient age at the time of reconstruction is important. Before age 3 years routine dilatation as relatively easy to achieve but after that age cooperation on the part of the child may prove difficult to obtain.

Children are best served by an exhaustive preoperative anatomical and functional evaluation followed by thorough preoperative parental counselling about realistic expectations and the need for continued cooperation and compliance. A coordinated approach to reconstruction, rather than a fragmented conceptual and reconstructive approach, is necessary to achieve optimal surgical restoration of anatomy and function in these children.

**Vaginoplasty**

Vaginoplasties have long been fraught with complications of poor cosmetics from abnormal location or size to more severe problems resulting in incontinence, or stenosis. These procedures continue to evolve, and current procedures have as their building blocks a few landmark techniques. In 1964, Fortunoff described a posteriorly based perineal flap, which is used nearly in all repairs today. The most important advance came from Hendren and Crawford in 1969 when they defined the variable of anatomy of the confluence of the vagina with the urinary tract noting that the vagina may insert proximal (suprasphincteric, high vagina) or distal (infrasphincteric, low vagina) to the external sphincter
They also described the pull through vaginoplasty, which remains the basis of vaginoplasty for high confluence today. Vaginoplasty is generally done by one of four procedures:

1. Cutback vaginoplasty
2. Flap vaginoplasty
3. Pull-through vaginoplasty
4. Vaginal replacement.

**APPROACH TO A LOW VAGINA**

**Cutback Vaginoplasty**

The cutback vaginoplasty should be used in mild forms of labial fusion. Before any vaginal surgery is undertaken, the position of the vagina with respects to both the pelvic floor and perineal skin must be accurately determined from the genitogram, supplemented if necessary by endoscopy. When the vagina opens vary low, it may be laid open by a simple cutback, suturing the vaginal wall to the perineal skin with 6-0 absorbable sutures (Fig. 116.2). In most cases, however, a posteriorly based U flap will be necessary to ensure a tension free anastomosis, reducing the risk of postoperative stenosis.

**Flap Vaginoplasty**

The posteriorly based flap as an isolated procedure is applicable for only those with a low (infrasphincteric)
confluence as it serves only to open the urogenital sinus more widely, not change the level of the confluence (Figs 116.3A and B). When used alone in those with a high confluence, a short hypospadiac urethra will result with the potential for vaginal voiding, stasis and even incontinence.

A urethral catheter is inserted. The posterior flap, which must be sufficiently long to reach the vagina without tension and wide enough to ensure a good blood supply, is elevated together with a generous covering of subcutaneous tissue. A plane is then developed in the midline immediately behind the urethra to expose the vagina. The posterior wall of the vagina is now widely opened in the same flap sutured down. The remainder of the flap is brought down using 6-0 absorbable sutures, the vulvoplasty is now completed. Ten days postoperatively the vagina is inspected under anesthesia and its caliber determined, separating any flimsy adhesions.

**APPROACH TO A HIGH VAGINA**

Reconstruction of the genitalia in severely virilized patient presents particular difficulties because the vagina has a high confluence and is often small.

**Pull-through Vaginoplasty**

First described by Hendren, it is used for high (suprasphincteric) confluence of vagina. A Fogarty catheter is first introduced endoscopically into the vagina to facilitate its identification during the dissection, and the balloon is inflated. A second catheter is placed in the bladder. The rectum is then cleaned by insertion of a Betadine soaked swab, which is retained for the duration of the procedure. Two U shaped perineal skin flaps, one based posteriorly and the other anteriorly (Figs 116.4A to F). These are elevated and the dissection continued, keeping strictly to midline until with gentle traction on the Fogarty the vagina can be felt in the depth of the field. A nerve stimulator is used at this point to identify the levator muscles and the external sphincter. The former is divided in the sagittal plane and the vaginal wall is stabilized with a series of 6-0 silk stay sutures. The Fogarty catheter is withdrawn. The vagina is then detached from the urethra and opened as widely as possible. The urethral defect is carefully closed transversely with interrupted 6-0 polyglycolic sutures. Using cautions blunt dissection the surgeon mobilizes the vagina from the back of the bladder and rectum. The anterior and posterior flaps are then brought down and sutured to the vaginal margins.

The mobilization of a high vagina is sometimes difficult particularly when there has been prior infection in a hydrocolpos. It may be then necessary to turn the child and free the vagina via a laparotomy from the back of the bladder.

Although this is the most commonly used technique, there are certain disadvantages to this technique.

![Figs 116.3A and B: Steps of posterior flap vaginoplasty](image-url)
1. The vaginal introitus is located in the perineal wall far from the urethral meatus and the result is that of an isolated hole in the perineum.

2. There is no evidence of mucous lining is present in the front wall of the perineum between the urethral meatus and the vagina.

3. Vaginal opening has a tendency to stenose, requiring periodic dilatations.

**Passerini-Glazel Procedure**

For the severely virilized infant whose phallus resembles a normal penis, a satisfactory total reconstruction can be carried out using the technique described by Passerini and Glazel. This procedure takes advantage of the sheath of penile skin, which is tubularized and brought up through the perineum to form the lower portion of the vagina, and provides a cosmetically pleasing midline strip of mucosa in vulva (Figs 116.5A to I).

The patient is positioned and prepared for both a perineal and an abdominal dissection, although the procedure can be carried out entirely from below. A circumferential incision is first made around the coronal sulcus, and the skin and subcutaneous tissue are peeled back to the base of the penis. The corpus spongiosum is then separated from the corpora cavernosa and laid open. The skin sleeve split dorsally and ventrally in the midline, and the corpora cavernosa are transected close to the inferior pubic rami after careful preservation of the dorsal neurovascular bundles. A wedge resection of the glans is carried out and the corporeal stumps are brought together by fine interrupted circumferential sutures. The split penile skin is then brought down on either side and sutured to the opened spongiosum. The resulting rectangular flap is rolled in with a running suture to form a composite tube that will serve as the lower portion of the vagina. The upper vagina is then exposed as in Hendren’s operation and the

---

**Figs 116.4A to F:** Operative steps of Hendren’s vaginal pull through. A. High confluence of vagina, B. Fogarty catheter placed endoscopically in vagina helps in identification of the vagina, C. Vagina is detached from the urethra, D. The urethral defect is closed transversely. The vagina is mobilized further, E. The posterior flap is sutured to the posterior vaginal wall, F. Completed Hendren’s vaginal pull through.
anastomosis completed. Finally, the skin margins are brought together to complete the vulvoplasty.

Advantages

1. It allows clitorovaginoplasty to be completed in a single stage.
2. It preserves the neurovascular supply and allows an easy reduction clitoroplasty.
3. Since no vaginal dilatations are required, it can be carried out at any age.
4. Low risk of urethral meatal stenosis.
5. Construction of a vagina of appropriate size and position for the child.

Figs 116.5A to I: Passerini – Glazel operation for one stage clitorovaginoplasty. A. The penis is degloved, the urethral plate and corpus spongiosum are separated from the corpora cavernosa, B. The corpus spongiosum is detached from the glans, C. The dorsal neurovascular bundles are mobilized on a generous strip of investing fascia and the bulk of corpora cavernosa is resected. D. A deep edge is excised from the ventral glans. The glans is closed and the corporeal stumps are approximated. The penile skin tube is cutback dorsally and ventrally. E. The skin flaps are elevated and the urethra and corpus spongiosum are incised. These are laid open, F. The dorsal flap is sutured to use base of the glans, G. The skin flaps are brought down and sutured to the lateral edges of the urethra, H. The composite flap is rolled into a tube with a running stitch, I. The upper portion of the vagina is now exposed. The skin tunnel is sutured to the vagina.
A variant technique to the onestage clitorovaginoplasty in severely masculinized female pseudohermaphrodites is the anterior sagittal transano-rectal approach (ASTRA). With the patient placed in the prone position, after that a clitoroplasty is performed by the Paserini-Glazel procedure ASTRA permits to perform the dissection between the vagina and the urethra, the suture of the vaginal stump and the anastomosis between the neointroitus vaginalis and the vagina under direct vision. The anorectal sphincteric mechanism is divided in the anterior midline, and the rectum is opened just in the anterior rectal wall. This provides an excellent exposure to urogenital sinus. The vagina is then easily and fully separated from the urogenital sinus, the vaginal stump sutured and the anastomosis between the mucocutaneous cylinder (neointroitus vaginalis) and the vagina performed. The rectum, perineal body and the anterior sphincteric mechanism are then reconstructed. An anterior sagittal midline incision provides excellent exposure to the urogenital sinus and assures the preservation of the anorectal innervation and the sphincter mechanism.

**Posterior Sagittal Approach**

This approach was originally described for the rectal reconstruction of a cloacal anomaly but is adapted for repair of a urogenital sinus by opening the posterior and anterior walls of the intervening rectum. This provides excellent exposure of the vagina and its insertion into the urethra and, provided the dissection is carried strictly in, the midline safeguards the pelvic nerves and the integrity of the pelvic floor musculature. Unless a perfect bowel preparation can be assured, a preliminary colostomy will be necessary. A Fogarty catheter is first inserted in to the vagina endoscopically and the balloon inflated. A Foley catheter is inserted in to the bladder. With the patient in prone jack knife position incision is made extending from the tip of the coccyx anteriorly to the urogenital sinus opening. The dissection proceeds through the perineal body and fat until the muscle bundles of the levator muscle are visible. These are carefully identified by electrical stimulation and marked with long 6-0 silk sutures to facilitate accurate realignment at the end of the procedure. The posterior and anterior walls are then opened in the midline and the position of the vagina and its junction with the urethra determined by feeling for the presence of Fogarty catheter. The inferior aspect of the posterior vaginal wall is now marked with series of 6-0 silk stay sutures, gentle traction upon which allows the junction with the urethra to be clearly defined. The vagina is then detached, the urethral defect closed with fine polyglycolic sutures, and the vagina widely opened. Continuing gentle traction and blunt dissection in the surrounding connective tissues allow the vagina to be progressively mobilized towards the perineum to which it is sutured.

Because of the difficulty which is sometimes encountered in separating the vagina from the urethral wall, to which it may be fused for some distance above the confluence, it is often easier to carry out a total urogenital sinus mobilization in which the sinus, urethra, and the vagina are freed as a single unit. These structures are progressively mobilized together down towards the perineum, where the redundant portion of the urogenital sinus is excised. After completion of the perineal anastomosis, the posterior and anterior rectal walls are closed in layers and the pelvic floor musculature is reapproximated prior to closing the superficial tissues.

The posterior sagittal approach has been beneficial for acquiring exposure to high urogenital sinus anomalies but it has been thought to require splitting of the rectum and temporary colostomy. Rink et al, have described a modification of this technique without division of the rectum. This midline perineal prone approach has allowed excellent exposure of the high vagina even in infants. In their series of 8 patients with high vagina all reconstruction was done without difficulty and no patient required incision of the rectum or colostomy. This procedure did not preclude the use of a posteriorly based flap for vaginal reconstruction. While patients with low confluence can be treated with single posteriorly based flap vaginoplasty, those with higher confluence may benefit from a perineal prone approach to achieve adequate exposure for pull-through vaginoplasty. This prone approach to the high urogenital sinus anomaly can be performed without division of the rectum, provides excellent exposure of the high confluence even in small children and does not preclude the use of posterior flaps for vaginal reconstruction.
VAGINAL SUBSTITUTION

Improvements in the preoperative preparation, surgical techniques and postoperative management have made complex reconstruction of genital ambiguity possible. Efforts to create a viable vaginal substitute have been directed to improving cosmesis and functionality.

Timing of Surgery

Timing of surgery is crucial to the overall long-term success of the surgical approach utilized. If early surgery is contemplated (in infancy), then the tissue utilized should be one that will grow with the patient. Initial feminization (reduction clitoroplasty) with later completion of vaginal substitution may be undertaken with good results.

Non-surgical Technique

The only non-surgical technique reported is that of forceful dilatation of the perineal pit with a dilator over a protracted period of time to create a skin tube of adequate depth to permit intercourse. While this technique obviates operative intervention it is only suited to those individuals with a deep vaginal dimple and who are adequately motivated.

Surgical Techniques

Vaginal substitution techniques can be broadly divided into those utilizing,
1. Skin flaps, including expanded skin
2. Bowel substitution
3. Other tissue substitutes.

SKIN FLAPS

Use of split thickness meshed skin graft, was first described by McIndoe. A thin meshed skin graft is moulded around a Styrofoam or other mold and placed in cavity created between bladder and the rectum through a perineal incision. Once the graft has taken, the mold may be removed but early and repeated dilatation is required to prevent contraction and maintain size. Hockel et al have proposed the use of the scalp as the donor site for vaginoplasty with split skin grafts. Patients with a congenital absence of a vagina should also benefit from the obvious advantages, which made the scalp the preferred donor site in burn patients.

Advantages of split thickness grafts:
• Adequate tissue readily available for reconstruction
• It is well accepted and widely taught surgical technique.

Disadvantages of split thickness skin graft: No potential for growth, therefore reconstruction should be delayed until puberty:
• Potential for “poor uptake”
• Use of mold or other dilating method required
• Dyspareunia may be noted
• Can undergo scarring and reduction in size over a period of time
• May be site for development of malignancy.

Results and complications of McIndoe procedure for vaginal agenesis have been presented in a large series by Buss et al. During a 10 years interval, 50 patients with congenital absence of the vagina underwent McIndoe vaginoplasty. The mean duration of follow-up was 6.5 years. Two rectovaginal fistulas and one graft failure were among the complications that occurred. Five patients required additional reconstructive vaginal operations. Operative vaginoplasty was considered functionally successful by 40 of the 47 patients (85%) who responded to the survey, yet only 36 of these 40 (90%) had remained coitally active by the time of the survey. Recognizing the potential for complications, the need for long-term follow-up and care of the neovagina, and the less than perfect results achieved, they continue to consider the McIndoe operation as the procedure of choice for most patients with vaginal agenesis.

Modified McIndoe Procedure for Vaginal Agenesis

Ozek et al have proposed a modification of the original McIndoe procedure, by using a X incision instead of a straight-line horizontal or sagittal incision. During the first postoperative week, a perforated Pyrex rigid mold was used. This was replaced with an unperforated mold at the end of the first week. Complications encountered included infection, total lack of skin graft take, stress urinary incontinence, partial graft loss, and vaginal stricture. All complications were treatable except the stress urinary incontinence, and the final results were satisfactory.
Full Thickness Skin Grafts

A full thickness skin graft from iliac crest has been used in the formation of a neovagina. The potential risks and benefits of this procedure are similar to that with split thickness grafts. Donor site scarring and shrinkage may be greater with full thickness grafts.

The ideal operation for a young woman born without a vagina would be a one stage procedure, creating a functionally normal vagina without cosmetically unattractive scars, without the need for subsequent dilatation, stents or obturators. This goal can be achieved with a free flap vaginoplasty using a full thickness skin graft taken from the scapula region. The blood supply of the graft is maintained by micro vascular anastomosis of the graft pedicles to vessels in the groin. This technique is demanding, and has the problems associated with the other forms of skin grafting, i.e. donor sites, shrinkage and appropriate take. Moreover, the operation is a major undertaking and needs to be performed by those with expertise in plastic surgery as well as in gynecology.

Myocutaneous Flaps

McGraw initially reported the use of a myocutaneous flap for the construction of neovagina. This technique was initially designed for the use in patients who had exenteration performed for malignancy. Since then the gracilis myocutaneous flap has become very popular in recent years perineal reconstruction. The basis of use of myocutaneous flaps is the fact that the blood supply for areas of skin is obtained from perforating vessels from the underlying muscle. A gracilis flap is the most superficial of the medial thigh muscles and is a weak adductor. It can be sacrificed without compromising leg functions or gait. Its blood supply comes from a branch of profunda femoris and its nervous supply is from the obturator nerve that provides both motor and sensory innervation. For vaginal reconstruction, bilateral flaps are usually required. The flaps are raised and passed medially into the perineum. A skin tube is constructed from the two flaps and rotated medially in to the pelvis between bladder and rectum. The tube is held in place with anchoring sutures to the periosteum of the symphysis and the levators.

In McGraws series of 22 patients, 6 suffered partial flap loss, while 1 patient suffered totally catastrophic loss of flap. Thus about a third of the patients suffered some sort of flap embarrassment—an unacceptably high failure rate.

In recent years two techniques of vaginal reconstruction with sensate tissue have emerged. Song et al, have used bilateral flaps of labia majora and minora to create a neovagina. In 14 patients with the longest follow-up of 10 years, soft, sensate, pliable vagina were created. A major disadvantage, however is the sacrifice of the labia majora and minora bilaterally, which scars and distorts the vulva. This technique also introduces hair bearing skin of the labia majore into the neovagina.

Wang et al, have described a fasciocutaneous flap from the medial upper thigh based on the suprafascial vascular plexus. A partially sensate flap, measuring 20 x 9 cm, without using gracilis as a vascular carrier, could be raised to reconstruct the vagina and to close the perineal defects. However, this flap has a high incidence of flap loss owing to its precarious blood supply.

Wee et al, introduced the use of bilateral pudendal thigh flaps for total vaginal reconstruction. The flap derives its blood supply from the posterior labial and perineal artery, which branches from the pudendal artery (Figs 116.6A to G). It retains its innervation from the pudendal labial branches of the perineal nerve, which arises from the pudendal nerve. The advantages of this procedure are:

1. It is a simple technique which can be completed in 2 to 2½ hours with little blood loss.
2. The blood supply of the flaps is reliable. This leads to early wound healing.
3. No stents are required, since the reconstructed vagina is stable.
4. The introduction of well vascularized flap tissue into the pelvic cavity after exenteration helps to obliterate the dead space.
5. The angle of inclination of the vagina is physiologic and natural.
6. The linear scars of the donor sites are well hidden in the groin crease and perineum.
7. The vagina is sensate, retaining the same innervation of the erogenous zones of the perineum and upper thigh.
Vaginal Anomalies and Reconstruction

Figs 11.6A to G: Pudendal thigh myocutaneous flap. A. Arterial anastomosis over the proximal part of the adductor muscles, B. Innervation of the female perineum, C. The subfascial plane of the flap elevation is beneath the deep fascia of the thigh. The flap is arterialized throughout, D. Two incisions are marked, slightly curved and tapered flap on either side of the vulva, centered on the crease of the groin. The base in an adult is 6 cm wide, and the length may be up to 15 cm, placing the tip over the femoral triangle, E. Incision is made down to the deep fascia, the flap is raised, taking care to include the perimycium of the adduction muscles to avoid damage to the nerves in the flap. At the base of the flap, the skin is divided through the dermis to a depth of 1 to 1.5 cm to allow freedom of the flap. Tunnels are formed under the labia by dissecting from the pubic ramus. The flaps are passed under the labia with the flaps everted from the introitus, F. The paired flaps are sutured together in the midline to close the posterior wall of neovagina, G. At the apex, suturing is continued to approximate the anterior wall by bringing the lateral border together to form the vaginal tube.
Advantages of Myocutaneous Flaps for Vaginal Substitution

- Extra-abdominal approach
- Vascularized and sensate skin flaps

Disadvantages

- No lubrication of vagina
- Reconstruction should be delayed until prior to start of sexual function
- Significant leg scarring that is cosmetically unappealing
- Pain in the thigh region during intercourse
- May have prolapse of the neovagina

Expanded Skin

Skin expansion has allowed the utilization of local skin for the reconstruction of complex anomalies. Expanders have been used to generate local skin for creation of the neovagina or as molds for skin grafts.

To generate a flap of 10 cm in length and 8 cm width a 250 ml capacity expander is required. Expanders with remote injection ports are used to prevent damage to the expander during filling. The expander is inserted into a labial pocket via an inguinal incision. The remote port is inserted in a subcutaneous pocket above the pubic hairline. Two weeks following the placement expansion is initiated and continued weekly. Volume of the fluid injected in to the expander
is dependent on the patients' tolerance to the discomfort. One week following complete expansion vaginoplasty is performed. In severe vaginal malformations, when the distance between the upper vaginal pouch and perineum is too long (6 cm or more), reconstruction of the vagina can be performed by long cutaneous flaps, obtained by the tissue expansion technique, as described by Belloli et al.\textsuperscript{59} Dissection and anastomosis between the vaginal remnant and cutaneous tube is performed by the transtrigonal approach. Expanded labial skin-flap vaginoplasty has three main advantages: (1) it permits the construction of a large, soft, well-vascularized neovagina using non-hair-bearing labial skin; (2) it obviates postoperative dilations and prevents delayed strictures; and (3) a transtrigonal approach permits an easy vaginal dissection and a careful, tension-free anastomosis.

**Advantages of Skin Expanders**
- Availability of large amounts of local skin for vaginal reconstruction
- Skin flaps are easy to rotate into place
- No separate site for harvest of skin
- Procedure is performed extraperitoneally
- Does not contract or develop cicatrix since it is a full thickness, vascularized flap.

**Disadvantages of Skin Expansion**
- Significant deformity created by insertion of the expander, which needs to stay in place for 6-8 weeks
- Non-lubricated vaginal pouch
- May require periodic dilatation prior to the initiation of intercourse
- If hair bearing elements are part of the vaginal pouch, can lead to irritation
- Need to delay reconstruction until post-puberty, as segments do not grow over time
- Potential risk of infection of the tissue expander.

**Vaginoplasty Using Deepithelialized Vulvar Transposition Flaps: The Grunberger Method**
One of the most important criteria indicative of the long-term success of vaginal enlargement is the absence of postoperative contracture. Numerous procedures have been developed for reconstruction of an inadequate vagina. Some are technically complex techniques (myo- and fasciocutaneous flaps) with few postoperative complications of vaginal contracture, and others implement autografts with a greater tendency of tissue contraction. Grunberger et al, have described a method of vaginoplasty using deepithelialized vulvar transposition flaps to enlarge the width of narrow vaginas found mainly in cases of congenital adrenogenital syndrome-associated vaginal atresia, but also in cases of acquired vaginal atresia (surgery and radiotherapy-induced).\textsuperscript{60} They used deepithelialized dermis from the labia majora to construct an enlarged vaginal entrance and cavity, a technique that is easy to learn and perform. The healing phase of this operation is free of tissue rejection, most likely because of the close embryologic relationship of the cornified, paravaginal squamous epithelium of the labia majora and the noncornified squamous epithelial lining of the lower third of the vagina. The epithelium of the graft loses its cornified layer and becomes nonhair-bearing; its cytology and histology mimic normal vaginal epithelium. Postoperative function and sexual contentment were reported to be satisfying.

**Use of Autologous Buccal Mucosa for Vaginoplasty**
Lin et al, studied the procedure and outcome of creating a neovaginal pouch lined with autologous buccal mucosa in patients with Mayer-Rokitansky-Kuster-Hauser syndrome.\textsuperscript{61} The buccal mucosal wound completely healed 2 weeks after the operation and the neovaginal length and calibre were well formed. This was the first reported procedure of vaginoplasty using autologous buccal mucosa as graft material. The method is ideal in its simplicity, provides good cosmetic results, and improves the vaginal length of the patient.

**BOWEL SEGMENTS**
Various bowel segments have been used for vaginal substitution (Figs 116.7A to E). Intestinal segments have potential for growth along with the child and generally need less dilatation.\textsuperscript{62} This allows performance of the procedure in infancy. Ileal, sigmoid, rectal, and hindgut segments have all been used. Preoperative bowel preparation is required and depending on the segments used, further cleansing with enemas or flushing is necessary.
Ileal Vaginal Substitution

Ileal vaginal substitution was initially described by Baldwin in 1904. More recently Hanna described a modification of this approach with the use of a U shaped segment of the ileum combined with a perineal skin flap. The ileum is opened on its antimesenteric edge and folded into a U shape. The medial edges of the limbs of the U age sutured together and then pouch is created by sewing the lateral edges to each other. This vaginal pouch is placed in a cavity created between the bladder and rectum and anastomosed to a perineal skin flap.

Cecal Vaginal Substitution

Use of the ileocecal region has the potential risk of vitamin malabsorption. Use of cecal segment has been suggested in patients who have had prior pelvic irradiation, in whom the sigmoid segment may be unsuitable for reconstruction. An 8-10 cm cecal and ascending colon segment is harvested and rotated on its mesentery to bring it in to the perineum (Fig. 116.7).

Sigmoid Vaginal Substitution

Sigmoid colon is the most frequently used bowel segment for vaginal substitution, since a capacious vaginal cavity can be achieved without bowel reconfiguration. Additionally the thick wall of the sigmoid makes its better suited for vaginal substitution. A 10-15 cm segment of sigmoid is harvested with its vascular supply and placed in a space between the bladder and rectum. The proximal end of the sigmoid is closed with a double layer technique. The distal end is brought out to the perineum and may be anastomosed to the opened rudimentary vaginal pit.

Advantages
- Immediate availability of tissue for reconstruction
- Segments produce mucus and permit a lubricated passage
- Adequate caliber vagina can be created
- Usually no requirement for dilatation
- Will grow with the patient
- Sigmoid segment able to tolerate trauma of intercourse better than small bowel segments.

Disadvantages
- Distal prolapse may occur
- Frequent flushing of mucus required to prevent odor, inspissations and stone formation
- Are usually combined with labioplasty to improve cosmesis
- Can develop ulcerative colitis
- Malignancy

OTHER TISSUES USED FOR VAGINAL SUBSTITUTION

Human Amnion

Use of human amnion has been recommended to obviate the need for a donor site. This graft is used instead of skin modification of the McIndoe procedure. Amniotic membranes are used as a graft on vaginoplasties. The amnion is not stripped from the chorion. Excellent epithelialization with good functional results have been reported. However, the potential for disease transmission from a third party has made this graft material less desirable for routine use. Early use of dilatation is recommended. An alternate tissue that has been suggested is the peritoneum and this will avoid some of the infectious problems of donor tissue.

Bladder

In girls with a hypoplastic bladder who undergo creation of a neobladder, the residual bladder may be used for reconstruction of the vagina.

Peritoneum

Vaginoplasty using pelvic peritoneum (Rothman’s method) has been reported by Tamaya et al in 24 patients with congenital absence of the vagina.

Additional Techniques

Apical Vaginal Extension

Incision into the vaginal pit in patients with congenital absence of the vagina leads to the potential space between the rectum and bladder. This space may be bluntly dissected and a posterior skin flap rotated in to this fossa. If a suitable mould is left in place the rotated flap of skin will act as a nidus for growth of
new skin. The mould will need to be left in place for a greater period than that used with a skin graft. This technique has the potential risk for the mould to erode into the bladder over time.

**Inferior Vaginal Extension**

Williams described the creation of a pouch anterior to the vagina. This pouch when combined with a short vagina can permit intercourse. A U-shaped incision is made around the posterior edge of the vulva and the skin edges are sewn to one another to create a pocket anterior to the penetration and this is a potential risk. Additionally the urethral meatus may be located so deep in the pouch that significant efforts need to be made to empty the pouch of urine following voiding.

**RECENT ADVANCES**

Total urogenital mobilization, a technique described by Pena is deemed to preserve the urogenital sinus blood supply and avoid ischemic complications. This procedure is an effective technique for repairing short and long common channels, and a low surgical complication rate can be anticipated. A modification of total urogenital mobilization by incorporating the mobilized urogenital sinus tissue that is a well vascularized flap into the repair rather than discarding it, has been found useful to create a mucosa lined vestibule, a posterior vaginal wall flap and an anterior vaginal wall flap. The mucous fistula segment has also been used to create the neovagina in some cases thus obviating the need for a bowel anastomosis.

A modified isolated ileal segment according to the Monti principle has also been reported in 6 patients to create the neovagina with excellent patient satisfaction and relatively low morbidity.

A case of vaginal reconstruction using a flap from urinary bladder in a girl born with cloacal malformation and hemivaginas connected to the urinary bladder has been recently reported. She had repeated urinary tract infection and vesicoureteral reflux. Urogenital reconstruction was performed at 14 months of age. After an initial posterior sagittal anorectoplasty. A part of the urinary bladder wall, which was connected to the vaginas, was used to lengthen the vagina so that the latter was able to pull down to the perineum.

**CONCLUSION**

Multiple techniques have been described for vaginal substitution. The choice of surgical technique employed is based on the timing of reconstruction, indication for reconstruction, patient and parental motivation. Intestinal segments provide a lubricated vagina and are suited for early reconstruction. In patients that have later reconstruction tissue expansion or other skin flaps techniques are useful.

**REFERENCES**

Adrenal Disorders

Anurag Bajpai, PSN Menon

Adrenal gland is responsible for the production of glucocorticoids, mineralocorticoids and androgens, which regulate intermediary metabolism, fluid and electrolyte homeostasis and virilization respectively. Important pediatric adrenal disorders include defects in steroidogenesis, and excess and deficiency of individual hormones. Early diagnosis and treatment of these conditions are important in preventing long and short-term morbidity and mortality.

**PHYSIOLOGY AND METABOLISM**

**Effects of Adrenal Cortex Hormones**

Adrenal cortex produces three important groups of hormones—the glucocorticoids, mineralocorticoids and androgens. Cortisol, the major glucocorticoid hormone has an important role in intermediary metabolism leading to increased blood glucose levels and enhanced catabolism of proteins and lipids. Mineralocorticoids (aldosterone) act on the distal renal tubules and the collecting duct to promote sodium and fluid absorption. This leads to enhanced sodium absorption with increased excretion of other cations (potassium and protons).

The selectivity of action of adrenal steroids is determined at the level of hormone receptors. Mineralocorticoids act only on the type I steroid receptor while cortisol can act on both type I and II receptors. The inactivation of cortisol to cortisone by locally present enzyme 11β-hydroxysteroid dehydrogenase ensures that cortisol cannot interact with type I receptor. The importance of this regulation is emphasized by the presence of severe hypertension seen in patients with deficiency of this enzyme. In these patients cortisol is not inactivated and thereby acts on the type I receptor leading to apparent mineralocorticoid excess. Type II receptor is specific for cortisol and is responsible for glucocorticoid actions. Adrenal androgens play an important role in virilization.

Dehydroepiandrosterone (DHEA) is the most abundant adrenal androgen while androstenedione is the most potent. In the peripheral tissues, these compounds can be converted to testosterone and estrogen.

**Adrenal Steroidogenesis**

Adrenal steroidogenesis is a multi-step enzyme pathway and is summarized in Figure 117.1. The adrenal cortex has been divided into various zones based upon histological and biochemical features. Different parts of adrenals have different biosynthetic capabilities due to the presence of specific enzymes. Zona glomerulosa, the outer most zone, synthesizes aldosterone while the zona reticularis and fasciculate synthesize both glucocorticoids (cortisol) as well as androgens (DHEA and androstenedione).

**Regulation of Adrenal Steroidogenesis**

Adrenocorticotropicin (ACTH), a polypeptide secreted by the anterior pituitary, is the principle regulator of glucocorticoid and androgen synthesis. ACTH secretion is influenced by the circadian rhythm, corticotropin-releasing hormone (CRH) secreted by the median eminence of hypothalamus and serum cortisol levels. Release of ACTH also leads to release of melanocyte stimulating hormone (MSH), which is responsible for pigmentation seen in conditions with increased ACTH production such as primary adrenal insufficiency.
Intravascular volume, serum potassium levels and renin-angiotensin system are the chief regulators of aldosterone synthesis. ACTH plays only a minimal role in aldosterone regulation. Patients with pituitary deficiency therefore do not present with salt wasting crisis, as aldosterone levels are normal.

**DISORDERS ASSOCIATED WITH EXCESS OF ADRENOCORTICAL HORMONES**

These disorders include conditions associated with excessive secretion of glucocorticoids, mineralocorticoids and adrenal androgens in isolation or in various combinations.

**CUSHING’S SYNDROME (GLUCOCORTICOID EXCESS)**

Cushing’s syndrome, manifestation of hypercortisolism, is characterized by central obesity, proximal myopathy, glucose intolerance and hypertension. Most of these cases have features of androgen excess in the form of hirsutism, amenorrhea and virilization. The term Cushing’s disease is reserved for those patients who have pituitary tumor as a cause of hypercortisolism while the constellation of clinical findings irrespective of etiology is described as Cushing’s syndrome.
Etiology

Cushing’s syndrome is a rare disease with a prevalence of 1-2/million general population. The exact prevalence in children is unknown but is lower compared to adults. Causes of Cushing’s syndrome are summarized in Table 117.1.

ACTH Dependent Causes

Majority of cases (80%) of Cushing’s syndrome in adults are related to increased levels of ACTH. However in children younger than 6 years adrenal causes are more common.

Pituitary Causes

Excessive secretion of CRH and ACTH are implicated in many cases of Cushing’s syndrome. Most are associated with pituitary microadenoma but macroadenoma is found in some cases. In a few cases with bilateral adrenal hyperplasia, no cause is found despite meticulous investigations. It is important to differentiate Cushing’s syndrome secondary to CRH stimulation from those due to ACTH excess, as resection of pituitary adenoma in patients with former is associated with high recurrence rates.

Ectopic ACTH Production

The syndrome of ectopic ACTH production is extremely rare in children. Extremely high levels of ACTH, hyperpigmentation and manifestations of Cushing’s disease are important findings. Features peculiar to the tumors like flushing and diarrhea (carcinoid tumor) and episodic hypertension (pheochromocytoma) may suggest the diagnosis. In patients with malignancies and ectopic ACTH secretion classical features of Cushing’s syndrome may not develop due to acute nature of the lesion and hypokalemic alkalosis with hypertension may be the presenting features.

ACTH Independent Causes

Adrenal Causes

Adrenal is the source of glucocorticoid excess in most children with Cushing’s syndrome. Adrenal carcinoma is commoner than adenoma and presents with rapid progression of clinical features and greatly elevated levels of DHEA and urinary ketosteroids. Patients with adrenal adenoma have on the other hand slower clinical course and mild elevation of these substances. Pigmented nodular hyperplasia is an important cause of Cushing’s syndrome in children and is associated with normal adrenal imaging. This disorder has been associated with a variety of autoimmune and cutaneous defects. The presence of bilateral adrenal hyperplasia suggests ACTH dependent Cushing’s syndrome.

Iatrogenic

Exogenous steroid intake is the commonest cause of Cushing’s syndrome. Long-term treatment with any steroid leads to the condition. Drugs with high potency and prolonged half-life (dexamethasone) are more prone to toxicity than those with shorter half-life and lower potency (hydrocortisone). These patients can be identified by careful history. The diagnosis can be confirmed by normal serum and urinary levels of cortisol.

Clinical Features

Clinical features of Cushing’s syndrome are summarized in Table 117.2. Features such as excessive

Table 117.2: Clinical features of Cushing’s syndrome

- Central obesity
- Hirsutism
- Hypertension
- Striae (wide purple)
- Easy bruisability
- Proximal myopathy
- Polyuria
weight gain, hypertension and glucose tolerance are common but non-specific features of Cushing’s syndrome. On the other hand hirsutism, central obesity, striae and proximal myopathy strongly indicate the need of evaluation for hypercortisolism. Children with constitutional obesity are most likely to be confused with Cushing’s syndrome. They have generalized obesity, hypertension and high normal steroid excretion rates. These children are tall for their age and have advanced skeletal maturity. In contradistinction children with Cushing’s syndrome have retarded somatic and skeletal development.

**Diagnostic Evaluation**

Diagnosis of Cushing’s syndrome is complex and involves multi-step approach. First step is to presumptively diagnose the disease using screening tests. Diagnosis is then confirmed using diagnostic tests. Once the diagnosis of Cushing’s syndrome is established, further tests to diagnose the etiology are performed. Careful clinical evaluation forms an important part of such an approach. Hyperpigmentation suggests the possibility of excessive ACTH production (pituitary or ectopic tumor). Rapid progression with hirsutism indicates adrenal carcinoma while gradual progression is characteristic of pituitary adenoma. Features of CNS involvement and additional pituitary defects go in favor of pituitary lesions while hypertension out of proportion to other features indicates phaeochromocytoma as a cause of ectopic ACTH production. The biochemical tests for evaluation of Cushing’s syndrome are summarized in Tables 117.3 and 117.4.

**Screening Tests**

Twenty-four hour urinary cortisol is the best screening test for Cushing’s syndrome and should be performed in all cases wherever it is possible. It provides accurate estimation of daily steroid production and has the advantage of being diagnostic at higher values. Its high sensitivity and specificity (95-100% and 98%) makes it superior to overnight suppression test, which has high sensitivity but low specificity (98% and 70%). Mid night cortisol is emerging as a simple measure of evaluating cortisol excess but is in experimental stages.

UFC- urinary free cortisol, Dexa- Dexamethasone, CRH- Corticotropin releasing hormone, LDDST- Low dose dexam suppression test, HDDST- High dose dexam suppression test, ACTH- Adrenocorticotropic, IPSS- Inferior petrosal selective sampling
All patients with high index of suspicion but negative screening tests should be closely followed up with repeat biochemical evaluations in view of the possibility of periodic steroidogenesis.

**Confirmatory Tests**
High levels of urinary free cortisol (>150 μg/m²/day) are diagnostic of Cushing’s syndrome and no other confirmatory test is required. In patients with lesser degree of elevation of urinary free cortisol who have low clinical suspicion, a confirmatory test is required. Low dose dexamethasone suppression test (LDDST) is based upon the principle that dexamethasone in low dose does not to suppress cortisol levels in patients with Cushing’s syndrome while suppresses them in other causes of hypercortisolism. Some patients with pituitary microadenoma however show suppression by this test. These patients are responsive to stimulation with CRH. This has led to evaluation by CRH stimulation test after the standard LDDST. This test is emerging as the investigation for choice of confirming the diagnosis of Cushing’s syndrome.

**Etiological Diagnosis**
Approach to diagnosis of Cushing’s syndrome is presented in Figure 117.1. Initial step in etiological diagnosis is to distinguish ACTH dependent (hypothalamic-pituitary related and ectopic ACTH) causes from ACTH independent (adrenal) causes. Plasma ACTH levels are helpful in distinguishing ACTH dependent (ACTH > 10 pg/ml) from ACTH independent (ACTH < 5 pg/ml) cases. Cases with borderline ACTH levels (5-10 pg/ml) should be categorized by CRH stimulation test.

Spiral CT scan for adrenals should be performed in all patients with ACTH independent Cushing’s syndrome. In patients with elevated levels of ACTH high dose dexamethasone suppression test (HDDST) and CRH stimulation test are helpful in differentiating pituitary adenomas from ectopic ACTH producing tumors. In cases with suspected pituitary tumors gadolinium contrast MRI followed by invasive petrosal sampling can be used to determine the location of the tumor. Imaging of adrenal and pituitary should ideally be performed only after the diagnosis of Cushing’s syndrome is confirmed. This is to avoid confusion due to frequent occurrence of incidentalomas in both adrenals and pituitary.

**Management**
Surgery is the main modality of choice in Cushing’s syndrome. Medical management is important and recommended as a stopgap measure before surgery or when surgery is contraindicated (Fig. 117.2).

**Adrenal Causes**
*Adenoma:* Surgical resection is the treatment of choice. In most of these cases excessive secretion of cortisol suppresses the remaining adrenal tissue leading to adrenal insufficiency once the tumor is resected. This should be prevented by steroid replacement as done for stress conditions (discussed in adrenal crises states below).

*Carcinoma:* The outcome of these tumors is poor in view of highly invasive nature and high rates of metastasis. Adjunct treatment with chemotherapeutic agents like mitotane and cisplatinum has not improved the outcome in these patients.

Adrenal Disorders

1409

Pituitary Adenoma

Transsphenoidal resection of adenoma is the procedure of choice. It is important to rule out CRH dependent pituitary hyperplasia, as this is associated with high rates of recurrence after surgery.

Adrenal Hyperplasia without Pituitary Tumor

This condition is most likely due to undetectable pituitary tumors; ectopic ACTH secretion should however be ruled out by detailed evaluation. There is controversy regarding management of these cases. Bilateral adrenalectomy has been tried by some but has the problem of life-long replacement of corticosteroids and the high incidence of development of pituitary tumors (Nelson’s syndrome). Hypophysectomy, the alternative to bilateral adrenalectomy, entails the risk of permanent hypopituitarism. The management of these patients remains highly unsatisfactory.

Medical Management

Anti-adrenal drugs (mitotane, ketokonazole, spironolactone) have been used as temporary measures in management of Cushing’s syndrome. Cyproheptadine, a serotonin antagonist, has been found to be effective in management of Cushing’s syndrome.

HYPERALDOSTERONISM

Excessive secretion of aldosterone is associated with hypertension and hypokalemic alkalosis.

Causes

The causes of hyperaldosteronism are summarized in Table 117.5. Pituitary tumors do not cause hyperaldosteronism as ACTH has minor role in aldosterone regulation. Most cases of hyperaldosteronism are due to increase in renin levels, which is a compensatory response to reduced intravascular fluid volume. Aldosterone secreting adrenal tumors are smaller compared to those associated with Cushing’s syndrome or androgen excess. Bilateral adrenal hyperplasia can rarely present with features of aldosterone excess.

Clinical Features and Diagnosis

Hyperaldosteronism should be suspected in children with hypertension and hypokalemia. These children may present with features of hypokalemia in the form of muscle cramps and weakness (myopathy) and polyuria (impaired urinary concentration). Atrial natriuretic peptide is secreted in states of aldosterone excess. This provides escape from the fluid retaining effect of aldosterone.

</table>
effect of aldosterone. Patients with hyperaldosteronism thereby do not have edema unless complicating conditions like cardiac failure or renal dysfunction are present. These patients have borderline hypernatremia, marked hypokalemia, modest alkalosis and magnesium deficiency. Diagnosis of primary hyperaldosteronism requires the presence of diastolic hypertension, elevated and nonsuppressible aldosterone levels and low peripheral renin activity. Aldosteronomas should be differentiated from causes of apparent aldosterone excess mentioned in Table 117.5. Spiral thin slice CT scan should be performed in these patients considering the small size of most aldosteronomas.

Management

Hyperaldosteronism should be initially managed with salt restriction and anti-aldosterone agent spironolactone. Angiotensin convertase enzyme inhibitors are ineffective in these patients as renin-angiotensin system is already suppressed. Surgery is the treatment of choice for adrenal adenoma. Surgery however does not cause reduction of blood pressure in patients with bilateral hyperplasia. Surgery should thereby be performed only in those patients who have refractory hypokalemia.

ADRENAL ANDROGEN EXCESS

Congenital adrenal hyperplasia is the commonest cause of adrenal hyperandrogenism. Adrenal tumors associated with androgen excess are usually aggressive and have high rates of malignancy. They present with hirsutism, virilization and premature adrenarchae in girls and peripheral precocious puberty in boys. Elevated urinary levels of 17-keto steroids and serum levels of DHEA and androstenedione suggest the diagnosis. CT scan of the abdomen helps in localizing the tumor and also provides information regarding the extent of tumor spread. Treatment involves surgery in combination with radiotherapy and chemotherapy with antimitotic agent mitotane.

TUMORS OF THE ADRENALS

Adrenal cortical tumors present with excess secretion of glucocorticoids (Cushing’s syndrome), aldosterone (hyperaldosteronism) or androgens (virilization). Rapid onset, young age and virilization points towards malignant tumor while slowly progressive features are suggestive of adenoma. A small proportion of adrenal tumors are diagnosed as part of routine abdominal imaging. These incidentalomas should prompt evaluation for adrenal excess (urine free cortisol, serum sodium and potassium and DHEA). If these tests are normal and imaging is suggestive of benign tumor (small size, encapsulated, homogenous, no calcification), the patient should be followed up by periodic imaging. Treatment of most adrenal tumors is surgery. Surgery is effective in adenomas while carcinomas are invasive and metastatic and respond poorly. Medical management with cyproheptadine (Cushing’s syndrome), spironolactone (aldosteronoma) and ketokonazole (androgen excess) provide transient benefit.

ADRENAL INSUFFICIENCY (ADDISON’S DISEASE)

Insufficient synthesis or action of adrenal hormone can present as slowly progressive deterioration or salt wasting crises.

Causes

The causes of adrenal insufficiency are presented in Table 117.6. Pituitary deficiency is associated with preservation of mineralocorticoid function and does not lead to salt wasting. Adrenal hemorrhage, congenial adrenal hyperplasia and rapid tapering of corticosteroids are important causes of acute adrenal insufficiency. Autoimmune destruction and tuberculosis are the major causes of acquired adrenal insufficiency.

Clinical Features

Defect in steroid synthesis and congenital adrenal hypoplasia present in early neonatal period with polyuria, failure to thrive, recurrent vomiting and shock. Investigations reveal hyponatremia, hyperkalemia, metabolic acidosis, hemocoagulation and hypoglycemia. Acquired adrenal insufficiency presents with slowly progressive lethargy, vomiting, salt craving and fatigue. Adrenal insufficiency is manifest only after 90% of adrenal is damaged. Primary adrenal insufficiency is characterized by
Hypercortisolism due to elevated levels of MSH. Hyperpigmentation is present in sun-exposed areas as elbows, palmar creases and areas that are normally hyperpigmented as areolae and genitals. Features of hypoparathyroidism, hypothyroidism and diabetes mellitus suggest the diagnosis of polyglandular autoimmune syndromes (PGA I and II). Ectodermal dystrophy and chronic mucosal candidiasis are characteristic of PGA I.

**Evaluation and Diagnosis**

All patients suspected to have adrenal insufficiency should have urgent estimation of serum electrolytes and blood sugar. Basal levels of cortisol are low but can be in the low normal range. Rapid ACTH stimulation test (cortisol estimation 60 min after 0.25 mg of ACTH injection IM) is the best test for adrenocortical reserve. Serum cortisol levels lower than 15 μg/dl are suggestive of adrenal insufficiency. In patients with prolonged adrenal insufficiency long ACTH stimulation test (ACTH 1 mg/day IM for 3 days) is required for establishing the diagnosis.

Next step in evaluation of adrenal insufficiency is the estimation of ACTH levels. Elevated ACTH levels suggest primary adrenal pathology while low levels point toward pituitary defect. Further evaluation of primary adrenal insufficiency includes abdominal CT scan, estimation of anti-adrenal antibodies and workup for tuberculosis. Evaluation of hypothalamic-pituitary function (growth hormone stimulation test, FT4, LH, FSH and urinary specific gravity) is essential in patients with low ACTH levels.

**Management**

Initial management of salt wasting crises includes correction of shock by fluid boluses and management of hyponatremia and hypernatremia. Hydrocortisone should be administered immediately in a dose of 50 mg/m² followed by 100 mg/m²/day. The patient should be started on twice maintenance fluids. Frequent monitoring of hemodynamic parameters, urine output and serum electrolytes are required. Once the child is hemodynamically stable hydrocortisone can be tapered gradually to a dose of 15-25 mg/m²/day. Mineralocorticoids (fludrocortisone acetate 0.1 mg/day) should be added once the hydrocortisone dose is less than 50 mg/m²/day.

Long-term management of adrenal insufficiency requires life long replacement of glucocorticoids and mineralocorticoids. The dose is regulated by clinical features and serum levels of cortisol and aldosterone. Parents should be educated about the need of increasing dose during periods of stress. Need of urgent medical attention in conditions of decreased oral intake and stress should be emphasized. The dose of glucocorticoid should be increased 2-3 times in conditions of minor stress (fever, mild infection) and 4-5 times in severe stress (severe infection, surgery). These doses should continue throughout the period of stress. Patients with pituitary deficiency do not require mineralocorticoid. Their glucocorticoid requirements are also lower than those with primary adrenal insufficiency.

**CONGENITAL ADRENAL HYPERPLASIA**

Congenital adrenal hyperplasia (CAH), a group of autosomal recessive defects in steroid synthesis, is characterized by deficiency of adrenocortical hormones on one hand and excess of steroid precursor on the other (Fig. 117.3). CAH is the commonest adrenal disorder in childhood.
Types
The manifestations of CAH vary with the type of enzymatic defect.

21-hydroxylase Deficiency
21-hydroxylase deficiency is the commonest form of CAH accounting for 90% cases. This disorder is associated with diminished synthesis of the hormones cortisol and aldosterone. Low cortisol levels stimulate ACTH synthesis. Elevated ACTH level causes accumulation of steroid precursors (DHEA, androstenedione and 17-hydroxy progesterone, 17OHP) prior to 21-hydroxylase. There is a wide variation in presentation of 21-hydroxylase deficiency ranging from acute life threatening salt wasting crises to virilization and premature adrenarche. These variations can be explained by different enzyme levels, which in turn depend upon the nature of mutation. This disorder has been classified into three groups based on clinical features. These subsets are not separate disorders but are part of a spectrum and have significant overlap.

Classical Salt Wasting (CSW)
These patients have the lowest levels of 21-hydroxylase and present in the neonatal period with virilization.

The level of virilization extends from mild clitoromegaly and labioscrotal fusion to the extreme levels where genitalia resemble that of a boy with cryptorchidism. Associated hyperpigmentation points towards the diagnosis of CAH. Diagnosis is delayed in boys as they lack specific clinical features. They present in the second week of life with failure to thrive, polyuria, hyperpigmentation, and shock. Early diagnosis is mandatory to prevent high rates of mortality. 21-hydroxyalse deficiency should be suspected in all neonates with ambiguous genitalia, polyuria, shock, recurrent vomiting and features of sepsis with negative septic screen. The diagnosis should be confirmed immediately by hormonal assay. If these are not available the child should be managed empirically in the lines of adrenal insufficiency.

Classical Virilizing (CV)
A subset of patients with classical 21-hydroxylase deficiency (25%) synthesizes enough aldosterone so as to prevent adrenal crises. These patients have features of androgen excess in the form of virilization in girls and peripheral precocious puberty in boys. Boys with this disorder have prepubertal testicular volume, a finding that differentiates them from those with central precocious puberty. Prolonged androgenic stimulation in untreated boys leads to triggering

Fig. 117.3: Steroidogenic pathway
of central precocious puberty. These patients also have an increased incidence of ectopic adrenal rest tumors due to elevated ACTH levels. Testicular adrenal rests can mimic testicular tumors. The possibility of adrenal rests should be excluded by ultrasonogram and endocrine investigations before proceeding with invasive procedures like biopsy or surgical excision.

Non-classic (NC)

This disorder is associated with partial deficiency of the enzyme 21-hydroxylase. They present with mild hyperandrogenism in the form of premature adrenarche in girls and penile enlargement in boys. Aldosterone levels are normal and salt wasting is absent.

Diagnosis

Diagnosis of CSW is established by demonstration of extreme elevation of 17 OHP levels (10000-20000 ng/dl, normal < 90 ng/dl) in the presence of clinical and laboratory features of adrenal insufficiency. In patients where therapy had been started empirically 17 OHP levels should be estimated 2 days after discontinuation of hydrocortisone. This should be done under hospital setting so as to monitor for adrenal crises. The 17 OHP levels are elevated in patients with CV and NC; the elevations are however not as high as in CSW. The best method of diagnosing these patients is the estimation of 17 OHP levels before and 60 min after an intramuscular injection of ACTH (0.25 mg). These values should be plotted against the standard nomogram that classifies the patients into CSW, CV, NC, carrier state or no disease.

Management

These patients require life long treatment. Patients with CSW and CV should be treated with hydrocortisone (15-25 mg/m²/day) and fludrocortisone (0.1 mg/day). Although features of aldosterone deficiency are absent in patients with CV, aldosterone therapy reduces the requirement of hydrocortisone by suppressing antidiuretic hormone (ADH) levels. Doses should be adjusted based on clinical (growth, cushingoid features and blood pressure) and laboratory parameters (17OHP 500-1000 ng/dl, androstenedione 20-50 ng/dl and normal serum electrolytes). Doses should be increased under stressful conditions as for adrenal insufficiency. Patients with NC variety do not require mineralocorticoid treatment. In adolescent girls and young women longer acting analogs of glucocorticoids (dexamethasone, prednisolone) can be used. These drugs should be avoided during periods of growth as they have significant growth-inhibiting activity.

Role of Surgery

Girls with CSW and CV present with ambiguous genitalia at the time of birth. These girls have normal uterus and ovaries and have the potential for normal reproductive function. They should be reared as girls. Pediatric surgical approach includes clitoral recession, labioscrotal reduction and exteriorization of vagina. Single step procedures are replacing the cumbersome two-step procedure in most centers.

Adrenalectomy is emerging as a promising modality in the management of patients with CSW CAH. It has been observed that natriuretic steroid precursors antagonize the actions of aldosterone. Increased androgen production leads to growth retardation, enhanced skeletal maturity and virilization. Adrenalectomy helps in these patients by reducing the production of these substances.

Other Variants

Enzyme deficiencies other than 21-hydroxylase deficiency account for 10% of cases of CAH. Their clinical, laboratory features and management are summarized in Table 117.7. Patients with 11β-hydroxlase deficiency and 17α-hydroxylase deficiency present with hypertension and should be managed with hydrocortisone alone. Deficiencies of StAR and 3β-hydroxysteroid dehydrogenase manifest as salt wasting crisis and require addition of mineralocorticoid. Virilization of 11β-hydroxylase deficiency should be managed surgically as for 21-hydroxylase deficiency.

CONCLUSIONS

Adrenal disorders in children are associated with many short and long-term consequences. Appropriate diagnosis and management of these disorders require cooperation between neonatologists, pediatric surgeons and pediatric endocrinologists.

Min- Mineralocorticoid, Glu-Glucocorticoid, Sex- Sex Hormone, HC- Hydrocortisone, Flu- Fludrocortisone, CSW- Classical salt wasting, CV- Classical virilizing, NC- Non classical
The incidence of obesity has seen a sharp rise in the past few years. The western hemisphere is faced with an epidemic of childhood and adolescent obesity with doubling of the prevalence of obesity in the pediatric age group over the last thirty years. In India protein energy malnutrition remains the major nutritional challenge; economic disparity has led to the emergence of obesity as a pediatric health problem. Childhood obesity is associated with serious consequences such as coronary artery disease, hypertension and type 2 diabetes mellitus. This coupled with the observation that as many as 80% of obese adolescents become obese adults emphasizes the need of prevention and treatment of childhood obesity.

ASSESSMENT

Obesity implies excessive fat in the body and not merely excess weight. Body weight thus is not a reliable criterion for defining obesity. Long-term complications of obesity correlate best with body fat (specially visceral and intra-abdominal free fat) content. As methods of measuring body fat are cumbersome and expensive, clinical parameters are used as markers of obesity.

Body Mass Index (BMI)

BMI is the most widely used parameter to define obesity. It takes into account body weight as well as the height of the individual. It is calculated by the formula:

\[
\text{BMI} = \frac{\text{Weight (Kg)}}{\text{Height (m)}^2}
\]

Individuals above 18 years with BMI > 25 kg/m² are defined as at-risk for obesity while those with values > 30 kg/m² are diagnosed as obese. In view of the wide variation of BMI at different ages, age-specific cut-offs are used in the pediatric age group. Children with BMI > 85 percentile for age are considered at-risk for obesity while those > 95 percentile for age are labeled obese. BMI correlates well with intra-abdominal fat content on one hand and with complications of obesity on the other. There is however a problem in its sensitivity in that a few obese children are likely to be missed by these criteria. BMI also tends to overestimate the nutritional status of stunted children. Despite these shortcomings, BMI remains the most important anthropometric measure in evaluating a child for obesity.

Weight for Height

This parameter compares the child’s weight to the expected weight for his/her height. Weight for height > 120% is diagnosed as obesity.

Skin Fold Thickness

Skin fold thickness measured over the subscapular, triceps or biceps regions is a reliable indicator for subcutaneous fat. Age specific percentile cut-offs should be used with values > 85 percentile being abnormal. WHO recommends combination of BMI and skin fold thickness for diagnosing obesity.

Waist-hip Ratio

This has been used as an indicator of intra-abdominal fat in adult populations. Its value in the pediatric age
group has not been established. Values greater than 0.8 in women and 0.9 in men suggest obesity.

**Precise Estimation of Body Fat**

Bioelectric impedance studies are used to estimate skin fold thickness and body fat. Dual-energy X-ray absorptiometry (DEXA) provides accurate measurement of body fat but has the problem of radiation exposure. CT scan is helpful in delineating the distribution of fat in the body. MRI scanning is emerging as an excellent method of evaluating body fat stores without radiation exposure.

**ETIOLOGY**

In a vast majority of children with obesity, environmental and hereditary factors play the major role. In only 5-10% cases endocrine, syndromic or CNS causes are implicated. The causes of childhood obesity are classified in Table 118.1 and summarized below.

**Constitutional Obesity**

Majority of children with obesity do not have an organic cause. These children grow normally and are tall for their age. They have proportional obesity and normal development. Important environmental influences include excessive calorie intake, sedentary life style, television viewing and playing computer games. It is important to identify this subgroup of children so as to avoid unnecessary investigations.

**Endocrine Causes**

Cushing’s syndrome is characterized by central obesity, hypertension, striae and retarded skeletal maturation. Hypothyroidism is an extremely rare cause of isolated obesity. In most of these cases obesity is an additional feature to the other more prominent manifestations like short stature, developmental delay and coarse skin. In growth hormone deficiency and psuedohypoparathyroidism, growth retardation and hypocalcemia are dominant clinical features and obesity is a less prominent manifestation. It is important to emphasize that an endocrine cause of obesity is extremely unlikely in a child with normal height and skeletal maturation.

**Genetic Syndromes**

A variety of genetic syndromes have obesity as their major clinical feature. Klinefelter and Turner syndrome are readily identifiable by their clinical characteristics. Many of these syndromes are associated with hypogonadism or hypotonia (Prader-Willi, Carpenter, Laurence Moon Biedl-LMB).

**Central Nervous System Causes**

CNS insults in the form of surgery, radiation, tumors and trauma present with rapid onset obesity. These disorders are associated with excessive appetite, signs and symptoms of CNS involvement and other hypothalamic-pituitary defects. Children with features

of CNS involvement and rapid onset obesity should therefore be evaluated by appropriate CNS imaging modality.

**Miscellaneous Causes**

There has been growing interest in the role of leptin in the pathogenesis of obesity. A 17 kd polypeptide secreted by the adipocytes, leptin acts on the hypothalamus to control appetite. Cases of obesity with documented leptin deficiency have been shown to respond to treatment with leptin. Treatment with corticosteroids and anti-epileptic agents leads to obesity as do psychological disorders like bulimia, depression and attention seeking behavior.

**EVALUATION (FIG. 118.1)**

Initial step in evaluation of a child with history of excessive weight gain is to confirm the presence of obesity using BMI and skin fold thickness. Next step is to determine whether obesity is constitutional or pathological (Table 118.2). History should include family history of obesity and its complications, clues to pathological cause and features of complications such as hypertension, diabetes and respiratory problems (Table 118.3). Examination should focus on features of endocrinopathy, dysmorphic syndromes and complications such as hypertension and acanthosis nigricans. Special emphasis should be given to sexual maturity and ocular examination, as they provide clues to specific etiology. Stretched penile length should be measured carefully, as in many cases of constitutional obesity penis may be buried in pubic fat giving a false impression of hypogonadism.

Investigations for obesity are decided based on the degree of obesity and associated complications. According to the expert group on clinical guidelines for overweight investigations are required for all children with BMI > 30 kg/m² (or > 95 percentile) and for those with BMI > 25 kg/m² (or > 85 percentile) associated with any one of the following:

1. Family history of cardiovascular complications/type 2 diabetes
2. Rapid increase in obesity
3. Hypertension
4. Concern about obesity.

Evaluation should include blood sugar (fasting and postprandial), serum cholesterol, liver function tests and skeletal maturity evaluation. Complete lipid profile should be requisitioned if serum cholesterol level is >200 mg/dl once or >170 mg/dl on two occasions. Tests for endocrine causes (Urine free cortisol and FT4 / TSH) should be guided by clinical suspicion.
COMPLICATIONS

Childhood obesity has multi-system effects and is associated with significant complications.

Cardiovascular

Obesity has been linked with hyperlipidemia, hypertension and premature coronary artery disease. Hypertension is associated with high cardiac output and increased sympathetic output and has been shown to respond to lowering of body weight. Hyperlipidemia is related more closely to visceral fat than subcutaneous fat and also responds to weight reduction.

Endocrine

Most important endocrine complication of obesity is insulin resistance. This presents as a spectrum of changes ranging from elevated insulin levels to impaired glucose tolerance to frank type 2 diabetes. A characteristic clinical feature is acanthosis nigricans, dark and rough areas on the exposed areas of skin including back of neck, axilla and thigh. Syndrome X (hyperlipidemia, insulin resistance and obesity) is a well-known manifestation of obesity. Ovarian hyperandrogenism leading to premature adrenarche and ovarian dysfunction has also been associated with obesity. Growth hormone deficiency and thyroid resistance though common are usually of no clinical consequence.

Respiratory

Obesity is associated with restrictive (decreased respiratory movements due to obesity) as well as obstructive pulmonary disease (fatty deposition in the airway). The most severe respiratory complication is the obesity-hypoventilation syndrome (Pickwickian syndrome) associated with hypoxia and features of cor pulmonale. In its milder form it is associated with snoring, irritability, hyperactivity and day time somnolence. Weight reduction leads to improvement in lung function.

Orthopedic

Obese children are prone to slipped femoral epiphses, flat feet, Blount’s disease (tibia vara) and early onset osteoarthritis.

Hepatic

Obesity has been linked with fatty changes in liver along with hepatitis resembling alcoholic liver disease. The incidence of cholelithiasis is greater in obese children and has been shown to increase with treatment for obesity.

MANAGEMENT

Management of childhood obesity is extremely difficult and unsatisfactory and rarely leads to long-term success. Diet, activity and behavioral measures are the cornerstones of therapy with intensive measures like drug therapy, severe dietary restriction and surgery reserved for morbid cases.

Dietary Measures

Initial dietary measures for obesity includes mild caloric restriction and alteration in dietary habits. Intake of 1200-1800 calories depending upon the age of the individual with 30-40% restriction is recommended initially. Over-aggressive restriction of calorie and

nutrition is associated with poor compliance and growth faltering. Apart from restricting calorie intake, efforts should be directed towards improving the nutritive value of the diet. Reduction in consumption of junk foods, carbonated drinks and saturated fat along with an increase in fiber, fruits and vegetable intake are helpful in improving body composition.

Intensive approaches to decrease dietary intake have also been tried. Regimens sparing protein (1.5-2 gm/kg/day for the expected body weight) with severe caloric restriction (750-1000 cal/kg/day) have been demonstrated to be effective over short periods of time (10-12 weeks). These Protein Sparing Modified Fast (PMSF) regimens fortified with micronutrients and vitamins lead to 0.5 kg/week reduction in body weight. They are too intensive for long-term use in pediatric population and require intense monitoring.

Lifestyle Modification

Increase in physical activity along with reduction in sedentary life-style is an important part of obesity management.6 Swimming, running and playing outdoor games should be encouraged. Activities like TV viewing, videogames and internet surfing, which promote snack eating, should be restricted. Psychological and behavior therapy are also helpful. It is important to emphasize that dietary intake should not be increased in view of increased activity as this would offset the advantage of increased activity.

Drugs

Drug therapy is reserved for severe cases of obesity (weight for height >140%). Most of the anti-obesity drugs have not been tried extensively in children and thus cannot be recommended for routine use. Drugs used in obesity are summarized in Table 118.4. Stimulant drugs like amphetamines have been withdrawn due to high rates of dependency. Fenfluramine, a serotenergic agent, was withdrawn due to severe side effects like cardiac valvulopathies. Current medical treatment of obesity consists of drugs decreasing appetite through effects on neurotransmitters (sibutramine) and those interfering with absorption by inhibiting gastric enzymes (orlistast). Leptin (for those with leptin deficiency) and octreotide (for hypothalamic obesity) are promising approaches for sub-groups of children with obesity. The efficacy of pharmacological therapy for obesity has however been modest compared to surgery.

Surgery

Surgery for obesity is the last resort in treatment.7 It is indicated for morbid obesity (BMI > 40 kg/m² or BMI > 35 kg/m² with complications of obesity) when other measures have failed. Experience with surgery for obesity in children is limited but has been shown to cause significant reduction in body weight (> 33% of pre-surgery weight) sustained for a period of 1 year. Surgery is the only modality with proven and sustained efficacy in the management of obesity. The various surgical techniques are summarized in Table 118.5. These have been described is detail in chap 119.
Jejuno-ileal Bypass

In this procedure a segment of proximal jejunum is anastomosed to distal ileum. The remaining portion of small intestine acts as a blind loop. This leads to decrease in absorption and thereby decreased caloric intake. Weight loss in this procedure is however greater than that achieved by resecting the same extent of the intestine indicating that the blind loop plays an important role in weight loss. The procedure is highly effective in lowering lipid levels in these patients. The initial enthusiasm of this procedure has however faded away due to the significant adverse effects including hepatic dysfunction and failure, renal dysfunction, renal calculi and multiple vitamin deficiencies. Most of these adverse outcomes are related to blind loop syndrome and bacterial overgrowth. Treatment with anti-anaerobic antibiotics like metronidazole is helpful in alleviating some of them. In view of these life-threatening complications, this procedure has been largely replaced by gastric bypass.

Gastric Bypass

These procedures take the advantage of decreased absorption without the limitation of blind loop. Roux-en-Y loop is the most commonly practiced procedure. A small portion of the stomach is anastomosed with a segment of jejunum 15-45 cm distal to ligament of Treitz. Proximal jejunum is re-anastomosed around 50-60 cm distal to gastrojejunostomy. This is the surgical technique of choice for treatment of obesity. The effects on weight loss are similar to jejunoileal bypass but the effect on lipid levels is less remarkable. Stomal stenosis and intussusception are important adverse effects.

Surgery to Decrease Gastric Capacity

Gastric balloon implantation and vertical band gastroplasty have been tried in adults aiming at decreased gastric capacity and thereby decreased caloric intake. The experience in these procedures in children is limited.

Other procedures like biliopancreatic bypass, jaw wiring and liposuction have not been used extensively in children and are not recommended for pediatric use.

CONCLUSIONS

Management of obesity is a therapeutic challenge and requires multi-disciplinary approach. In view of long-term complications drugs and surgery should be used for only morbid obesity where complications of the disease outweigh those of drug therapy or surgery. Under most of these circumstances surgical management is preferable to drug therapy.

REFERENCES

Obesity is a disease process with multiple etiologies influenced by genetics, culture, economics and psychological issues. Identification of effective obesity treatment modalities continue to challenge, the medical community. Results from the American National Health and Nutrition Examination Survey demonstrate that approximately 65% of Americans aged 20 years of age or older are overweight (BMI > 25) and 31% are obese (BMI > 35) or morbidly obese (BMI > 40). Amongst American children and adolescents, 21-24% are overweight and 10-11% are obese or morbidly obese. 50-77% of children and adolescents who are obese carry their obesity into adulthood, thus increasing their risks of developing serious and often life-threatening conditions. The risk increases to 80% if one parent is obese.

Obesity prevalence among children and adolescent is a serious health care issue all over the world. Statistics in USA and UK is raising alarm and issues are discussed to address changes in lifestyle. The prevalence of childhood obesity in the UK continues to escalate with an estimated 1.3 million obese children forecast by 2010. The developing countries with emerging economy are already seeing childhood obesity as a major health issue.

As the prevalence of obesity and obesity-related disease among adolescents increases, physicians are faced with the challenge of determining the best treatment strategies for affected patients. In order to determine who qualifies for bariatric surgery, a number of factors need to be considered. This includes patient comorbidities as well as a number of factors unique to overweight youths. The appropriate consideration of these factors preoperatively is important in order to increase compliance and decrease risk of adverse medical and psychosocial outcomes postoperatively.

WHAT IS OBESITY?

Obesity is a condition where weight has got to the point that it poses a serious threat to health. It is measured in terms of a person’s body mass index, which is determined both by weight and height. BMI cut-off points have been agreed for obese and overweight adults, but for children the situation is more complex. A child’s BMI varies with age, different cut-off points have to be used to define overweight and obese children depending on age (Table 119.1). A BMI of 25 or more is considered overweight; 30 or more, obese; and 40 or more, morbidly obese (Table 119.2, Fig. 119.1).

PATHOPHYSIOLOGY OF OBESITY

There is no denial of the fact that obesity is caused mostly because of imbalance in intake and consumption of calories. The current lifestyle is promoting less consumption of calories and easy availability of fast food loaded with calories is fuelling this epidemic of obesity all over the world.

It is also important to understand that fat cells are no longer viewed as inert packets of energy, but they are two faced master minds of metabolism. It is now very well documented that there are two types of “fat” cells and they secrete hormones like leptin, and molecules called adipokines. The signals from ‘fat’ fat cells (in obese people) produce TNF $\alpha$ and make a circulating factor that makes other tissues resistant to insulin. Obesity-related comorbid conditions in children and adolescents include:

1. Hypertension
2. Impaired glucose tolerance
3. Diabetes mellitus
4. Hyperlipidemia
5. Obstructive sleep apnea
6. Cardiovascular disease
7. Degenerative joint disease
8. Gynecological and obstetric comorbidities.

**ROLE OF BARIATRIC SURGERY IN CHILDREN AND ADOLESCENTS**

The role of bariatric surgery in treating childhood obesity has been in flare recently. As obesity has been referred to as a worldwide epidemic, there is an increasing trend towards Bariatric surgery even in children and adolescents worldwide. It is considered as one of the most alarming public health issues facing the world today. In North America, nearly one-third of the population is obese, and this figure includes children and adolescents who are likely to become obese adults. As obesity carries a great financial impact on society, treating morbidly obese patients with surgery may offer substantial economic savings. Thus, early rather than later use of bariatric surgery in the treatment of extreme obesity has been recommended. It has been found that adolescents undergoing bariatric surgery have a significantly shorter length of hospital stay compared to adults.

In the US, extreme obesity affects approximately 9 million adults and 2 million children and is associated with both immediate health problems and later health risk, including premature mortality. Increasing pediatric obesity is especially alarming because obesity is associated with significant medical and psychosocial consequences like cardiovascular, metabolic, hepatic complications and psychiatric difficulties.

From 1997 to 2003, the estimated number of adolescent bariatric procedures performed nationally increased 5-fold in a series. In another study, the population-based annual adolescent bariatric case volume varied little between 1996 and 2000 but more than tripled from 2000 to 2003. Despite this trend, in this series, only 771 bariatric procedures performed in adolescents in 2003, representing fewer than 0.7% of bariatric procedures performed nationwide.

Most hospitals that perform bariatric procedures on adolescents have limited experience with adolescent bariatric patients, although many of these hospitals have high overall bariatric volume (adolescents and adults). Thus there are not much experienced pediatric bariatric surgeons. It has been suggested that bariatric surgery should be limited to selected adolescents in Institutional Review Board-approved research studies.

**INDICATIONS FOR SURGERY**

To be considered for bariatric surgery, adolescents should have attempted and failed six months of...
Surgery for Pediatric Morbid Obesity

Table 119.3: Criteria for bariatric surgery in adolescents

Adolescents being considered for bariatric surgery should:

- Have failed 6 months of organized attempts at weight management, as determined by their primary care provider
- Have attained or nearly attained physiologic maturity
- Be very severely obese (BMI 40) with serious obesity-related comorbidities or have a BMI of 50 with less severe comorbidities
- Demonstrate commitment to comprehensive medical and psychologic evaluations both before and after surgery
- Agree to avoid pregnancy for at least 1 year postoperatively
- Be capable of and willing to adhere to nutritional guidelines postoperatively
- Provide informed assent to surgical treatment
- Demonstrate decisional capacity

Current modalities for the treatment of morbid obesity include dietary modification, exercise, pharmacologic intervention and surgery. Indications for surgical weight loss are for the improvement or resolution of comorbid adverse health conditions present in many obese people. The term “morbid obesity” was developed to describe the significant morbidity associated with severe obesity including diabetes, sleep apnea, venous stasis, heart failure, deep venous thrombosis, pulmonary emboli, hypertension, degenerative arthritis, gallstones, hernias, and an increased incidence of ovarian, breast, prostate and colon cancer. Candidates for bariatric surgery have a BMI of greater than 35 in the presence of comorbidities or a BMI of 40 or greater in the absence of comorbidities. Individuals with a BMI less than 35 are counseled on non-surgical methods of weight loss such as pharmacologic intervention, dietary modification, exercise, and psychotherapy. International Pediatric Endosurgery Group has come up with following recommendations:

- Be very severely obese (BMI 40) with serious obesity related comorbidities and; have attained nearly adult stature
- Have failed at least 6 months of organized conventional attempts at weight management
- Demonstrate commitment to comprehensive pediatric psychological evaluation both before and after surgery and agree to avoid pregnancy for at least one year postoperatively
- Be capable of and willing to adhere to nutritional guidelines postoperatively, and
- Have decisional capacity and provide informed assent for surgical management.

For morbidly obese individuals, obesity surgery is the only proven method to lose weight and keep it off in long term, when all other therapies have failed. A recent study/meta-analysis of more than 22,000 patients has shown the mean percentages of excess weight loss was 61.2% for all patients and was 47.5% for patients who underwent gastric banding. Diabetes was completely resolved in 76.8% of patients and resolved or improved in 86.0%. Hyperlipidemia improved in 70.0%. Hypertension was resolved in 62.7%. Obstructive sleep apnea was resolved in 85.7%.

- A person who has repeatedly tried and failed to lose weight with the aid of diets, exercise, behavior modification, or weight loss.
PREOPERATIVE COUNSELLING

The counselling should include discussion of the various options for treatment of obesity. The three main treatment modalities of childhood obesity are lifestyle interventions, medications, and bariatric surgery. Primary prevention of childhood obesity is important. A trial of new medications including orlistat, sibutramine, and metformin can be offered to the older adolescents. The ultimate goal should be an improvement in health resulting in a reduction of life-threatening risk factors—A staged approach, emphasizing early intervention and lifestyle changes is important. Continued behavioral intervention increases the likelihood of a sustained effect for up to 2 years. The various risks involved with the procedure should be discussed in detail with the patient. This should include the long-term side effects, such as possible need for reoperation, gallbladder disease, and malabsorption.

The need for lifelong medical surveillance after surgical therapy should be explained. The option of surgical treatment is a very serious decision and should be offered to patients who are morbidly obese, well informed, motivated and able to make a decision on their own. Patients with manifest psychopathology that affects an informed consent and long-term cooperation with follow-up should be excluded. Numerous parallels exist between obesity and addictive behaviors, including genetic predisposition, personality, environmental risk factors, and common neurobiological pathways in the brain. A 5-10% reduction in weight can result in a 35% decrease in health risk. Obesity treatments should include counselling and behavioral approaches besides bariatric surgery. Present medical and behavioral interventions for extreme obesity in adults and children rarely result in the significant, durable weight loss necessary to improve health outcomes, prompting a search for more aggressive measures. Current evidence suggests that after bariatric surgery, adolescents lose significant weight and serious obesity-related medical conditions and psychosocial status are improved. A decision to have surgical treatment requires an assessment of the risk and benefit in each case. The risks including association of iron deficiency following bariatric surgery should be well explained.

Obese adolescent girls should be warned to use secure birth control methods during the period of postoperational weight loss. This period of rapid weight loss could cause maternal malnutrition and may impair normal fetal development.

FACTORS IN PATIENT DECISION MAKING

The European guidelines for bariatric surgery clearly define criteria for operating children with morbidity obesity. However, the appropriate technique for this age-group has not been identified yet. Gastric banding and Roux-en-Y bypass represent the standards, but they demand life-long tolerance of either an artificial device or significant malabsorption. The absence of significant nutritional deficiency, the continued adjustability, and potential reversibility of LAGB make it the safest, least invasive, and most effective surgical procedure to offer adolescents. However longer follow-up is required before universally recommending this procedure.

OVERVIEW OF BARIATRIC SURGERY

Obesity surgery stems from surgical weight loss identified in patients who underwent gastric and small bowel resections for treatment of diseases other than morbid obesity. Weight loss procedures have been performed based on malabsorptive techniques, restrictive techniques, and a combination of both. Early attempts at weight loss procedures were based on properties of malabsorption via shortening the length of the digestive tract through which food travels. The jejuno-ileal bypass was effective in achieving weight loss from the bypass of significant lengths of small bowel. Although effective in achieving weight loss, several complications of malabsorption ensued including socially limiting diarrhea, vitamin and protein deficiencies, arthritis, renal failure, liver failure and death. These early malabsorptive operations should no longer be performed or recommended for surgical weight loss but rather reversed or converted to acceptable weight loss procedures when recognized.

In the 1960’s gastric bypass surgery was pioneered by Dr Edward Mason at the University of Iowa, emerging from observations of sustained weight loss after gastric ulcer surgery and stomach resection.
This procedure offered both components of weight loss surgery that have been previously used singularly: malabsorption and restriction. The complications from this Roux-en-Y gastric bypass (RNYGB) were less than those reported with the jejunoileal bypass and specifically did not include the severe malabsorptive side effects associated with earlier weight loss procedures.\textsuperscript{21,29}

In 1982 the vertical banded gastroplasty (VBG) was first introduced.\textsuperscript{30} The VBG procedure is a restrictive procedure limiting caloric intake by restriction of food volume (Fig. 119.4). The benefits of restrictive only procedures is that unlike their malabsorptive counterparts, there is a lesser likelihood of nutritional deficiencies, since absorption of nutrients is unaffected by the restrictive component of the surgery. Although effective in achieving weight loss, patients are counseled in avoidance of high caloric liquids that may lead to weight loss failures. VBG has fallen out of favor due to inferior long-term weight loss in comparison to the RNYGB.\textsuperscript{31}

The first laparoscopic RNYGB was reported by Wittgrove et al in 1994.\textsuperscript{32} The advent of minimally invasive surgery has helped place laparoscopic
bariatric surgery at the forefront of general surgery. Complex procedures once performed with large incisions are being performed with equal safety and efficacy. Patients benefit from minimally invasive RNYGB due to decreased post-operative pain, a decrease in the frequency of iatrogenic splenectomies, fewer wound complications, shorter hospital lengths of stay, and an overall decrease in mortality.

Laparoscopic adjustable banding was approved for use by the Food and Drug Administration in 1991. Analogous to VBG, this is a restrictive procedure which involves placement of an inflatable silastic cuff around the upper portion of the stomach.

**CURRENT BARIATRIC SURGERY PROCEDURES RECOMMENDED BY INTERNATIONAL PEDIATRIC ENDOSURGERY GROUP (IPEG)**

**Roux-Y Gastric Bypass**

This procedure has a good weight loss effectiveness and low complication profile, hence is considered as a “gold standard” to which all other procedures are compared. This procedure is favored in US centers. The operation has been performed both laparoscopic and open; the overall technique is the same. Mason, of the University of Iowa, developed gastric bypass and Ito (1967) first developed the gastric bypass with loop gastrojejunostomy. Subsequently, he modified the procedure by creating the gastric bypass with lesser curve pouch of 50 ml. or less, a gastro-enterostomy stoma of 0.9 mm and Roux-en-Y technique to avoid loop gastroenterostomy and the bile reflux which may ensue (Fig. 119.2).

Gastric bypass has stood the test of time, with one series of greater than 500 cases, followed for 14 years, maintaining 50% excess weight loss. The most common form of gastric bypass surgery is Roux-en-Y gastric bypass surgery. Here, a small stomach pouch is created with a stapler device, and connected to the distal small intestine. The upper part of the small intestine is then reattached in a Y-shaped configuration.

The gastric bypass is the most commonly performed operation for weight loss in the United States. In the US, approximately 140,000 gastric bypass have been performed for almost 50 years, the gastric bypass has become the “gold standard” operation for weight loss in the US. An emerging factor in the success of gastric bypass surgery is following an established gastric bypass diet after surgery. Complications of gastric bypass are much less severe than those of intestinal bypass. The most serious acute complications include leaks at the junction of stomach and small intestine.

A comparison of complications between the laparoscopic and open Roux-en-y gastric bypass procedure has been outlined in Table 119.4. Brolin et al compared selected series of laparoscopic Roux-en-y gastric bypass procedure (Table 119.5).

More recently, Capella and Capella reported a staple-line disruption rate of 22% in patients whose stomachs were stapled in-continuity using the TA90B and a reduction in that rate to 2% when the stomach was divided between two applications of that stapler. They recommend interposing a limb of jejunum as a

A study was performed by Nguyen et al on 155 patients. They performed a prospective randomized trial to compare outcomes, quality of life, and costs of laparoscopic vs open RNYGB. The table compares open vs laparoscopic major complications.

Various bariatric surgery procedures described. Here we will describe those commonly used for children and adolescents.
serosal patch, and report no further occurrence of staple-line leaks. They advocate this modification of gastric bypass as the procedure of choice for treating morbid obesity with lowest rate of major complications.

Gastric bypass results in consistently greater sustained weight loss than from gastroplasty or gastric banding by altering resting energy expenditure, avoiding the observed reduction in resting energy expenditure usually found in persons restricting their dietary Intake.

Iron deficiency develops after gastric bypass for several reasons including intolerance for red meat, diminished gastric acid secretion, and exclusion of the duodenum from the alimentary tract. Menstruating women, pregnant women, and adolescents may be particularly predisposed toward developing iron deficiency and microcytic anemias after bypass surgery.24

Adjustable Gastric Banding

A constricting ring is applied completely around the fundus of the stomach, creating an hour-glass effect (Fig. 119.5). The ring has to be placed near the upper end of the stomach, just below the junction of stomach and esophagus. The silicone band can be adjusted by addition or removal of saline through a port placed just under the skin. This procedure can be performed laparoscopically, and is commonly called a “lap band.”

An inflatable band connected to a small reservoir which is placed under the skin of the abdomen, through which the balloon can be inflated, thus reducing the size of the stoma, or deflated thus enlarging the stoma, has been described. Laparoscopic models have been developed that are associated with a short length of stay and a low frequency of complications. Since the hour glass configuration only constricts the upper stomach, with no malabsorptive effect, it acts as a pure restrictive operation. The favorable points are absence of anemia, dumping and malabsorption, while the disadvantages include the need for strict patient compliance. The Lap Band is freely available in the USA, been approved for use by the FDA. Laparoscopic adjustable gastric banding has been considered a procedure of choice for adolescent morbid obesity.41

When the Band is placed the balloon is empty, providing slight restriction to eating. Over the months following surgery, the balloon within the Band is gradually filled (outlet is tightened) to provide progressively increasing restriction matched to each patient, the balloon adjustment is accomplished using the access port (which is buried under the skin) to increase or decrease the amount of saline fluid contained in the balloon.
Advantages

1. Reduced the risk of surgery, especially important in obese patients.
2. There is no risk of leak or obstruction of the intestines.
3. Silastic substance even if it gets eroded has no tissue reaction.
4. The procedure is reversible.
5. The Lap Band aims to create slower and steadier weight loss. Lap Band patients begin with a relatively loose Band that allows ongoing intake of nutrition, and the Band is gradually “tightened” according to the patient’s weight progress and satiety symptoms. This approach aims to achieve a weight loss of 1-2 pounds per week, that continues up to or beyond 24 months after surgery.

Disadvantages

1. The band can get eroded into the stomach, become infected, or slip out of position.
2. Some patients have reported painful swallowing; reflux, or regurgitation. This may result from tightening the band too aggressively, and band deflation or removal is required.

Mean excess weight loss was 42% at 6 months and 60% at 1 year follow-up in a series with Lap Band in pediatric patients. Patients are advised that weight loss is slower than that reported with RNYGB (47.5% vs. 61.6%, respectively). Complications of band erosion and slippage have been reduced with improved techniques in band placement. Gastric banding in adolescents has been reported as a safe, satisfactory and reversible weight reduction procedure with a mean preoperative BMI of 43 (35-61) kg/m² and mean postoperative BMI after 39.5 months follow-up as 30 (20-39) kg/m².

Surgical Risks of Laparoscopic and Open Procedures

The risk of maintaining oneself in a morbidly obese state carries a high morbidity and mortality. This risk needs to be weighed against the risks of bariatric surgery which is a major operation whether performed laparoscopically or open. Those individuals who are at prohibitive risk for surgery in general are not candidates for weight loss surgery.

The overall morbidity resulting from bariatric surgery is reported as being in between 9.6-10%. The resultant mortality has been reported as being between 0.1-1.5%. Risks are stratified into those occurring early (within 24-48 hours) and those occurring late (after 48 hours). Improved outcomes are realized in the setting of qualified and experienced bariatric surgeons in conjunction with a qualified bariatric team composed of experienced surgeons, dieticians, exercise physiologists, mental health professionals and other support personnel.

OUTCOME

No matter what therapy is chosen, the patient must be aware that success may depend on adherence and long-term follow-up. Careful, lifelong medical supervision of adolescent patients who undergo a bariatric procedures will help in improving the outcome. Although there are numerous dietary guidelines for bariatric patients, most importantly, patients must consume 60-70 g of lean protein per day following operation. Supplementation of multivitamins, calcium, vitamin B₁₂, and iron in menstruating females must be provided after gastric bypass and to a lesser extent after banding. Ranitidine and ursodiol is also recommended for six months after surgery.

The malabsorptive procedures lead to more weight loss than the restrictive procedures. A meta-analysis from UCLA reports the following weight loss at 36 months: Biliopancreatic diversion - 53 kg, Roux-en-Y gastric bypass (RYGB) - 41 kg, Open - 42 kg, laparoscopic - 38 kg, Adjustable gastric banding - 35 kg and Vertical banded gastroplasty - 32 kg in adults.

Several recent studies report decrease in mortality and severity of medical conditions after bariatric surgery.

Complications from weight loss surgery are frequent including gastric dumping syndrome in about 20% (bloatedness and diarrhoea after eating, necessitating small meals or medication), leaks at the surgical site (12%), incisional hernia (7%), infections (6%) and pneumonia (4%). Mortality is low (0.2%).

EMERGING PROCEDURES AND FUTURE RESEARCH

A variation of the biliopancreatic diversion includes Duodenal switch. The part of the stomach along its
graeture curve is resected. The stomach is “tubulized” with a residual volume of about 150 ml. This volume reduction provides the food intake restriction component of this operation. This type of gastric resection is anatomically and functionally irreversible. In 2003 a two stage BPD-DS was described consisting of laparoscopic sleeve gastrectomy as stage one of the procedure. There is increasing interest in this procedure among Pediatric Surgeons, but one should understand that currently, Laparoscopic sleeve gastrectomy as a primary bariatric procedure is in its infancy because long term data are lacking. Randomized controlled trials are necessary to determine the outcomes and appropriateness of laparoscopic sleeve gastrectomy as a primary obesity operation.

Because of the evergrowing obesity epidemic, there is an increasing demand of procedures and industry is funding to find some new natural orifice transluminal endoscopic surgery (NOTES) procedures like endoluminal suturing and stapling devices. Other endoscopically delivered prostheses could be used to endoluminally bypass the stomach and proximal small bowel to effectively reduce the amount of food intake and the amount of nutrients absorbed.

The work of Dr V Cigaina of exogenous gastric electrical stimulation, has led to many randomized controlled trials throughout the world using various types of electrical stimulators. To date these technologies have shown some promise, but the weight loss effectiveness seems significantly less potent than traditional bariatric procedures.

CONCLUSION

Bariatric surgery is one of several options for morbidly obese individuals seeking weight loss. Current data suggests marked improvement in co-morbidities from resultant weight loss. Although morbid obesity surgery is controversial in adolescents. Appropriate patient education includes dietary counseling, support group counseling, preoperative psychological, exercise and pulmonary evaluation, as well as, lifelong surgical follow-up. A well educated patient and established bariatric team is imperative for successful outcomes. The decision to undergo weight loss surgery should be made after consideration of all weight loss options and should involve patients, families, and clinicians.

Recent Advances
Molecular Genetics of Hirschsprung’s Disease

Paul KH Tam, Mercè Garcia-Barcelo

Understanding how genes and other DNA sequences function together and interact with proteins and environmental factors is paramount to the discovery of the pathways involved in normal processes and in disease pathogenesis. In this respect, the study of the molecular basis of Hirschsprung’s disease (HSCR) has made a marked contribution to the understanding of complex diseases which result from the interaction of two or more genes and/or gene-environment interactions.1

Hirschsprung’s disease (HSCR) is a developmental disorder characterized by the absence of ganglion cells in of the lower digestive tract. Aganglionosis is attributed to a disorder of the enteric nervous system (ENS) in which ganglion cells fail to innervate the lower gastrointestinal tract during embryonic development. There is significant racial variation in the incidence of the disease, and it is most often found among Asians (2.8 per 10,000 life births).2 HSCR has a complex pattern of inheritance and manifests with low, sex-dependent penetrance and variability in the length of the aganglionic segment. HSCR most commonly presents sporadically although it can be familial (approximately 20% of the cases) and is frequently associated with many other neurocristopathies and chromosomes abnormalities.3

The genetic complexity observed in HSCR can be conceptually understood in the light of the molecular and cellular events that take place during the ENS development in the embryonic stage. The ganglion cells of the fully developed ENS are derived from neural crest cells (NCCs) of the vagal, sacral and truncal regions of the neural tube.4 During the colonization process, the NCCs have to adapt to a constantly changing intestinal environment that strongly influences their differentiation into enteric neurons.5 The entire process is regulated by specific molecular signals from both within the neural crest and intestinal environment, and the success of the colonization of the gut depends on the synchronization and balance of the signaling network implicated.6 DNA alterations in the genes codifying for the signaling molecules may interfere with the colonization process, and consequently represent a primary etiology for HSCR or other neurocristopathies. Since the range of interactions during the ENS development is large, the HSCR phenotype is variable, and may result from single severe mutations in a major gene encoding a crucial molecule or from accumulation of less severe mutations in several genes. The existence of non-clinically affected individuals carrying mutations in major genes invokes a compensatory effect by other genes. HSCR has become a model for oligogenic and polygenic disorders in which the phenotypes and mode of transmission result from interactions between different genes.

CLINICAL PRESENTATION AND CLASSIFICATION

The clinical presentation of HSCR is well documented. About 80% of HSCR patients can be diagnosed within the first few months of life presenting the following symptoms: (1) bilious vomiting; (2) enterocolitis-associated diarrhea; (3) difficulties in bowel movements; (4) progressive abdominal distension, and; (5) failure to pass meconium within the first 24 hours of life. Some patients show symptoms later in infancy or in adulthood with severe constipation, progressive abdominal distension, malnutrition and failure to thrive.7
The intestinal tract of HSCR patients can be categorized into three portions starting from the internal anal sphincter to the proximal part of intestinal tract: (1) aganglionic segment (segment without intrinsic nerves); (2) hypoganglionic segment (characterized by the reduced number of enteric ganglia), and (3) ganglionic segment (segment with enough number of enteroanal ganglia). HSCR patients are classified according to the length of the aganglionic segment into: short segment HSCR (SS-HSCR) (~80% of HSCR cases) and long segment HSCR (LS-HSCR) (~20% of HSCR cases). The rectosigmoid region acts as the boundary between LS-HSCR and SS-HSCR. LS-HSCR is defined as aganglionic segment extending to or beyond the proximal sigmoid colon, whereas, the remaining cases are grouped as SS-HSCR.

Four other HSCR variants have also been reported: (1) total colonic aganglionosis (TCA) affecting the whole colon with or without the involvement of distal ileum; (2) total intestinal aganglionosis characterized by the absence of enteric ganglia in the whole bowel; (3) ultra short segment HSCR affecting the distal rectum below the pelvic floor and the anus, and (4) suspended HSCR, in which an aganglionic segment is proximal to the ganglionic part, however, the presence of this condition is still controversial.

**DIAGNOSIS**

A diluted small intestine or proximal colon with empty rectum may be visible on a plain X-ray radiograph. On barium enema radiographs, a transition zone may be identified which serves as a diagnostic indicator of HSCR, especially when other radiographic features (such as barium retention and mixing of stool and barium) are also taken in to account. Barium enema radiography can also serve as a tool to roughly define the length of aganglionic bowel in SS-HSCR (Jamieson et al., 2004). Anorectal manometry of HSCR patients shows the failure of internal anal sphincter relaxation upon rectal distension. Although contrast barium enema and anorectal manometry can help in HSCR diagnosis, there are drawbacks in these methods. It has been shown that the false-positive rate of HSCR diagnosis is high when using contrast barium enema, especially for LSA-HSCR cases and the anorectal manometry may not be reliable for <12 months infant as the normal rectoenteric reflex is not yet present and the relaxation of internal anal sphincter may be masked by the contraction of external anal sphincter. Therefore, full thickness rectal suction biopsy is a gold standard in HSCR diagnosis in most cases.

Rectal suction biopsy has high predictive value in HSCR diagnosis. The diagnosis can be confirmed by the absence of ganglion cells in myenteric plexus, the presence of hypertrophic nerve trunks and the elevated acetylcholinesterase (AChE) level in mucosa and submucosa.

**TREATMENT AND COMPLICATIONS**

The treatment of HSCR is surgical and pull-through operations (Swenson, Duhamel and Soave operations) are commonly used nowadays. The basic principle of the pull-through operation is to remove the aganglionic intestinal segment and connect the ganglionic segment at the anus. One-stage operation is possible only in newborns with SS-HSCR if the colon is not yet dilated and there is not enterocolitis. If the child has enterocolitis and/or dilated colon, a colostomy should be placed. The pull-through operation should only be performed when the child recovers.

Constipation, fecal incontinence, colonic rupture and Hirschsprung’s disease associated enterocolitis (HAEC) are the major complications, in which, HAEC is the most common cause of HSCR-associated mortality. However, complications only occur in about 10% of HSCR patients after surgery.

**THE GENETIC ETIOLOGY OF HIRSCHSPRUNG’S DISEASE**

In 1886, the Danish pediatrician Harald Hirschsprung (1830–1916), described the disease as a cause of constipation in early infancy due to congenital dilatation of the colon. But it was not till the 1940’s, when histological studies revealed absence of intramural ganglion cells of the myenteric and submucosa plexuses downstream the dilated colon (megacolon), that the primary pathology of the disease was discovered.

The development of a pull-through surgical procedure by Swenson and Bill in 1948, made a major contribution to our understanding of the disease. This innovative surgical technique enabled the disease to be treated with considerable success. The result was a far higher survival rate among patients, which
created the conditions for the discovery of the familial transmission of the disease and the determination of its genetic nature. Additional evidence for a role of genetic factors in the pathology of HSCR was indicated by (i) an increased risk of recurrence for sibs of affected individuals compared with the population at large; (ii) an unbalanced sex-ratio; (iii) the association of HSCR with other genetic diseases, including malformation syndromes and chromosomal anomalies; and (iv) the existence of several animal models of colonic aganglionosis showing specific mendelian modes of inheritance.

In the late 1980s, the locus for multiple endocrine neoplasia (MEN) was assigned to chromosome 10q11.2.14,15 The same locus was also identified as the cause of papillary thyroid carcinoma (PTC) and familiar medullary thyroid carcinoma (FMTC).16-19 The cooccurrence of HSCR with multiple endocrine neoplasia type 2 (MEN2) and the observation of a deletion comprising the MEN2 locus in some HSCR patients, prompted the search for a HSCR gene in that chromosomal region.20-21 Linkage analysis using chromosome 10 markers in HSCR families revealed a HSCR locus in the pericentromeric region of chromosome 10.22,23 The observation of a HSCR-phenotype in mice with disrupted RET gene and the detection of RET germline mutations in HSCR families lead to the recognition RET as the cause of HSCR, almost a century after Harald Hirschsprung first described the disease.24-26

Subsequent studies lead to the identification of several genes implicated in the HSCR phenotype. To date, mutations in nine different genes (RET, GDNF, NRTN, PHOX2B, EDNRB, EDN3, ECE1, SOX10, ZFHX1B, and KIAA1279) have been detected in individuals affected with either isolated or syndromic HSCR (Table 120.1).8-27 Most of these genes, genes encode protein members of important inter-related signaling pathways critical the development of enteric ganglia: the GDNF/RET receptor tyrosine kinase, the endothelin type B receptor and SOX10 mediated transcription. Nonetheless, RET is the major gene involved in all forms of HSCR, and its expression is critical for the normal development of the ENS.28,29 Interaction between those signaling pathways governing the development of the enteric nervous system could therefore alter the expression of RET and influence the manifestation of the HSCR phenotype.30-34 Similarly, yet unknown loci can modify RET expression and act as a disease promoting or suppressing genes. Common features to the mutations found in the HSCR genes are low and sex dependent penetrance (frequency of individuals carrying a mutation who develop disease as opposed to healthy carriers) and variable expression of the HSCR phenotype (variability in the length of the aganglionic segment and in the manifestation of associated anomalies). These characteristics are consistent with the expression of a HSCR gene subject to modification by other loci, perhaps as a result of cross-talk between signaling pathways.35-36 In addition, phenotypic/genotypic assessment of the disease has become more difficult since a subset of the observed mutations in HSCR genes is also associated with several additional anomalies (syndromic HSCR).

**RET RECEPTOR TYROSINE KINASE PATHWAY**

The RET protein functions as a receptor for the Glial cell line-Derived Neurotrophic Factor (GDNF) family. Receptor-ligand interactions are mediated by RET co-receptors (GDNF-family receptors-α, GFRα).37,38 Activation of the RET receptor by these neurotrophic factors is essential for the migration and differentiation of specific cell lineages of neural crest origin into enteric neurons.24,39,40 The correct development of the ENS therefore depends on the ability of these neurotrophic factors to activate RET, on the ability of the RET receptor to transduce the signal, and on the competence of the intracellular machinery to elaborate a response (Figs 120.1 and 120.2).
RET PROTO-ONCOGENE AND HSCR

RET, also known as RET proto-oncogene, is composed of 21 exons that encode the RET receptor tyrosine kinase protein, a cell-surface molecule that transduces signals. Germline mutations in RET are responsible for four unrelated disorders in humans, HSCR, MEN2A, MEN type 2B and medullary thyroid carcinoma (MTC). RET is a single-pass membrane protein with two main domains: extracellular (EC) and intracellular (IC). The extracellular domain contains a cadherin-like domain (CAD) and a large conserved cystein rich region (CYS). The IC domain contains a typical tyrosine kinase domain (TK) (Fig. 120.1). The RET protein presents three isoforms of 1114 (RET51), 1106 (RET 43) and 1072 (RET 9) amino acids respectively, with distinct biological roles.

Ligand and coreceptor complexes interact with the EC domain of two RET molecules inducing their homodimerization and tyrosine autophosphorylation. Once phosphorylated, the tyrosine residues (TK domain) serve as high affinity binding sites for various intracellular signaling proteins. Activating mutations in the RET gene cause MTC, MEN2A and MEN2B, whereas inactivating mutations lead to Hirschsprung’s disease. A large number of RET mutations have been reported in HSCR patients. In general, RET gene mutations affecting the RET EC domain alter the folding of the protein impairing its maturation. RET mutations affecting the RET TK domain abolish the kinase activity or interfere with the binding to intracellular signaling proteins. Mutations in exons 20 and 21 of RET may affect the specific isoforms of the RET protein and modify their differential roles in signaling. Mutations in any intron/exon boundary affecting the splicing consensus sequences can alter mRNA processing. Remarkably, silent mutations (i.e. the mutation does not result in an amino acid change in the protein) in any of the RET exons can also affect mRNA processing. Unlike in MEN2, RET mutations causing HSCR are, with a very few exceptions, scattered throughout the gene, affecting indiscriminately any part of the RET protein. However, many RET mutations have not been functionally tested and is very difficult to discern between truly deleterious substitutions and non-deleterious ones. A recent study based on the alignment of the human RET protein with 12 orthologous sequences provides an insight on the prediction of the effect of the RET mutations.

Mutations in the coding regions of RET and other HSCR genes (see below) only account for over 50% of the familial cases, and between 7 and 35% of the sporadic cases. Intriguingly, genetic-linkage analyses in HSCR families keep implicating the 10q11 chromosomal region (RET locus) even though no RET coding regions can be found. This, besides confirming the central role of RET in HSCR, also indicates that mutations in non-coding (regulatory)
regions RET remain to be found. Mutations in regulatory regions can alter the DNA binding sites of transcriptional regulators and reduce or abolish the expression of RET. In addition to RET mutations, a possible role in HSCR has been attributed to several single nucleotides polymorphisms (SNPs) of the RET gene since they have been found associated with the disease. Variant alleles of the RET coding-region polymorphisms are over-represented in HSCR sporadic patients. The current data indicates that
these RET specific SNPs, either singly or in combination (haplotypes), could act as modifiers by modulating the penetrance of mutations in other HSCR genes and possibly of those mutations in the RET gene itself.\textsuperscript{32,74,75} They might also act as low penetrance alleles conferring risk of or protection against disease, or be in linkage disequilibrium (LD) with a yet unidentified susceptibility locus located in the regulatory regions of the gene.\textsuperscript{76,77} This possibility has been corroborated by the identification of two polymorphisms in the proximal promoter region of RET and in intron 1 in LD with the coding region SNPs.\textsuperscript{78-83} In vitro functional analyses have demonstrated a direct effect of HSCR-associated SNPs on the RET expression although additional cis/trans regulatory element may also contribute to the manifestation of the phenotype. The promoter polymorphisms disrupt the binding site of the transcription factor NK2.1. This gene has also been considered as a HSCR candidate gene and 3 mutations with possible damaging effect in the protein have recently been identified.\textsuperscript{84}

Noteworthy, the overall frequencies of the HSCR-associated RET SNPs and haplotypes are significantly higher in Chinese, not only in patients but also in the general population, possibly explaining the higher incidence of HSCR in Asians when compared to Caucasians.\textsuperscript{2,83,85}

**GDNF Family Ligands and their Receptors (GDNF-family receptors-\(\alpha\), GFR\(\alpha\))**

The relevance of RET signaling pathway in the ENS development and the phenotypic similarities between RET, GDNF and GFR\(\alpha\)-1 knock-out mice, prompted an extensive mutation screening of the genes encoding the GDNF family of ligands -GDNF, Neurturin (NTN) artemin (ARTN) and persepin (PSPN)- and of the genes encoding their coreceptors (GFR-\(\alpha\)1-4) and adaptors.\textsuperscript{24,86-88} However, mutations in those genes have been identified in a very small number of patients and generally co-segregate with mutations in RET.\textsuperscript{89-93} None of the of mutations identified in the GDNF gene are likely \textit{per se} to cause HSCR, although it is thought they can contribute to disease via interaction with other susceptibility loci.\textsuperscript{94,95} Surprisingly, RET is virtually the only target of HSCR mutations in the RET signalling pathway. It is possible that homozygous mutations in the GDNF family of ligands were lethal, and that these ligands, particularly GDNF, may have other functions not mediated by RET, and therefore come under selective pressure against mutations.

**HSCR Genes Involved in the Transcriptional Regulation of RET**

Because of the key role played by RET in HSCR, mutations in genes known to be involved in the regulation of RET are likely to give rise to phenotypes involving aganglionosis. Not all the genes involved in the regulation process are known and the precise mechanisms of regulation involved also remain unclear. Further investigation on the molecules involved in the regulation of the RET gene is certain to shed more light to the mechanisms underlying HSCR.

**SOX10**

The SOX10 gene encodes a transcriptional regulator whose expression is essential for the development of cells in the neural crest cell lineage, including melanocytes and enteric neurons. During the development of the ENS, the SOX10 protein physically interacts and cooperates with another transcriptional regulator (PAX3) to activate transcription of RET.\textsuperscript{40,96,97} Importantly, SOX10 also interacts with EDNRB in mice.\textsuperscript{98,99}

The significance of the SOX10 gene in HSCR was revealed through the study of a mouse model of HSCR (\textit{Dom}) fortuitously generated at the Jackson Laboratory.\textsuperscript{100} The molecular defect in \textit{Dom} mice was a mutation in the SOX10 gene.\textsuperscript{101-104} Heterozygous \textit{Dom} mice presented with distal colonic aganglionosis and localized hypomelanosis of the skin and hair (features similar to those in Waardenburg’s syndrome), which indicated that neural crest-derived melanocytes and enteric neurons were affected in SOX10 mutants. \textit{Dom} homozygous mice were embryonic lethal.

In humans, heterozygous SOX10 mutations have been identified in patients with Waardenburg-Shah syndrome (WS4; HSCR type 2). Patients with WS4 display a combination of the features of Waardenburg’s syndrome (wide bridge of the nose, pigmentary abnormalities, and cochlear deafness) and Hirschsprung’s disease.\textsuperscript{101,105-111} SOX10 mutations also lead to Yemenite deaf-blind hypopigmentation syndrome and other myelin deficiencies.\textsuperscript{112} To date, no SOX10
mutations have been found in patients presenting aganglionosis as an isolated trait. SOX10 is therefore unlikely to be major gene in isolated HSCR. Interestingly, and despite the absence of genetic mutations, abnormal SOX10 gene expression can be observed in aganglionic intestine of isolate HSCR patients.\(^{111}\)

**PHOX2B**

The paired mesoderm homeobox 2B gene (PHOX2) encodes a transcription factor which is involved in the development of several noradrenergic neuron populations. In mice homozygous disruption of the PHOX2B gene results in absence enteric ganglia, a feature reminiscent of HSCR. Furthermore, there is no Ret expression in PHOX2B mutant embryos indicating that regulation of Ret by PHOX2B could account for the failure of the ENS to develop.\(^{113,114}\) All these observations make the PHOX2B a candidate gene for HSCR. Interestingly, a chromosomal alteration involving the deletion of the PHOX2B locus has been described in a patient with syndromic HSCR (developmental delay, severe hypotonia, facial dysmorphism, and short segment aganglionosis).\(^{115}\) This suggests that PHOX2B haploinsufficiency may predispose to HSCR. A SNP of the PHOX2B gene has been found to be associated with HSCR and importantly, the interaction between PHOX2B and RET HSCR-associated SNPs increase to susceptibility to HSCR.\(^{116,117}\)

PHOX2B represents the first gene for which germline mutations predispose to neuroblastoma and is the major locus for congenital central hypoventilation syndrome (CCHS, Ondine’s curse).\(^{118-121}\) In particular, 25–30\% of the CCHS patients are affected with aganglionosis (Haddad syndrome).\(^{122}\) Intriguingly, both neuroblastoma and CCHS are frequently associated with HSCR.\(^{8}\) Taken together these data support the contribution of PHOX2B to HSCR.

**ENDOTHELIN TYPE B RECEPTOR PATHWAY**

The endothelins are a family of three signaling peptides (EDN1, EDN2 and EDN3) that can act on two subtypes of G protein-coupled receptors, termed endothelin A and endothelin B receptors (EDNRA and EDNRB) (Fig. 120.2). The endothelins are synthesized as much larger proteins which are cleaved by the endothelin converting enzyme (ECE-1) to produce an active peptide. The human genes coding for these proteins are EDN1, EDN2, EDN3, EDNRA and EDNRB respectively.

The involvement of the endothelin type B receptor pathway in the pathology of HSCR was demonstrated when a targeted disruption of the mouse endothelin B receptor gene (EDNRB) resulted in an autosomal recessive phenotype with aganglionic megacolon and white spotting of the coat.\(^{123}\) A targeted disruption of the mouse endothelin 3 ligand (EDN3) gene produced a similar recessive phenotype of megacolon and white coat spotting.\(^{124}\) These findings indicated an essential role for the members of the EDNRB pathway in the development of two neural crest-derived cell lineages, enteric neurons and epidermal melanocytes. EDNRB signaling not only regulates migration of the ENS progenitors but can also modulate the response of NCCs to GDNF.\(^{5,33}\) This provides evidence of interaction between two different pathways implicated in the pathogenesis of HSCR.

**EDNRB Gene and HSCR**

The occurrence of multiple cases of both isolated HSCR and WS4 in an inbred old order mennonite community facilitated the mapping of another major HSCR susceptibility gene to the chromosomal region 13q22.\(^{125,126}\) The gene identified on 13q22 was the endothelin type B receptor (EDNRB) which had a mutation that resulted in the W276C amino acid change in the protein. In contrast to the recessive, fully penetrant defects of the rodent model, this human mutation was neither fully dominant not fully recessive. The homozygous W276C mutation (CC) was more penetrant than the heterozygous (WC), and that penetrance was sex dependent. Individuals homozygous (CC) presented with WS4 features, while those with the heterozygous mutation (WC) presented with isolated HSCR. Furthermore, some family members with no W279C mutation were clinically affected. This implied the presence of additional predisposing genes among this closely-related group. In fact, a genetic modifier of HSCR found among the group was mapped to chromosome 21q21.\(^{125}\) Subsequent EDNRB mutation analyses conducted on both isolated HSCR and WS4 patients revealed other EDNRB mutations with similar genetic behavior to W279C. Homozygous
EDNRB mutations were associated with WS4 and heterozygous mutations with isolated HSCR. Overall, EDNRB mutations account for 5% of the isolated HSCR phenotype. Functional analyses of EDNRB missense mutations showed impairment of the intracellular signaling. EDNRB mutations found this far, are mainly inherited from unaffected parents, and associated with short-segment aganglionosis.

**EDN3 and ECE1 Genes**

HSCR patients are being screened for mutations in the human EDN3 because of the HSCR-like phenotype presented by mice with disruption of the EDN3 gene. To the best of our knowledge, very few EDN3 mutations have been characterized in HSCR patients. With very few exceptions, heterozygous EDN3 mutations are associated with isolated HSCR and homozygous mutations with WS4. Another knock-out mouse model again provided evidence of the involvement of another member of the EDNRB pathway in HSCR. The gene encodes the endothelin converting enzyme (ECE1), which cleaves the large inactive endothelins into smaller 21 amino acids active endothelins. Mice carrying an ECE1 null mutation (no protein is synthesized) present with craniofacial and cardiac abnormalities, absence of melanocytes and absence of the enteric neurons in the distal gut. This phenotype is similar to that presented by mice with mutations in the genes encoding other members of the EDNRB pathway (EDN3 and EDNRB). To date, only one mutation in the ECE1 gene has been found and the patient was affected with syndromic HSCR.

**ZFHX1B (previously SIP1)**

The observation of a translocation involving the ZFHX1B locus (2q22) in a patient with HSCR disease, microcephaly, mental retardation, epilepsy and characteristic facial appearance, led to the first documentation of ZFHX1B involvement in this syndromic form of HSCR. Other chromosomal abnormalities involving 2q22 and mutations in the ZFHX1B gene are being described in patients with similar clinical features (recently named Mowat-Wilson syndrome) although not all of them present with aganglionosis. ZFHX1B encodes a transcriptional repressor (SIP1, Smad Interacting Protein 1), which interacts with several members of the Smad family. Some Smad proteins act as transducers in signaling cascades critical to embryogenesis. It is not yet known how mutations in ZFHX1B may result in defects of the ENS, although it is tempting to speculate on a possible functional link between SIP1 and the signaling pathways currently known to be essential for the ENS development. As in SOX10, no mutations have been found in patients with isolated HSCR, and therefore ZFHX1B is unlikely to be major gene in non-syndromic HSCR.

**KIAA1279**

By homoygosity mapping, a novel locus on 10q21.3-q22.1 for Goldberg-Shprintzen syndrome (GOSHS) was identified in an inbred family. Phenotypic features of GOSHS in this inbred family included microcephaly, polymicrogyria and mental retardation, as well as HSCR. Homozygous nonsense mutations were identified in the KIAA1279 gene at 10q22.1. This finding established the importance of KIAA1279 in both enteric and central nervous system development although the role of KIAA1279 is not yet understood. No mutations in this gene have been found in isolated HSCR patients.
MODIFYING GENES AND INTERACTION BETWEEN SIGNALING PATHWAYS

It has already been stressed that the successful colonization of the gut by the ENS precursors depends on a coordinated and balanced network of interacting molecules (Fig. 120.2). Conceivably, there should be a functional and genetic link among these molecules for them to interact. The mechanisms underlying these interactions may help to explain the complexity of the HSCR phenotype and resolve puzzling genetic observations, e.g. that in some cases more than one mutated gene is needed to produce the phenotype, while (conversely) healthy individuals exist with mutations in HSCR genes. Interaction between pathways requires not only coordination among the pathway members but also with those molecules that mediate their interaction.

The RET and EDNRB signaling pathways were initially thought to be biochemically independent. However, the case of an HSCR patient with a weak mutation in both RET and EDNRB whose healthy parents were heterozygous for one mutation implies interaction between these two pathways. Some reports have also hinted the possibility of cross-talk between G-protein-coupled-receptors (EDNRB) and tyrosine kinase receptors (i.e. RET). The genetic interaction between mutations in RET and EDNRB in HSCR was verified in 2002 in an association study conducted on 43 Mennonite family trios segregating the W276C mutation in the EDNRB described above. The study demonstrated the joint transmission of both, the W276C mutation in EDNRB and HSCR-associated haplotypes in RET in affected individuals. The combination of these two genotypes increased the penetrance of the mutation and therefore the risk to disease. Genetic interaction between RET and EDNRB pathways has also been demonstrated in mice. The fact that two mutated genes are needed for the manifestation of the disease also implies functional interaction. EDN3 and GDNF seem to have a synergistic effect on the proliferation of the undifferentiated ENS progenitors and an antagonistic effect on the migration of differentiated enteric ganglia. It appears that EDN3 has a variable distribution along the developing gut with differential effects on processes regulated by the RET. It has been firmly established that the interaction between these signaling pathways controls ENS development throughout the intestine. However, both pathways have to be integrated by additional molecules or “mediators”. Protein kinase A has been suggested as a key component of the molecular mechanisms that mediate and link the RET and EDNRB signaling pathways. Also, in mice, SOX10 has been shown to act on both RET and EDNRB genes further linking these two signaling pathways. Additional investigation is needed to identify all molecules members of these pathways/networks. This means that genes involved in the development of the enteric nervous system still await discovery, and that DNA alterations in multiple genes have the potential to combine and hinder a phenotype. Obviously, defective functioning of these still unknown “mediators” could modify the outcome of the development of the ENS. RET and EDNRB are central to the genesis of HSCR but little is yet known of the influence of variation in multiple genes or genetic background. Unknown loci (that could encode protein members of the RET and EDNRB pathways) can modify RET expression and act as a disease promoting or suppressing genes (modifiers). Therefore, the poor genotype-phenotype correlation in HSCR is due to the effects of multiple genes combined, including HSCR known genes and still unknown loci. A linkage study conducted on 12 HSCR families enriched for L-HSCR demonstrated linkage to RET in all but one family. However, 6 out the 11 families linked to RET, also showed linkage to the 9q31 locus. Interestingly, no severe RET mutations were detected in those 6 families. It was concluded that these 6 families harbored “weak” RET DNA alterations and that the effect of the 9q31 locus was required to produce the phenotype. A genome-wide scan on 49 S-HSCR families detected linkage to three chromosomal regions, 10q12, 3p21 and 19q12. The 10q21 region corresponded to RET although causative RET mutations were present in only 40% of the linked families, again stressing the importance of variations in noncoding regions. Further analyses of the data demonstrated oligogenic inheritance of S-HSCR. The action of RET (10q12) and 3q21 and/or 19q12 seemed to be necessary and sufficient for the manifestation of S-HSCR. Since S-HSCR did not segregate in the absence of RET, the authors suggested that 3q21 and 19q12 loci are RET-dependent, therefore, modifiers of the RET expression. A recent study on the 3p21 chromosomal region narrowed down a HSCR-
associated region comprising three genes involved in neurological phenotypes. Follow-up studies on these genes are therefore warranted.\textsuperscript{151}

These studies emphasize the central role of RET in all forms of HSCR (short and long) and explained the non-mendelian inheritance of the disease. Also, they suggest that the genetics of long-segment Hirschsprung’s disease and short-segment Hirschsprung’s disease may depend on the effects of the different RET modifiers.

**OTHER HSCR CANDIDATE GENES**

Mouse models and syndromes associated with HSCR provide insights into the genes that may share a common signaling pathway involved in the development of the ENS and therefore in the pathogenesis of HSCR. It is therefore logical to study the possible contribution of these genes to HSCR. This can be illustrated by the example posed by the Indian Hedgehog Gene (IHH). The Hedgehog gene family encodes a group of secreted signaling molecules that are essential for growth and patterning of many different body parts of vertebrate and invertebrate embryos.\textsuperscript{152} In particular, IHH signaling controls growth of bones and is required for the proper development of the ENS and the intestinal stem cell proliferation and differentiation.\textsuperscript{153} IHH mutant mice present with dilated colon with abnormally thin wall, and enteric neurons missing from parts of the small intestine and from the dilated regions of the colon. This HSCR-like phenotype is observed with an incomplete penetrance of 50\%, which suggest that interaction with other factors will be required for full expression of the phenotype. These features are strikingly similar to those observed in HSCR patients. In humans, mutations in the IHH gene (2q33-35) are associated with congenital limbs malformations and other skeleton dysplasias some of which are also seen in some HSCR patients.\textsuperscript{3,154,155} Nevertheless, IHH mutation analysis in over 60 HSCR patients with no mutations in the HSCR genes described so far, reveal no coding region mutations that could account for the disease.\textsuperscript{156}

Similar results were obtained for the human L1CAM gene. This gene encodes the L1 cell adhesion molecule involved in the development of the nervous system.\textsuperscript{157} Mutations in L1CAM are linked to a recessive form of congenital hydrocephalus.\textsuperscript{158} The detection of L1CAM mutations in individuals with congenital hydrocephalus and HSCR and the fact that L1CAM maps to chromosome Xq28, (which could account for the higher penetrance of HSCR in males) encouraged the mutational screening of this gene in isolated HSCR patients.\textsuperscript{159-161} Although no coding region mutations were identified, it was hypothesized that L1CAM-mediated cell adhesion may be important for the ability of ganglion cell precursors to populate the gut, and that the L1CAM gene could modify the effects of a Hirschsprung’s disease-associated gene to cause intestinal aganglionosis.

Recently, using transgenic mouse technology, it has been shown that the transcription factor Hoxb5 may contribute to HSCR by interfering with the regulation of the RET gene. A fraction of HOXB5 mutant mice presented with reduction of ganglia (hypoganglionosis) and slow peristalsis and, occasionally, absence of ganglia. In addition Ret expression was markedly reduced or absent in neural crest cells and ganglia suggesting that HOXB5 may contribute to the etiology of Hirschsprung’s disease.\textsuperscript{162} In additional, HOXB5 SNPs were found associated to HSCR in humans. Taken altogether, these data also suggests a role for HOXB5 in HSCR.

Due to the current ambiguity regarding the role played by rare gene mutations it is important to perform exhaustive functional analysis in order to determine their association with the disease. Even so, the disease is likely to results from the combined effects of mutations or variants in many genes. The characterization of the gene network directing the development of the ENS may help in the identification of additional HSCR candidate genes. These genes may play a minor role in the expression of the disease, and they are likely to be modifiers of the already known HSCR major genes.

**GENETIC COUNSELING**

In isolated HSCR, a relatively precise recurrence risk tailored to individual families could be estimated based on the estimates provided by Badner.\textsuperscript{163} The highest recurrence risk is for a male sib of a female proband with L-HSCR.\textsuperscript{3} Nonetheless, the reduced penetrance of the HSCR mutations makes it difficult to rationally predict and assess the risk to disease. Genetic testing is only performed on a research basis, and due to the advances of the surgical management of HSCR, its utility is questionable.
As outlined earlier, mutations in the RET proto-oncogene are also the underlying cause of the inherited cancer syndromes MEN2A and MEN2B and FMTC. In HSCR patients, RET mutations are dispersed throughout the gene, while in MEN2A and FMTC patients, mutations are clustered in the cysteine codons of the RET extracellular domain (exons 10 and 11). Although HSCR and MEN2A are two different entities, occasionally they co-segregate in some families, and affected individuals carry a single mutations in exons 10 or 11. RET Importantly, mutations identical to those found in MEN2A have been detected in HSCR patients with no clinical symptoms of MEN2A.169,170 That means that some HSCR patients may be exposed to a highly increased risk of tumors. Where HSCR patients carry these tumor specific mutations, exploration of the family history of MEN2A and periodic screening for tumors is advisable. In families segregating both MEN2A and HSCR, RET gene testing, tumor screening, and prophylactic thyroidectomy is also warranted.

**FUTURE DIRECTIONS**

Although modern surgical procedures have already achieved a high success rate in the treatment of Hirschsprung’s disease (HSCR), a better understanding of the mechanisms involved in the pathogenesis of this disease should enable doctors to prevent and diagnose it more easily and treat it even more effectively.

The major breakthrough in the study of the pathogenesis of HSCR has been the demonstration of the genetic and functional interaction between the RET and EDNRB signaling pathways and their establishment as key players in the development of the ENS. These important findings should lead to the study of the complete gene network that makes the genesis of the ENS possible. Regarding HSCR gene-discovery, genome-wide association studies and whole-genome sequencing of DNA of HSCR patients are currently underway. The challenge is using this newly-available genomic information to elucidate normal gene function, and determine how DNA alterations cause disease in humans. For obvious reasons, conducting gene or protein expression analyses for the study of HSCR and other human diseases that result from gene dysfunction during development is not feasible. Mice can provide access to the study of human genes and proteins that have an equivalent in mice. Scientists are now resorting to the isolation individual mouse cell types by making use of stem cell research. This has allowed the study the specific requirements of the gut neural crest stem cells (NCSCs).33,171-172 A recent study has shown that Prokineticin-1 (Prok-1) can induce both proliferation and expression of differentiation markers of RET deficient mouse NCCs, suggesting that Prok-1 may provide a complementary pathway to GDNF/RET signaling during the ENS development. This indicates that Prok-1 crosstalks with GDNF/RET signaling and probably provides an additional layer of signaling refinement to maintain proliferation and differentiation of enteric NCCs.

If the behavior of the gut NCSCs is better understood, it may be possible to treat HSCR by transplanting NCSCs directly into the aganglionic gut. It will be intriguing to determine whether these NCSCs are able to mature and engraft in the forming gut and enhance bowel motility, and further research of this kind should yield new therapeutic approaches.

HISTORY

Bernard Duhamel first described his operation for Hirschsprung’s disease in 1956. This was described as a Modification of Swenson’s procedure. In the original procedure, a retrorectal approach was used, and a significant portion of the aganglionic rectum had to be left behind. The rationale for this operation was the ease of surgery, prevention of anastomotic leak and elimination of strictures. As no anterior rectal resection was involved sensory innervation was left undisturbed. The operative principle of this technique included minimal pelvic dissection, a wide but unsutured approximation (anastomosis) between aganglionic rectum and the pulled through ganglionic colon, a retrorectal approach, division of the internal anal sphincter and the preservation of anterior rectal wall.

Duhamel devised this operation with an intention to apply this procedure earlier in infancy. However, the retention of the rectal spur, development of a rectal pouch, continuance of constipation, fecoloma impaction and incontinence were reported as the significant complications. This was followed by several modifications of Duhamel’s procedure. Most of these modifications were centered around the elimination of the common wall of the rectal pouch “spur” and the effect of the stool filled blind rectal pouch (within the aganglionic rectal wall). Martin and Altemeier and Martin and Caudill described the technique to apply the clamps meticulously and eliminate the problem of rectal pouch completely. Over the years, the surgeons have used many instruments like Kocher’s forceps, crushing intestinal clamps and Lloyd-Davies crushing clamp to achieve the same purpose. A modification of heavy Kocher’s clamp was designed by Dr Irani and this has been in practice for nearly three decades. Dr Kittur designed a stainless steel clip having two prongs revetted at one end and free at the other. The free ends have a flange to accommodate a latex band when the two prongs are mated. The clip bears a pelvic curve and serrations to crush the opposing surfaces of the “spur”. Application of mechanical stapling device to the colorectal anastomosis and the simultaneous division of the common rectal was facilitated by Ikeda, Soper, Talbert and Ravitch. This is the most commonly adapted technique for Duhamel’s Pull through procedure these days and barring the cost of staplers, has several advantages including the convenience to the patient.

MANAGEMENT

The conventional management of Hirschsprung’s disease is staged. There are reports of primary one stage pull through Soave or modified Duhamel’s procedures without a diverting colostomy; still most of the centers worldwide confine themselves to a diverting colostomy as the first stage. Rectal biopsy confirms aganglionosis and a definitive pull through (modified Duhamel) is planned when the patient weighs 8-10 kg. The optimal age for the procedure is about 9-12 months.

With the help of a Proximate Linear Cutter device (TLC55), it is possible to perform the operation by the age of 6-7 months. Younger age does at times pose difficulty in accommodating Proximate Linear Cutter in the pelvis. Our preference of Duhamel’s procedure is due to its technical ease, less morbid complications and preservation of sensory nerves and receptors.
Duhamel’s Pull-through Using Staplers

along the anterior wall of rectum. The anterior pelvic extrarectal nerves to the bladder and ejaculatory mechanisms are also protected with the application of staplers, it is suggested that a definitive pull through can be done even without a diverting colostomy but in our series up till now, we have always employed a proximal diverting stoma.

The child is anesthetized with an endotracheal general anesthesia. An epidural regional block is given to ensure postoperative analgesia. The child is catheterized with a size 8 Fr or 10 Fr indwelling Foley catheter. Abdomen is opened through a left lower quadrant curvilinear incision. On opening of the peritoneum, multiple seromuscular biopsies are taken from the zones of lowermost left normal colon, zone of transition and the distal most dilated part of bowel (Fig. 121.1). The fold of peritoneum at the rectosigmoid junction is incised on either side and the rectum is mobilized. Ureters on both sides are identified and protected. The vascular supply to the aganglionic rectosigmoid is identified and divided. Anterior traction on the rectum allows an entry into retrorectal space. The space is explored by a blunt finger dissection and adequate tunnel is created to admit a retrorectal colon. This dissection is mostly carried down caudally and the finger is made to project in the posterior rectal wall at the anorectal junction. The proximal ganglionic colon is divided from the aganglionic intestine that will be resected later in the procedure. The mesenteric and the antimesenteric sides of colon are marked with different color stay sutures so that orientation can be secured at the time of pull-through.

Attention is now directed towards the abdomen. The vessels are ligated proximally towards the root of the mesentery; keeping the mesenteric arterial arcades intact. Usually ligation of two vessels gives adequate length and pliability for the ganglionic colon and mesentery to be pulled through the retrorectal space. The vascularity of the distal most part of ganglionic colon is ensured, by confirming the presence of pulsations through the mesenteric arcades and the peristalsis of the segment, before ligating and cutting the taught vessels towards the root on mesentery. It is also essential not to keep the bulky mesentery near the bowel to be pulled through, otherwise accommodating this bulk in the retrorectal space becomes difficult.

A finger is now reinserted into newly created retrorectal tunnel and made to project in the posterior anorectal junction 1 cm above the dentate line. An electrocautery makes an incision at this level and an intestinal clamp or a grasper is passed through this incision to catch the ganglionic colon readied for pull through. It is easier to take two silk stay sutures at both lateral ends of this incised posterior rectal wall so that this wall of the spur does not retract upwards.

The grasper forceps introduced through the rent in the posterior rectal wall, is pushed upwards in the retrorectal tunnel, the ganglionic colon ready for pull through is held by the forceps and pulled through. This colon now appears at the anal verge (Figs 121.2A and B).

Mesenteric and antimesenteric borders must again be oriented and mesentery must be made to lie at 6 o’clock position. Color of the mucous membrane and fresh bleeding is confirmed. Pulled bowel is sutured (vicryl/PDS) full thickness into the anal zone from 3 o’clock to 9 o’clock position posteriorly and secured to anocutaneous junction. Thus, the rectum and the anterior wall of normal colon come to lie in close apposition and thus form a septum. From the perineal end, two red rubber tubes are passed, one each into the upper aganglionic bowel and the lower ganglionic bowel lumen through the anal opening.

A 3 cm transverse incision is now made in the anterior wall to the pulled through colon at the level of rectosigmoid junction. Two stay sutures are taken to hold the posterior wall of aganglionic rectum and anterior wall of pulled through colon at this newly made transverse incision. This forms the upper part of the “spur” to be cut.

Fig. 121.1: Operative photograph depicting dilated bowel in Hirschprung’s disease.
The red rubber catheters introduced from the anal end are now recovered at the abdominal end from the colon and rectum at the level of the upper end of ‘spur’. Now a 55 mm Linear Cutter cartridge is chosen. Its orange colored staple retaining cap is removed and it is loaded on the cartridge half of TLC 55. Cartridge half of Proximate Linear Cutter is now railroaded with the red rubber tube in the posterior pulled through ganglionic colon (Fig. 121.3).

Anvil half is railroaded into anterior (upper) aganglionic rectum and inserted into the lumen. Both the halves are now made to project at the upper end; mated and the assembly is locked. The positioning of proximate linear cutter is now checked again to confirm that the spur now lies in between the mated and locked halves of the cutter. The firing knob is now pushed ahead towards the locking lever all along the locking rib and returned back to its original return position in one single, smooth uninterrupted movement (Fig. 121.4). This movement brings the cutter into action and the spur is divided. At the same time, the staples are also fired from the cartridge and two parallel rows of staples create a longitudinal 5.5 cm of anastomosis between the rectum and the pulled colon. If the spur is too long, the apex of the spur may remain uncut. This can be easily divided with the help of an electrocautery and a colorectal anastomosis achieved by hand sewing with multiple stitches.
interrupted 3-0/4-0 vicryl/PDS sutures. Alternatively
a second TCR 55 mm cartridge can be fired from
cranial end of spur to achieve cutting and suturing.

After the spur has been divided, the upper end
anastomosis is completed between the rectum and the
colotomy site at the rectosigmoid junction. This
completely renders two bowels into one lumen and
obviates the possibility of any residual rectal pouch.

A corrugated rubber drain is kept in the pelvis from
abdominal side. Routinely there is no need to keep a
retrorectal drain from the anal side. Seventy patients
ranging from 6 months to 10 years have undergone
this procedure during 1995-2002. The application of
the Proximate Linear Cutter stapler device not only
reduces the operation time but also ensures a stapled
longitudinal anastomosis between the rectum and the
pulled colon and provides an excellent hemostasis.
Also, there is no bulky crushing clamp application
which would otherwise stay in place for 5-7 days
postoperatively, causing lot of inconvenience to the
patient. Indwelling urinary catheter can be removed
on 2nd postoperative day and the patients legs need
not be tied together. The patient can therefore be
ambulated on the second day.

It takes about 6-7 days for the opposing wall to get
necrosed and natural adhesions to occur. We have
recently modified our technique by using an Endo-
Linear Cutter with a 45 mm length cartridge to crush
the spur from anal end in patients with 5-6 months of
age.

Patients who have internal diameter of rectum and
the colon, smaller than the thickness of the locked
assembly of Proximate Linear Cutter; we strongly
recommend the use of Endo-Linear Cutter device. It
is advisable neither to stretch nor to overdistend the
bowel by forcing in the locked assembly to cut the spur.

Morbidity and mortality was assessed in 70 patients
who had undergone modified Duhamel’s pull-through
with staplers. Episodes of enterocolitis were noted
before and after colostomy and also before and after
modified Duhamel’s definitive procedure. Other
complications noted included residual constipation,
abdominal distension, and soiling.

Frank fecal incontinence was not seen in our series.
Long-term problems of constipation, soiling and
incontinence have been emphasized by Duhamel,
Soave and Rehbein.11-19 The various reported results
for the Duhamel procedure are summarised in
Table 121.1.

The potentials for sub optimal outcome are often
associated with an anterior rectal pouch caused by a
colorectal spur. Application of a Proximate Linear
Cutter definitely reduces the percentage of sub optimal
outcome. Constipation may also result from outlet
obstruction caused by residual spasticity of the internal
sphincter. Some of these patients would settle down
with anal dilatation. Suggested explanations for sub
optimal outcome after operation for Hirschsprung’s
disease include associated neuronal intestinal
dysplasia significant neurological impairment and
enterocolitis.17,20,21

Rectal achalasia is yet another reason which leads
to increasing colonic inertia and ensuing symptoms
of severe constipation. Modified Duhamel pull-
through with staplers has also been employed in
treating strictures and acquired aganglionosis
following a Soave procedure.20 Modified Duhamel’s
operation with Endo-linear cutter has also been used

| Table 121.1: Outcome of Duhamel’s procedure
| in various studies |

mebooksfree.com
as a primary definitive procedure in neonate and young infants. 

**PRECAUTIONS WHILE STAPLING**

1. Never force the halves of the instrument.
2. Halves must be properly mated.
3. Locking assembly must be checked before firing.
4. The septum (spur) to be cut must be included entirely within the firing range.
5. Staples are not designed to control bleeding from mesenteric vessels.
6. Inspect completeness of ‘spur’ cutting before closure of abdominal part of colorectal anastomosis.

**PROBLEMS AND COMPLICATIONS OF STAPLERS**

Mishaps are inherent in the use of devices as they are in all other aspects of surgery.

1. Technical failures
   - Staples are not fired properly
   - Many of the staples do not get engaged
   - Stapler becomes locked, making their removal from the bowel difficult.
2. Staple-related bleeding.
3. Anastomotic leaks leading to pelvic abscess.

**REFERENCES**

Laparoscopy as a diagnostic tool for abdominal viscera was recommended as early as 1901 by Kelling.1 Almost 5 decades later, gynecologists were the first to use this technique. Laparoscopy was used as a diagnostic tool in the pediatric age group in the 1970s.2-4 With advances in imaging however, the interest in diagnostic laparoscopy faded. It was only with the introduction of therapeutic techniques like cholecystectomy that surgeons started to take interest in the procedure. Previously an exploratory laparotomy was undertaken for diagnosis when simple investigative techniques or procedures were not adequate. In today’s era, the indications for laparoscopy have remained the same as they were for laparotomy. A major advantage of laparoscopy however is that it therapeutic for most of its indications hence bringing about a significant reduction in the morbidity of the procedure.

INDICATIONS OF LAPAROSCOPY FOR ABDOMINAL PROBLEMS

- Acute abdominal pain
- Chronic abdominal pain
- Gastrointestinal bleeding
- Pathologies of the liver and biliary tree
- Oncology
- Trauma
- Ascites
- Determination of contralateral patent processus vaginalis in inguinal hernia
- Cryptorchidism
- Dysfunction of V-P Shunts or P-D catheters.

Laparoscopy in Acute Abdomen

Ruddock in 1937, described the use of laparoscopic surgery for acute abdomen. The benefits of the same were also described by Fahrlander (1969), Baderstock et al (1973), Frangenheim (1974) and Sugarbaker et al (1975).3,5-7 Acute abdominal symptoms can be secondary to inflammation, obstruction or strangulation.

Common Causes of Acute Abdomen
1. Constipation
2. Gastroenteritis
3. Acute appendicitis (Figs 122.1A and B)
4. Urinary tract infection.

Uncommon Causes of Acute Abdomen
1. Intussusception
2. Congenital obstruction
3. Adhesive obstruction
4. Strangulated inguinal hernia
5. Meckel’s diverticulitis
6. Torsion of ovarian cyst (Fig. 122.2)
7. Acute Cholecystitis and Cholelithiasis
8. Nephrolithiasis
9. Pneumonia
10. Pancreatitis
11. Retroperitoneal hematoma
12. Paitonites (Fig. 122.3).

With a good history, clinical examination, relevant imaging and laboratory investigations most of the above mentioned pathologies can be diagnosed without laparoscopy. Laparoscopy only comes into picture when a speedy diagnosis cannot be made otherwise but should be made.
Diagnostic Laparoscopy in Acute Abdominal Pain

Diagnostic laparoscopy is most important when the possibility of acute appendicitis is raised. The diagnosis is many times difficult in view of the doubtful history and clinical presentation. Laboratory investigations like total and differential leucocyte count and imaging like ultrasound are often not conclusive in early appendicitis. More so a thorough examination of the abdominal cavity is not possible in the event of finding a so called 'negative appendix' through the small McBurney’s incision. Judicious application of laparoscopy to patients with equivocal findings of appendicitis is helpful in reducing the negative appendicectomy rate and also the changes of missing a hidden but grave pathology. In a sick intensive care child or children with abdominal pain and severe underlying disease like diabetes mellitus, congenital or acquired immunopathy or nephrotic syndrome it may be sometimes difficult to put a finger on a single intra-abdominal pathology. Here too, diagnostic laparoscopy may play a vital role in excluding intra-abdominal disease. In children with colicky abdominal pain and a possible intestinal obstruction, a diagnostic laparoscopy helps to furnish a rapid and precise diagnosis. It can also be therapeutic in patients with congenital problems like internal herniation or volvulus around a vitello-intestinal duct remnant or acquired problems like adhesions from previous surgery.
Laparoscopy in Chronic Abdominal Pain

Laparoscopy is only one of the many diagnostic tools in children with chronic abdominal pain. At no means should laparoscopy replace a detailed history, careful clinical examination, selective additional imaging studies and laboratory investigations. The diagnostic yield of laparoscopy varies considerably from study to study. Leape and Ramenofsky (1977) in their initial series found no pathology in 11 out of 14 children. However, in their subsequent series in 1980, 16 of their 33 patients were diagnosed to have pathology on laparoscopy. Waldschmidt subjected almost 50% of his cases with chronic abdominal pain to laparoscopy and found pathology in more than 99% of them. Goldstein and Ozaksit et al found pathology in almost 90% of adolescent girls subjected to laparoscopy for chronic pelvic pain.

A major problem of laparoscopy for chronic abdominal pain remains the interpretation of so called pathological findings and the question whether the finding is really responsible for the pain should always be asked. The matter of chronic appendicitis should certainly be addressed (Fig. 122.4). Does this exist and if so, what is the incidence. In a series of 660 children in which an identifiable cause for the chronic abdominal pain was found at laparoscopy. Waldschmidt diagnosed so called chronic recurrent appendicitis in more than half of them. In contrast, in Utrecht, this diagnosis is hardly ever made. There is also the difficult matter of postoperative adhesions (Fig. 122.5). After any surgery, there are always adhesions. The question is whether these are responsible for pain and if so, does adhesiolysis prevent recurrence of adhesions and complains. Complete disappearance of the symptoms after treatment of the pathological findings is probably the best indicator of whether the pathology found was really responsible for the complains although there may be significant placebo effect from the laparoscopy itself. Leape reported that 18% were relieved of pain without any therapeutic action. Goldstein experienced recurrence of the complains in 25% of the adolescent girls after they had undergone laparoscopy.

Laparoscopy in Gastrointestinal Bleeding

In the event of unclear gastrointestinal bleeding, laparotomy used to be the last resort when other diagnostic tools like upper and lower GI Endoscopy, radioisotope study or angiography fail to identify the exact localization of the bleeding. Children who are hemodynamically stable should have a laparoscopy before a formal laparotomy as a few causative conditions like Meckel’s diverticulum, small bowel tumor, vascular malformation of the bowel wall, etc. can be diagnosed as well as treated laparoscopically (Fig. 122.6). In the event of a negative laparoscopy exteriorization of a bowel loop, subsequent enterotomy and introduction of a flexible scope can improve the diagnostic yield.
Laparoscopy in Pathologies of Liver and Biliary Tree

Neonatal Cholestasis

The diagnosis of a surgical cause is mandatory in any neonate who presents with conjugated hyperbilirubinemia. Surgically approachable cholestasis in the newborn or young infant include biliary atresia, choledochal cyst, inspissated bile syndrome (Fig. 122.7). In the event of dilated ducts, the diagnosis of extra hepatic biliary obstruction is easy. When the whole biliary tree is uniformly dilated with sludge in the gallbladder or bile ducts, the diagnosis of inspissated bile syndrome should be made. When the intra hepatic biliary tree is dilated, type 1 or 2 biliary atresia is present. In contrast, when neither the intra nor extra hepatic ducts are dilated, it is difficult to differentiate between type 3 biliary atresia and nonsurgical causes of cholestasis. In the year 1973, Gans and Bercy described laparoscopic cholangiography to differentiate between surgical approachable and medical causes of neonatal hyperbilirubinemia. Nuclear scans do not have a high sensitivity for biliary atresia or neonatal hepatitis. In this scenario, laparoscopic cholangiography plays an important role in diagnosing children with biliary atresia preventing unnecessary exploration in the other group (Fig. 122.8).

Liver Biopsy

Liver biopsy is often needed in the diagnostic work up of liver diseases. Ultrasound guided liver biopsy or percutaneous liver biopsies are normally taken. However, in the event of a localized disease where a specific area must be biopsied, a laparoscopic biopsy may offer a solution to the problem. Direct inspection of the liver in case of a suspected disease is an additional advantage (Figs 122.9 and 112.10). In the event of coagulation disturbances, a laparoscopic liver biopsy is helpful as bleeding from the biopsy site can be controlled at the same time.
Cholecystectomy

The overwhelming indication for laparoscopic cholecystectomy in children is the development of gallstones and related symptoms. Previously in many centers, it was reported that the majority of patients with gallstones developed them secondary to hemolysis. However, the trend towards non-hemolytic cholelithiasis seems to be increasing in recent years.

Laparoscopy in Oncology

The role of laparoscopy in pediatric oncology is still limited. At present, it is not included in the pediatric oncology protocols except for the Hodgkin’s study HD96 in the German speaking countries.

Lymphomas

There are several reports on laparoscopic staging of Hodgkin’s and non-Hodgkin’s lymphoma (Figs 122.11 and 122.12). Laparoscopy allows sampling of the lymph nodes and liver biopsy along with oophropexy in preparation for radiotherapy.

Other Malignancies

Laparoscopy is an ideal tool when a biopsy is essential before therapy is started or when residual or recurrent
disease is suspected (Fig. 122.13). Holcomb et al (1995), reported on 60 laparoscopies in children for oncology purposes.\(^\text{19}\) Laparoscopy can also be used for cannulation of vessels for regional chemotherapy and for the insertion of thermal or laser probes into tumors and metastasis.

However, as for open surgery, laparoscopic biopsy also upstages the tumor. Tumor implants at the site of laparoscopy have been reported in the sampling of both solid tumors and lymphomas.\(^\text{20}\) Whole lymph nodes should be taken as far as possible to prevent metastasis. Specimen should be removed in a recipient bag.

**Laparoscopy in Trauma**

Assessment of blunt abdominal injury may be very difficult in children and especially in the event of polytrauma. Associated head injuries compromises consciousness making interpretation of the clinical picture difficult. The decision to open the abdomen is easy in the event of a penetrating trauma. To decrease the number of negative laparotomies in blunt trauma Root et al 1965, advocated diagnostic peritoneal lavage. However, this may have its own disadvantages.\(^\text{21}\) In the early 1970’s Heselson introduced diagnostic laparoscopy to evaluate abdominal trauma. However, this did not gain popularity.\(^\text{22}\) Leape and Ramenofsky in 1977 and Austin and Gans in 1983, wrote about the role of diagnostic laparoscopy in the traumatized child.\(^\text{8,23}\) The rapidly improving new imaging methods such as ultrasound and CT Scan in contrast to the then amateur technique like laparoscopy did not contribute to its use. However, due to technical improvements, a renewed interest in the use of laparoscopy in trauma has emerged. One must be cautious in laparoscopy in children with head injury as pneumoperitoneum increases the intracranial pressure. The key for success of laparoscopy in trauma is a stable patient, good equipment and an experienced surgeon.

**Diagnostic Laparoscopy in Trauma**

**In Blunt Abdominal Trauma:** In cases of multiple injuries, decreased consciousness, persisting equivocal abdominal signs, diagnostic laparoscopy can help exclude an unstable abdominal injury such as bleeding liver injury, mesenteric tear and splenic laceration. A negative laparotomy in such circumstances unnecessarily adds morbidity in the already compromised child.\(^\text{24}\) Laparoscopy however still lacks wide popularity in the diagnosis of blunt abdominal trauma.

**In Penetrating Trauma:** Laparoscopy is an excellent diagnostic tool in looking for violation of peritoneum, diaphragmatic injuries in the case of penetrating trauma. Not every stab wound penetrates the abdominal wall or causes injury to the intra-abdominal viscera. Laparoscopy can help identify whether the peritoneum has been penetrated.\(^\text{24,25}\)

**Laparoscopy in Ascites**

Ascites in children as it is in adults may be hepatic, renal, cardiac, pancreatic, gastrointestinal, infectious, neoplastic or gynecological. It could also be secondary to a congenital or acquired lymphatic cause. Laparoscopy is rarely indicated in children with ascites (Fig. 122.14). An exception may be lymphatic or cystic ascites where laparoscopy may be able to detect or even treat the leak. Intestinal lymphangiectasia can be very well diagnosed laparoscopically.\(^\text{26}\)

**Laparoscopy in Determination of Contralateral Patent Processus Vaginales**

In recent years few topics have raised as much controversy across the world as has the role of laparoscopy in the treatment of children with inguinal hernia (Fig. 122.15). A very high number of North
American Pediatric Surgeons routinely explore the contralateral groin when operating children below the age of 2 years with inguinal hernias (Fig. 122.16). The reported incidence of contralateral patency is about 40%. However, the incidence of later development of a symptomatic hernia after unilateral hernia repair is only 10-20%. Studies need to be carried out to laparoscopically evaluate the characteristics of the contralateral ring in children undergoing surgery for inguinal hernia. This can help us predict which of these children have a high incidence of developing a contralateral hernia in the future.

**Laparoscopy in Cryptorchidism**

Cryptorchidism is one of the most frequent anomalies where laparoscopy has been used in today’s pediatric practice. Testicular maldescent is not a uniform disorder but rather a spectrum of clinical situations in which it may not be possible to define the exact etiology, pathogenesis, prognosis and appropriate treatment in a single case. The aim however is to relocate the cryptorchid testis in the scrotum before onset of parenchymal damage. Early orchidopexy seems to reduce the risk of future infertility and also makes self examination and early pick up malignancy possible. It is generally believed that success after orchidopexy is related to the preoperative testicular position. Impalpable testis falls into one of the five categories:

1. Absent gonad as a consequence of intrauterine torsion in the abdomen or in the inguinal canal (vanishing testis) or because of agenesis (rare).
2. Gonad present, but dysgenetic.
3. Normal testis present in the abdomen close to the internal ring and free to be mobilized into the inguinal canal (peeping testis).
4. Low abdominal testis.
5. High intra-abdominal testis.

Shah and Shah (1996) and Hrebinko and Bellinger (1993), studied children with undescended testis and found imaging studies to have a limited role in the pre-surgical evaluation of children with impalpable testes.
advocated for almost two decades. Combination blockage, obstruction and perforation has been related to the ventriculoperitoneal shunt like infection, use of laparoscopy for intra-abdominal complications when both are inserted under endoscopic control. The end of the shunt predisposes to complications than blind placement of either the ventricular or peritoneal V-Laparoscopy in Dysfunction of V-P Shunts and P-D Catheters

Blind placement of either the ventricular or peritoneal end of the shunt predisposes to complications than when both are inserted under endoscopic control. The use of laparoscopy for intra-abdominal complications related to the ventriculoperitoneal shunt like infection, blockage, obstruction and perforation has been advocated for almost two decades. Combination of neuroendoscopy with laparoscopy optimizes the placement of ventriculoperitoneal shunts and undoubtedly reduces complications related to shunt revisions by diminishing the incidence of distal obstruction. Moreover, the infection rate may further decline by using this almost no touch technique.

Laparoscopy has also shown to have a reliable role in the placement of peritoneal dialysis catheters in children. It provides a better catheter survival and trouble free dialysis in many series. The technique also allows a simultaneous partial to near total omentectomy which is crucial in preventing postoperative catheter occlusion. The approach also allows a clear inspection and prophylactic ligation of patent processus vaginalis to avoid hernia formation after commencement of peritoneal dialysis.

REFERENCES

The development of surgery knows number of “jumps” in its history; the last of which has been associated with progress of technology at the end of Twentieth century that gave us ability to perform traditional surgical manipulation through small incisions.

Laparoscopy that knows from early 80th has received fast progress with development of fiber optic technology and manufacturers of surgical instruments. Appendectomy is the most common intra-abdominal operation in western countries. There are three approaches to perform this operation: open, laparoscopic, and in the last a few years the one port laparoscopically assisted appendectomy that has become more and more popular. Each of these approaches has its own advantages and disadvantages.

The traditional open approach is safe, cheap and fast; however, it has a higher morbidity, late complications (like bowel obstruction due to intra-abdominal adhesions) and worse cosmetic results. Although an experienced surgeon can perform an appendectomy through a small incision, the scar grows with the child, and in the future, this can cause an aesthetic problem. This fact may be very important in young girls and adolescents.

The laparoscopic approach has been widely adopted for this operation for its ability to reduce morbidity and hospital stay and obtain good cosmetic results. This technique requires special technical skills, is more expensive and leaves three scars. A new approach combines the benefits of both techniques: the appendix is extracted from the abdominal cavity by an operating laparoscope through one intra-umbilical incision, after which the operation is completed in the traditional open manner.

Catheterization of bladder before the surgery is unnecessary, if the child has urinated recently. We use the operating laparoscope with long grasper (Fig. 123.1). Fig. 123.2: The site of the incision for entry of the port is the umbilicus

The operation is performed under general anesthesia. The patient is placed in a supine position with slight
left tilt. The pneumo-peritoneum is achieved by a 10 mm semi-lunar intraumbilical incision (Fig. 123.2) through which a Veres needle is placed (Fig. 123.3). A 10 mm trocar is inserted and an operating laparoscope is introduced (Fig. 123.4). The appendix is identified, grasped and removed through the intraumbilical incision (Fig. 123.5). The trocar is removed, and the operation is completed in the traditional open manner (Figs 123.6 to 123.9). Before the closure of fascia (Fig. 123.10) we put the trocar and laparoscope back for hemorrhage control, suction and wash out under direct vision. The skin is closed with an intradermal suture (Fig. 123.11).
Although the operation is simple and safe, not all the appendices can be managed by this manner. Short mesentery of the appendix may require insertion of additional 5 mm port for release of it. In case of extremely necrotizing appendix, when even slight traction can cause detachment of the appendix from its basis we advice not to hesitate convert this operation to open procedure. Additional reason for conversion is retrocaecal and/or subserotic localization, when appendix is not visualized. In some cases mobilization and removal of appendices through intraumbilical incision are difficult because of extremely short length or fixed caecum; if attempts to release the caecum are unsuccessful, the open procedure seems to be the best solution of this problem.

**EXPERIENCE AT KAPLAN MEDICAL CENTER (JAN. 2006-MARCH 2007)**

During the last 14 months, 106 appendectomies were performed in 61 boys and 45 girls. There were 14 normal, 65 phlegmonous, 9 gangrenous and 18 perforated appendices (Table 123.1).

We operated on 67 children with acute appendicitis through one umbilical port (Group 3). Records of 33 (Group 1) and 6 children (Group 2), who underwent open and laparoscopic appendectomy respectively, were also evaluated (Table 123.2). Observations were made regarding intra- and postoperative complications, postoperative analgesic requirement, and postoperative hospital stay.
One port trans-umbilical laparoscopically assisted appendectomies were completed in 61 children; in 2 cases an additional 5 mm port was placed for release of the mesentery. Conversion to an open procedure was necessary in 4 cases: one of which had a very short appendix and fixed cecum, and the remaining three were retrocecal. In all of the retrocecal cases, the appendices were not visualized by the laparoscope (Table 123.2).

There were no intraoperative complications. The postoperative analgesic requirement was similar in all three groups.

Intra-abdominal collection that resolved after antibiotic treatment and wound infection were in groups 1 and 3 (Table 123.3).

There were no differences in postoperative hospital stay between groups 1 and 3 after one port and open approaches for normal, phlegmonous and gangrenous appendice. Recovery was almost twice as fast after one port laparoscopically assisted appendectomy for perforated appendicitis as compared with open appendectomy (Table 123.4), perhaps because of the ability to wash out sites which are difficult to access (like sub-hepatic and sub-phrenic areas) by an open procedure. Although recovery time was shorter with the one port group, this is not a randomized trial and therefore our conclusions must be confirmed (or refuted) by further research.

**SUMMARY**

Though a learning curve does exist in all cases of laparoscopy, in this method the curve was very short. The indisputable benefit of one port laparoscopically assisted appendectomy is cosmetic: the scar after intra-umbilical 1.0 cm incision is absolutely invisible after couple of weeks.
The one port laparoscopically assisted appendectomy is easy to perform, as one becomes familiar with the equipment and technique.

The procedure is safe and the postoperative course and cosmetic results are excellent.

One port trans-umbilical laparoscopically assisted appendectomy is a simple method that combines the advantages of minimally invasive surgery with the safe classical approach.

REFERENCES

The introduction of laparoscopic techniques in the 1980s revolutionized surgery. It provided significant benefits for the patient (e.g. improved cosmetic effect, reduced postoperative pain, quicker recovery) and the health care system (e.g. quicker recovery times, shorter inpatient stay, earlier return to normal activity). However, with conventional endoscopic instrumentation, there are substantial difficulties. Loss of wrist articulation, poor touch feedback, the fulcrum effect, loss of 3-dimensional vision, and poor ergonomics of the tools mean that only relatively simple procedures are truly widespread. The promise of robotic assistance is to eliminate many of these impediments, with the concurrent enhancements of motion scaling and tremor filtration. It was suggested that laparoscopic surgery is a "transitional" technology leading to robotic surgery. The surgeon may now remotely teleoperate a robot in a comfortable, dexterous, and intuitive manner.

HISTORY OF ROBOTIC SURGERY

The word robot is derived from the Czech word robota, meaning “forced labor”. Use of this term gained popularity after Karel Capek’s play Rossum’s Universal Robots in 1921, where a scientist discovers the secret of creating humanlike machines which later dominate the human race and threaten it with extinction. Since then, robots have taken on increasingly more importance in both imagination and reality. It has evolved in meaning from dumb machines that perform menial, repetitive tasks to the highly intelligent anthropomorphic robots of popular culture.

The history of robotics in surgery begins with the Puma 560, a robot used in 1985 to perform neurosurgical biopsies with greater precision. Three years later, the Puma 560 was used to perform a transurethral resection of the prostate. The first surgical robot approved by the FDA was ROBODOC, a robotic system designed to machine the femur with greater precision in hip replacement surgeries.

This concept of telesurgery became one of the main driving forces behind the development of surgical robots. In the early 1990s, several of the scientists from the NASA-Ames team joined the Stanford Research Institute (SRI). Working with SRI’s other robotocists and virtual reality experts, these scientists developed a dexterous telemanipulator for hand surgery.

The US Army noticed the work on telesurgery, and it became interested in the possibility of decreasing wartime mortality by “bringing the surgeon to the wounded soldier-through telepresence.” With funding from the US Army, a system was devised whereby a wounded soldier could be loaded into a vehicle with robotic surgical equipment and be operated on remotely by a surgeon at a nearby Mobile Advanced Surgical Hospital (MASH). This system, it was hoped, would decrease wartime mortality by preventing wounded soldiers from exsanguinating before they reached the hospital. This system has been successfully demonstrated on animal models but has not yet been tested or implemented for actual battlefield casualty care.

Computer Motion, Inc. of Santa Barbara, CA, developed the Automated Endoscopic System for Optimal Positioning (AESOP), a robotic arm controlled by the surgeon voice commands to manipulate an
endoscopic camera. Shortly after AESOP was marketed, Integrated Surgical Systems (now Intuitive Surgical) of Mountain View, CA, licensed the SRI Green Telepresence Surgery System. This system underwent extensive redesign and was reintroduced as the da Vinci surgical system. Within a year, Computer Motion put the Zeus system into production.

**RATIONAL FOR ROBOTIC SURGERY**

The robotic surgical systems provide unique advantages (Table 124.1) when compared with conventional minimally access surgery: (1) the surgeon holds control of a stable camera-telescope platform, eliminating the dependence from a camera assistant. In addition, having the fourth arm will give the surgeon the ability to control more than two arms allowing them to become their own assistant, (2) the surgical field is presented to the surgeon in a 3-D display, (3) the robotic instruments have articulations near the tip that increase the degrees of freedom to function more like a human hand (Fig. 124.1); (4) the computer eliminates hand tremor and the scale of motion is programmable; and (5) the console provides a more ergonomic operating position for the surgeon. All together, these computer-enhanced functions add precision and dexterity to the MIS surgeon, particularly when performing microsurgical procedures. Further refinement of the computer motion enhancement has enabled the camera image to be synchronized with the beating of the heart in cardiac surgery, producing a virtual motionless cardiac image that allows coronary artery bypass surgery to be done without the need for cardiologic bypass.12

Surgeons using robotic technology experience these benefits that indirectly extend to patients. They allow surgeons to offer minimally access surgery approaches to patients who would not have been considered for these approaches before robotic technology was available.13,14 For example, performing laparoscopic surgery on small children and infants is difficult because of the challenge in performing laparoscopic anastomoses in small area. Fallopian tube reanastomosis is another example of a procedure that is very difficult to perform laparoscopically that can be performed more easily using robotics. Robotic technology also is transforming the surgical arena indirectly by changing surgical approaches, equipment, and instrumentation for nonrobotic procedures.13 For example, robotics renewed manufacturers’ interest in improving traditional laparoscopic instruments.14 To ensure that the traditional laparoscopic approach is competitive with the robotic approach, manufacturers now are investing effort and money in developing truly innovative laparoscopic instrumentation.14

**TYPES OF ROBOTIC SYSTEMS**

A variety of classifications for different types of robots help to describe these heterogeneous devices. Robots

can be characterized as automated arms, mobile devices, mills, or telerobotic devices. Additionally, they can be active, semiactive, or passive. Active devices are totally programmable and carry out tasks independently. Semiactive devices and passive robotic devices translate movements from an operator’s or surgeon’s hands into powered or unpowered movements of the robot arms. Surgical robots in use or research today include both active mills and semiactive telerobotic devices.

Passive robots function to hold a fixture at a desired location through which the surgeon introduces an instrument into an area of difficult access. The first passive robot appeared in 1985; was “Puma 560” used to guide drills and needles for intracranial biopsies.8,9

Semiactive robots are devices that combine the capability of some autonomous function with other actions carried out by the surgeon. One example is LARS (Laparoscopic Assistant Robotic System, Johns Hopkins University and IBM).15,16 LARS is a robotic arm that has four degrees of freedom for positioning of video camera or retracting instruments and is fitted with sensors that monitor forces and torque. The arm is driven by the operator, but should the forces exceed the programmed safety thresholds (e.g. tissue resistance), the robot halts the motion until the operator corrects the position. The arm is mounted in a cart that is rolled to the side of the operating table. LARS has been used in experimental surgery only.

Synergistic robots are devices simultaneously powered by both the robot’s engine and the surgeon. This hybrid platform establishes a partnership between the skills and experience of the surgeon and the geometric accuracy of a tireless machine. ACROBOT (Active Constraint Robot, Imperial College, London, UK) is an example of a synergistic robot ACROBOT was designed to cut bone with maximum precision and safety in preparation for knee replacement.17 Another example of synergistic robot is the Steady Hand Robot (Johns Hopkins).18 The Steady Hand Robot is a device under development with the purpose of enhancing the ability of the human hand to perform micromanipulations.

Active surgical robots are powered devices that can function with significant independence from the surgeon. These robots carry the greatest safety concerns and have been developed for specific purposes as follow:

**CAMERA HOLDER ROBOTS**

Robots for camera holding were the first active robots to be developed for commercial use. AESOP (Automated Endoscopic System for Optimal Positioning, Computer Motion, Inc.) and EndoAssist (Armstrong Healthcare, Ltd.) are the better-known robotic camera holder systems around the world.19,20 AESOP was the first laparoscopic robot to gain approval by the US. Food and Drug Administration.

This system is composed of a control computer, a power system, and an articulated, electromechanical arm for holding and maneuvering the telescope (Fig. 124.2).19 The arm attaches to the operating table,
and its action can be controlled via foot pedals, hand controls, or a voice activation/recognition system. The voice activation platform has been the preferred technique. The arm provides 7 degrees of freedom and centers at the point where the telescope enters the patient (e.g. abdominal or chest cavity). AESOP has been used extensively to assist in urologic (e.g. nephrectomy, prostatectomy), gynecologic (e.g. hysterectomy), gastrointestinal (e.g. cholecystectomy, colectomy, Nissen fundoplication), and thoracic (e.g. internal mammary artery) videoscopic operations.

ENDOASSIST (Fig. 124.3) is another robot for camera holding that differs from AESOP in the commanding mechanism. EndoAssist is a head-mounted navigation system that allows the laparoscopic camera to follow the surgeon’s head movements by tracking a headband sensor. The robot is in active mode only when a foot switch is pressed by the surgeon. In active mode, any glance of the operator in one direction on the video monitor causes the camera to pan in the same direction (left/right, up/down, zoom in/out).

ORTHOPEDIC ROBOTS

One of the first active robots was designed for orthopedic surgery. Robodoc (Integrated Surgical Systems) has been developed for primary total hip replacement, revision hip replacement, and total knee replacement. Robodoc is a computer-controlled mechanical arm capable of 5 degrees of freedom and force sensing in all axes. The tip of the arm holds a rotary bone cutter. Robodoc functions in coordination with a preoperative planning station, Orthodoc (Integrated Surgical Systems). Orthodoc is a computer workstation that converts actual CT images of the patient to create a 3-D reconstruction of the joint to be replaced. Using computer modeling, the surgeon can choose the prosthesis (from a software library) with the best fit and can simulate the joint replacement (virtual surgery).

There are other computer-assisted robotic systems under development for different orthopedic applications that integrate image reconstruction and guidance; some examples include CASPAR, CRIGOS, and Loughborough manipulator.

NEUROSURGERY ROBOTS

Minerva is a powered neurosurgery robot that functions under the guidance of a dedicated CT imaging system. Specifically designed instruments loaded onto a rotary carrousel can carry out the entire operation without assistance from the surgeon. Minerva was developed at the University of Lausanne and has not been commercialized.

NeuroMate (Integrated Surgical Systems) is a computer-assisted, image-guided device for stereotactic procedures in neurosurgery. (NeuroMate also classifies as a semi-active robot).

PathFinder (Figs 124.4A and B) (Armstrong-Healthcare, Ltd.) is a powered, image-guided robot for accurate positioning of stereotactic instruments.

CyberKnife (Accuray) is an advanced system for stereotactic radiosurgery in neurosurgery. It can be used for any other parts of the body.

UROLOGY ROBOTS

Probot (Mechatronics in Medicine, Imperial College) is a powered, image-guided, computercontrolled robot for Transurethral Resection of the Prostate (TURP). The operation is completely performed by Probot under the supervision of the surgeon. The surgeon follows the progression of the procedure at the workstation and can adjust the cutting parameters or can stop the robot at any time.
The RCM robot (Remote Center of Motion, Brady Urological Institute, Johns Hopkins University) was initially developed for percutaneous access of the kidney (PAKY), the device also has been referred to as the PAKY-RCM robot.\textsuperscript{40,41} The low and flexible profile of the robot makes it compatible with CT scanners and C-arms in operating rooms.

**MASTER-SLAVE ROBOTS**

Master-slave robots are powered, computer-controlled devices that do not perform autonomous tasks but are completely governed by the surgeon, thus the term master-slave system where the surgeon is the “master” and the robot is the “slave”. The master surgeon is seated at a control console (Fig. 124.5), and the slave robotic arm is located at the surgical field over the patient (Figs 124.6 and 124.7). They are also called telemanipulators, implying that the master and the slave are separated from each other by a distance but communicate through data cables. At the console, the surgeon observes the surgical field on a video display and actuates his or her hands not on traditional surgical instruments but on mechanical transducers (masters or joysticks) (Figs 124.8 and 124.9). The surgeon’s motions are telecasted from the console to the robotic arms, which, in turn, manipulate instruments and the telescope (Figs 124.10 to 124.13).

components may vary, from a few meters (e.g. inside the same operating room) to several kilometers apart (e.g. transatlantic operation).42

**ROBOTIC PEDIATRIC SURGERY**

Compared with the adult-sized patient, the pediatric patient poses additional challenges, such as smaller operative fields and more delicate tissues.43 Pediatric surgeons are particularly interested in robotic surgery, because they apply minimally invasive techniques to a broader range of procedures than adult general surgeons, and because we would like to apply the benefits of this approach to complex procedures in smaller patients and even smaller anatomic areas. In the pediatric population, surgeons most often use some degree of visual magnification either in the form of standard loupes for open surgery or via a telescope.
Currently robots are used on children to perform most procedures that can be done using minimally access surgery, including, cholecystectomy (Fig. 124.15), splenectomy (Fig. 124.16), fundoplication (Figs 124.17 and 124.18), Kasai procedure, choledochal cyst excision, and Heller myotomy. At our own institution, between June 2002 and December 2006, we have used da Vinci robotic system to perform surgery on 115 patients ranging in age from 1 month to 19 years and in weight from 3 to 150 kg, including 34 Nissen fundoplications, 37 cholecystectomies, 25 gastric banding (Table 124.2, Figs 124.19 to 124.22), 5 imperforate anus, 5 splenectomies, 2 diaphragmatic hernia repairs (Morgagni), 2 Heller myotomies, 1 adrenalectomy, 2 interval appendectomy, and 2 liver cyst (one hydatid).

**Procedure overview**

**Recommended port placement**

- Camera port (12 mm) cannula in umbilicus
- Left instrument port (8 mm) right mid-clavicular line, one hand-breadth (10 cm) away from camera port; at the level of the umbilicus.
- Right instrument port (8 mm) left mid-clavicular line one hand-breadth (10 cm) away from camera port; one handbreadth above the level of the umbilicus
- Accessory ports (5 mm) patient’s left side; between camera port and left instrument port.

**Instrument requirements**

- 30° Endoscope, angled downward wide-angle camera head
- Cardiac forceps
- Cautery hook
- Round tip scissors
- Large needle driver
- Conventional laparoscopic suction/irrigation
- Conventional laparoscopic grasper

**Fig. 124.15:** Robotic cholecystectomy set-up
**Fig. 124.16:** Port placement in combined robotic cholecystectomy and splenectomy
(C = Cholecystectomy, S = Splenectomy, LA = left arm, RA = right arm, CA = camera arm, A1 = assistant port)

**Procedure overview**

**Recommended port placement**

- **Camera port (12 mm):**
  Cannula in umbilicus

- **Left instrument port (8 mm):**
  Right mid-clavicular line, 2-3 finger breadths below right costal margin; at least one hand-breath (~10 cm) separation from camera port

- **Right instrument port (8 mm):**
  2 finger breadths lateral to left mid-clavicular line; 2-3 finger breadths below left costal margin; at least one hand-breath (~10 cm) away from camera port

**Accessory ports (10 mm and 5 mm):**

- 10 mm port half way between camera port and right instrument port

- 5 mm port half way between camera port and left instrument port.

**Instrument requirements**

- 30° Endoscope, angled downward
- Wide-angle camera head
- Cardiac forceps
- Cautery hook
- Large needle drivers
- da Vinci™ ultrasonic shears
- Conventional laparoscopic tissue graspers
- Conventional laparoscopic suction / irrigation
- Conventional laparoscopic clip applier
- Liver retractor (optional)

**Fig. 124.17:** Robotic Nissen setup
Current technology is primarily used to facilitate thorascoscopic pediatric procedures on extracardiac lesions, such as ligation of a patent ductus arteriosus and division of vascular rings. Although some studies have reported intracardiac robotic surgery applications in adults, the current size of the robotic surgical systems available is a critical limitation in preventing their application in pediatric cardiac surgery patients. In the field of pediatric urology, robotic assistance is described for nephrectomies, pyeloplasties, and appendicovesicostomies. Lee and colleagues assessed the usefulness of robot-assisted laparoscopic pyeloplasty in children in a retrospective case-control study. As experience increased, operative times improved, and the investigators noted a shorter mean length of stay as
well as significantly less total narcotic requirements in the robotic group as compared with the traditional open procedure.

Recently, successful robot-assisted complex, technically challenging procedures, such as robot-assisted fetal surgery, has been reported in animal models in addition to performing an esophagostomy and myelomeningocele repair.60-67

**FUTURE DIRECTION IN ROBOTIC SURGERY**

Future directions in robotic surgery are directed to development in haptics, augmented reality, miniaturization, telesurgery and telementoring.

Robotic devices with more-streamlined platforms, smaller instrumentation, and remote telementoring will all likely be a reality in the foreseeable future. Current and previously marketed telerobotic devices lack haptic or sensory feedback. While this technology has been the source of a great deal of research and funding, with numerous patents having been granted, it has not been applied clinically.66 The potential to improve upon current technology by the addition of haptic feedback exists and will likely continue to be a source of additional research.

A major concern in robotic surgery is the cumbersome and unwieldy nature of robotic systems that require considerable space and additional time for setup. In the time-pressed operating room, compact functionality is highly desirable, and current robotic systems have yet to deliver in this regard.

A new concept that will add to the importance of robotic surgery is augmented reality (AR) which refers to the superimposition of 3D computerized reconstructed images onto a real patient’s images and video, in real time.69,70 This gives the surgeon a transparent visual anatomy of the internal structures or lesions through the overlying tissues. The source of the reconstructed images is often based on pre-operative CT or MRI images. These reconstructed images are then registered onto anatomic landmarks and tracked by the computer according to the surgeon’s dissection and camera movements. The images are displayed through either heads-up or headmounted displays. Most of the existing research on medical AR focused on neurosurgery, maxillofacial surgery or orthopedic surgery where bony landmarks provided constant reference points for image registration and tracking. Marescaux et al. recently demonstrated the use of AR in laparoscopic adrenalectomy although AR in general surgical and urological procedures are usually more challenging since the organs get deformed during surgical manipulation.71

Telesurgery refers to surgical procedures performed by a surgeon located at a remote location for setup.
from the operating room via a telecommunication line. Telementoring refers to surgical guidance by a surgeon located remotely from the operating room where the procedure is performed. These capabilities have the potential for applications in the battle and disaster areas as well as guidance of surgeons in a different state or country less facile in specific complex surgeries. The first telesurgery was a laparoscopic cholecystectomy performed by surgeons in New York on a 68-year-old patient in Strasbourg, France on September 7, 2001.42,72 Telementoring was shown to be feasible by surgeons in different continents between United States and Austria, Singapore and Thailand.73-75 The future of telesurgery is limited by the availability of high bandwidth communication lines and lag time, cost of technology, ethical and liability issues and possible conflicts of jurisdictions between countries involved.

Another expected future work will focus on the continued development of miniature robots and its integration in Natural Orifice Translumenal Endoscopic Surgery (NOTES).

REFERENCES

Medical or surgical procedures that have attempted to partially replace lost tissue, account for a large part of health care resources which exceed over $400 billion per year. Replace like tissue with like tissue is a basic principle of surgery. However, certain congenital, posttraumatic, postablative, or even multiply operated deformities may be so severe that autologous tissue does not exist in sufficient quantity, or is difficult to obtain in order to achieve a favorable result (Fig. 125.1). Current therapeutic modalities to treat tissue or organ loss include total artificial or mechanical devices, biological processed tissues, transplanting organs from one individual into another, surgical reconstruction, autologous transfer of tissue to the diseased-site or supplementing metabolic products of the lost tissue.

Although these traditional forms of tissue replacement have rescued millions of patients and have improved countless lives, they suffer from problems of scarce supply, increased susceptibility to infection, immunologic rejection, as well as uncertain long-term interactions with the patients; and however still remain imperfect solutions. The problems are much more severe in the pediatric age group, since implantable mechanical devices do not grow as the child grows.

Tissue engineering is an interdisciplinary field which applies the principles and methods of engineering and the life sciences towards the fundamental understanding of structural and functional relationships in normal and pathological tissue and the development of biological substitutes to restore, maintain, or improve function. Tissues that are engineered using the patients own cells, or immunological inactive allogenic or xenogenic cells have the potential to overcome current problems of replacing lost tissue function and offer new therapeutic options for diseases where currently no options are available. Tissue engineering technology can play a vital role in the future management of pediatric patients. Tissues or organs absent at the time of birth, in congenital anomalies such as esophageus atresia, bladder extrophy and congenital diaphragmatic hernia to name a few, pose a serious challenge in surgical repair. The advances in prenatal diagnostics, that allow earlier detection of such anomalies, could give sufficient time to engineer the missing tissue or organs and have them fabricated for surgical replacement at the time of birth.
GENERAL STRATEGIES TO REPLACE TISSUE LOSS

The primary intention of all approaches in tissue engineering is the functional or structural restoration of tissue through the delivery of living elements which become integrated into the patient. Most of the techniques of guided tissue restoration developed during the last two decades have mainly been only cell based or only matrices based, however investigators in the rapidly emerging field of tissue engineering presently use a combination of both to achieve new tissue formation.

Cell and Cell Based Techniques

In cell based tissue engineering methods, isolated and disseminated cells are injected into the blood stream or a specific organ of the recipient. The cells transplanted using such injection methods will utilize the blood supply for nutrients and the ground substance provided by the host tissue as a matrix bed for attachment, reorganization and desired growth.\(^4\) The cell injection approach avoids the complications of surgery, allows substitution of only those cells that supply the needed function, and permits manipulation of cells before infusion. This method might find applications in replacing lost metabolic functions however its application in replacing functions of structural tissues is severely limited.

Cell Encapsulation Techniques

In this concept for cell transplantation, the cells are cultured and encapsulated in a semipermeable membrane that isolates the cells from the body. However, at the same time the semipermeable membrane, which allows the diffusion of nutrients and wastes, prevents macromolecules such as antibodies, complement factors and immune cells from accessing the transplant. This application of this system has been successfully demonstrated in the production of a bioartificial liver, using xenogenic hepatocytes, as an extracorporeal liver support system and was effective in clinical trials for the treatment of acute liver failure.\(^5\) Isolated cells also have the capability to reform their structure, however only up to a limited degree when placed as a suspension into the host. This is mainly due to the absence of an intrinsic tissue ground substance framework. Implantation of tissue in larger volumes is also severely restricted because diffusion limitations restrict interaction with the host environment for nutrition, gas exchange and waste elimination. Based on these observations, approaches to engineer tissue by attaching isolated cells to porous polymeric templates have been developed. The application and introduction of cell-polymer construct concept in the engineering of new tissue was to provide a structural foundation to support tissues undergoing constant remodeling, integration and restructuring (Fig. 125.2). Over the past two decades, a lot of research work has been done to design, develop and experimentally demonstrate the increasing advantages of polymer matrices based open cell system transplantation in the manufacturing of new tissues.

**Fig. 125.2:** Tissue engineering involves combining of cell along with biodegradable scaffolds to manufactures tissue or organs.
Polymer matrices used in tissue-engineered devices need to be biocompatible and have been designed to meet the nutritional and biological needs of the cell populations involved in the formation of new tissue (Fig. 125.3). The next important feature is that the materials should also be resorbable so that they leave a complete natural tissue replacement. Furthermore, polymer matrices should be reproducibly processable into desired structures and shapes and be able to retain their shapes after implantation in the host. If desired, the material should promote the growth of cells to increase the mass of the tissue. Finally, the surface of the material should interact with the transplanted cells to allow retention of differentiated cell function. Materials on the other hand that do not possess the above properties or are nonresorbable carry a permanent risk of infection. The most commonly used materials in tissue engineering are either synthetic polymers such as lactic-glycolic acid or polyacrylonitrile polyvinyl chloride, or natural materials such as collagen, hydroxyapatite, or alginates.

**CELL SOURCING IN TISSUE ENGINEERING**

Scientists have investigated virtually every tissue type in the human body in terms of tissue engineering. For clinical applications at present, cells have been derived from the patients themselves, from family members or close relatives, or other individuals. However, although this may be the most ideal source of cells, availability and accessibility may often be quite difficult. One approach to overcome the cell-source difficulty could be isolation of human stem cells. Human stem cells can be proliferated through multiple generations and made to differentiate into the appropriate cell type. Recent studies have shown that stem cells derived from human embryonic blastocysts possessed these characteristics. These stem cells identified, can be signaled to turn into different morphological cell types by changing the culturing conditions of the cells prior to implantation. Although there are a number of technical hurdles such as the need for pure stem-cell preparations, methods to reduce adhesion of cells during cell culture and processes to generate large number of cells to create tissue; work on stem cells involved in the creation of muscle, bone, and cartilage has demonstrated promising results in tissue engineering applications.

**IN VITRO CULTURE SYSTEMS**

**Static Cell-Cultures**

Early work in the field of tissue engineering was based on the use of standard static cell-culture conditions for the in vitro fabrication of tissues before implantation. However, there have been certain limitations to the exchange of nutrients and gases. These limitations are being overcome by advanced application of mechanical engineering expertise in the field of biotechnology by designing and producing dynamic cell culture systems, better known as bioreactors (Fig. 125.4).

**Bioreactors**

Bioreactors are dynamic cell culture systems that allow more control to generate larger volumes of cells when compared to conventional static-culture techniques. The flow of tissue culture medium and their mixing within bioreactors can be controlled to enhance mass transfer of nutrients, gases, and metabolites in order to regulate the size and structure of the tissue being generated.

**PRESENT STATUS OF TISSUE ENGINEERING**

Seeding of cells on 3-D biodegradable polymers in cell culture or flow bioreactor gave the opportunity to
study tissue development, tissue regeneration, and tissue repair in vitro. Investigators have attempted to study the properties of almost all mammalian cell types under in vitro conditions. Implantation of the cell polymer constructs allows further study in vivo. Knowledge obtained from the different disciplines participating in active tissue engineering research has promoted the evolution of this new field from primary animal research to clinical trials. The present status of different structural and functional tissue has been described below:

**Nervous System**

Progress has also been reported in attempts to regenerate the peripheral nerve. Synthetic nerve guides, fabricated in the shape of tubes, have been found to aid the regeneration of nerves that have been injured and separated by gaps that are too wide for healing. The tubes help the regenerating nerve from scar infiltration and also direct the new regenerating axons towards their target. It has been also demonstrated in several animal models that synthetic guides composed of natural polymers and synthetic polymers have enhanced axonal regeneration in vivo. The process of nerve regeneration has been further promoted by lining polymer membranes with Schwann cells. Additionally, polymers have been also designed to slowly release growth factors that aid in the regeneration of the damaged nerve over longer distances.

**Fig. 125.4:** Bioreactors are used to help cells integrate with the polymer scaffolds to generate new tissue.
Skin

Burn and burn related injuries are known to be associated with severe morbidity and mortality. In preclinical models, acellular dermis has been populated with keratinocytes and fibroblasts and has been tested as skin substitute. Biosynthetic analogs of skin on the other hand have combined cultured skin cells with polylactic/polyglycolic fabric, collagen gels, and collagen-glycosaminoglycan (GAG) sponges to provide skin replacements. This approach involves the in vitro culture of keratinocytes obtained from small skin biopsies (1 cm²) of burn patients. The rapid expansion of the keratinocyte population is achieved by cultivating keratinocytes on a feeder layer of irradiated fibroblasts (NIH 3T3) in association with certain media components. The advantage of this method is that it allows the graft to cover extremely large wounds; a disadvantage however is that a 3-4 week period is required for cell expansion. It is possible that cryopreserved allografts may help to address this problem.

Another approach to fabricate skin, utilizes human neonatal dermal fibroblasts grown on degradable polyglycolic acid polymers. In this method selective cultures of dermal fibroblasts are inoculated into the porous reticulations of the substrate. In case of severe burn injuries involving all the skin layers, the graft is placed directly on the wound bed and a skin graft (cultured epidermal autograft) is placed above. This graft then organizes and vascularizes to form organized dermis like tissue. Furthermore, the addition of a dermal matrix to epithelial tissue engineered replacements adds the theoretical advantage of a thicker, more durable graft that more closely resembles the ‘gold standard’ of split-thickness skin grafts.

Liver

Donor shortfall for liver transplantations presents a severe challenge to clinicians worldwide. After tedious research it has been found out that a number of critical steps determine the success of hepatocyte transplantation. Simple manipulations such as sandwiching the cells between hydrated collagen gels have prolonged the secretion of albumin, transferrin, fibrinogen, bile acids and urea from cultured hepatocytes. Furthermore, in order to maintain their differentiated function, hepatocytes must be attached to the polymer substrates, and also be implanted in vascular areas of the body so that a constant supply of hepatotrophic factors can be maintained. These factors taken in to account, have demonstrated that tissue structures can be formed when hepatocytes have been placed on appropriate polymers. The hepatocytes have been found to maintain a distribution of filament network similar to the in vivo state and the hepatic tissue generated has also shown evidence of bile ducts and bilirubin removal. Vast spectrum of investigations are presently being undertaken to enable larger transplantation of hepatocytes, as well as to prolong the cell viability, using various polymers.

Pancreas

Diabetes mellitus affects a major part of the adult population worldwide. Transplantation of grafts of isolated pancreas islets has been performed to tackle this problem, however despite immune
alterations of the transplants no success has been reported in animal models. To overcome the problem of immunorejection and autoimmune rejection, the concept of immunoisolation has been advocated. This is achieved by enclosing the pancreatic islets by semipermeable and biocompatible membrane (bioartificial pancreas). The semipermeable membrane is impermeable to high molecular weight antibodies, but permeable to oxygen, glucose and internally generated hormones (insulin, glucagons, somatostatin, pancreatic polypeptides and other islet proteins).

**Urinary Tubular Structures**

Replacement of the ureter, bladder, and urethra using parts of other organs for reconstruction, often leads to reflux, infection and dilatation of the upper urinary tract. Nonbiological or metal implants have been used to replace ureters but have largely failed due to poor biocompatibility, lack of peristaltic activity and deposition of salt on their surfaces. Since the urothelium has a good regenerative capability, the fabrication of urothelium-polymer constructs as implants for replacement therapy have been explored. Successful fabrication of the ureter and segmental ureteral replacement has been achieved using urothelial cells seeded onto polyglycolic acid polymer tubes.

**Esophagus**

The application of the concepts of using tubular polymers has broadened from ureter replacements to the possible replacements of other tubular structures such as the trachea, esophagus and intestines. Copolymer tubes of lactic-glycolic acid used in a dog model as an esophageal replacement have shown encouraging results. The tubes were over time covered by connective and epithelial tissue and the dogs were able to drink freely and eat semisolid foods. Further research using better designed copolymer tubes and cell seeding techniques could provide breakthrough for esophagus replacement and treatment for the management of malformations such as long-gap esophageal atresia.

**Small Intestine**

In a similar approach, fetal intestinal cells have been seeded onto polymers tubes and have shown promising results in new intestinal tissue generation. The new intestinal epithelium engineered has demonstrated the presence of differentiated intestinal epithelium cells lining the tubes. Histology has revealed the development of crypt-villus structures in the neointestine cells which have the functional capability to secrete mucous. Promising results emerging after the anastomosis of tissue-engineered neointestine to native small bowel, and its successful structural and functional integration, gives hope for the management of patients with short bowel syndromes.

**Cartilage**

Research has been aimed at creating new cartilage based on collagen-glycosaminoglycan templates, isolated chondrocytes and chondrocytes attached to natural or synthetic polymers. Articular cartilage is composed of a highly organized extracellular matrix, which consists mainly of type-II collagen and proteoglycan (chondroitin and keratan sulfate glycosaminoglycans) and a relatively sparse cell population of articular chondrocytes. The mechanical performance of articular cartilages is dependant on the architecture of its extracellular matrix and the ability of the constituent chondrocytes to maintain the matrix. The use of well-stirred bioreactors for cultivating chondrocytes on polymer
scaffolds in vitro may enable nutrients to penetrate the center of this nonvascularized tissue, leading to strong and thick implants. Cartilages for replacement of various tissue such as nasoseptum, human ear cartilage as well as trachea replacement have been engineered. In the case of joint replacements, tissue engineered cartilages have been shown to induce the same lubricity, produce the same coefficient of friction, as well as absorb and dampen the joint forces settings of a normal articular cartilage.

**Bone**

Culture of seeded osteoblastic cells in 3-D osteoconductive scaffolds in vitro is a promising approach to produce an osteoinductive matter for the repair of bone defects. Small phalanges and joints resembling the shape and composition of human phalanges have been successfully fabricated using periostem, chondrocytes, and tenocytes seeded differentially onto biodegradable polymer scaffolds. To achieve this, the gross form of a composite tissue structure was constituted in vitro by assembling the parts and suturing them to create models of the phalanges. The sutured composite tissues were then implanted subcutaneously and resulted in the formation of new tissue after 20 weeks.

**Muscle**

Skeletal muscle comprises approximately 48% of the body mass and is responsible for voluntary control and active movement of the body. Application of tissue engineering techniques and successful fabrication of skeletal muscle mass holds now a promising future for the restoration of 3-D contour as well as the loss of function for the affected part of the body. In order to generate skeletal muscle tissue, myoblasts which are skeletal muscle tissue precursors, have been employed. Myoblasts have been seeded onto polyglycolic acid porous polymers with successful generation of vascularized new skeletal muscle in vivo. Under cell culture conditions, myoblasts cultures have exhibited twitching movement on stimulation. This exhibition of movement by myoblasts in culture is very important for the fabrication of new skeletal muscle which is not only a structural but more an important functional tissue. Research is presently being carried out in improving the vascular infrastructure of the muscle to enable generation of larger muscle mass. Gel polymers have also been successfully used for the transplantation of myoblasts.

**Heart Valves and Blood Vessels**

Tissue engineering of heart valve was demonstrated using autologous myofibroblasts and endothelial cells harvested from the femoral artery of a lamb. The cells were expanded in culture and cell separation was performed using a fluorescent activated cell sorter. The myofibers were first seeded onto a polymer scaffold composed of polyglactin polymer mesh sandwiched between two polyglycolic acid meshes. The endothelial cells were seeded onto the polyglycolic acid meshes after a time lag of 7 days. The construct was trimmed to size and was implanted in the same lamb to replacing the right pulmonary leaflet. The polymer disappeared after 6 weeks of implantation leaving behind a leaflet histologically resembling the native pulmonary valvular architecture. The mechanical properties of the tissue engineered leaflet approached the natural parameters over time. Grafts are also being designed from relatively inert materials (with heparin coatings) or with materials that interact with blood cells in a desirable way.

**FUTURE ASPECTS AND RESEARCH**

For the clinical success of tissue engineering numerous areas of research are critical. Precise understanding of cell biology with emphasis on cellular differentiation, cell to cell interaction and
extracellular matrix formation will be of paramount importance. Cell sourcing, cell preservation and cryopreservation of cells, or establishment of cell banks, which are only possible for certain tissues at present must be made possible for other tissues in the future. Large-scale cell culture systems, capable of resolving the nutrient transport issue and allowing the proliferation of larger number of required cell types in vitro, must be designed. The continuous work performed in designing better polymers is another major area of study. Tissue engineering is a new technology, with profound benefits and an enormous potential that offers future promise in the treatment of loss of tissue or organ function as well as for genetic disorders with metabolic disorders.

REFERENCES

Stem cell research is today like an octopus expanding its tentacles into every field of medical science. Stem cells may hold the key to replacing cells lost in many diseases that are caused by loss of functioning cells.\(^1\)

It is thus a type of cell-based therapy for treating diseases. Cell based therapies are also often referred to as regenerative or reparative medicine. In future, stem cells may become the basis for treating diseases such as Parkinson’s disease, diabetes, and heart disease.

The 5th Annual Meeting of the International Society for Stem Cell Research focused on a number of issues, such as stem cell transplantation, tissue regeneration, biology of embryonic and adult stem cells of various species, regulation of stem cells epigenetic state and cancer stem cells.\(^2\)

It has been felt that the twenty-first century will belong to regeneration medicine, with therapeutic applications of stem cells.\(^3\)

**STEM CELL**

A stem cell is an undifferentiated cell in the body that in its original form has an undetermined function. However, the unique capability of this cell to form various tissues under definite signals received from the body, makes this cell an object of extensive research. Stem cells are unspecialized cells, can divide and renew themselves for long periods of time and become specific specialized cell types of the body.

**HISTORICAL BACKGROUND**

In 1981, researchers reported methods for growing mouse embryonic stem cells in the laboratory. Human embryonic stem cells have only been studied since 1998, when James Thomson at the University of Wisconsin-Madison isolated cells from the blastocyst, and developed the first human embryonic stem cell lines. At the same time, John Gearhart at Johns Hopkins University reported the first derivation of human embryonic germ cells from the primordial germ cells. Most of the knowledge about embryonic stem cells has emerged from in vitro fertilization technologies and basic research on mouse embryology.

After many years of isolating and characterizing stem cells, researchers are now exploring their utility for potential clinical applications (Fig. 126.1). Active stem cell research is going on with various animal models.

Autologous bone marrow stem cells have been used in various pilot studies for various disorders like cardiomyopathies, diabetes, bony disorders, biliary atresia and choledochal cyst (cirrhotic livers), spina bifida, multicystic kidney, cerebral palsy and muscular dystrophy.\(^4-6\) At AIIMS, with the help of the centralized stem cell facility, various specialities including cardiothoracic, ophthalmology, endocrinology, surgery, orthopedics and pediatric surgery, have used stem cells in more than 500 patients now, including neonates and infants for various disorders since the last 4 years.\(^1,4-12\)

**AREAS OF RESEARCH**

Today, scientists all over the globe are intensively studying the fundamental properties of stem cells, that is determining precisely how stem cells remain unspecialized and self renewing for many years; and identifying the signals that cause stem cells to become specialized cells. Stem cell research has been found beneficial in the following areas (Fig. 126.2).\(^13-34\)
1. Alzheimer's
2. Parkinson's
3. Myocardial infarction
4. Stroke
5. Spinal cord injuries
6. Chronic liver cirrhosis
7. Sickle cell anemia
8. Leukemia
9. Non-Hodgkin's lymphoma and some other cancers,
10. Auto-immune diseases
11. Multiple sclerosis
12. Diabetes
13. Chronic heart disease
14. End-stage kidney disease
15. Liver failure
16. Cancer
17. Burns
18. Baldness
19. Infertility

**CLASSIFICATION OF STEM CELLS BASED ON POTENTIALITY**

Stem cells may be classified into three basic types according to the potentiality to transform into different cells. These include:

1. **Totipotent Stem Cells:** These are capable of forming a completely new embryo that can develop into a new organism. A fertilized egg is totipotent. None of the stem cells used in research appear to have this capacity.

2. **Pluripotent Stem Cells:** These are unspecialized cells and have the potential to develop into any of the cell types found in an adult. Embryonic stem cells are pluripotent. Embryonic stem cells are able to renew themselves indefinitely in the laboratory and are therefore 'immortal'. Pluripotent stem cells from embryos and fetal tissue possess the ability to repair or replace cells or tissues that are damaged or destroyed by devastating diseases and disabilities.¹

3. **Multipotent Stem Cells:** These have the potential to make a few cell types in the body.

**SOURCES OF HUMAN STEM CELLS**

Stem cells have been isolated from human embryos, fetal tissue, umbilical cord blood and also from "adult" sources. There are six major types of human stem cells, based on their source:

**Adult Stem Cells**

These are undifferentiated cells found among specialized or differentiated cells in a tissue or organ after birth and are capable of maintaining, generating, and replacing terminally differentiated cells (Fig. 126.3). Based on current research they appear to have a more restricted ability to produce different cell types and to self-renew. They are thus multipotent. In some adult tissues, such as bone marrow, muscle, and brain, a discrete populations of adult stem cells generate replacements for cells that are lost through normal wear and tear, injury, or disease. These cells produce new cells to replace old ones, such as blood, liver and nerve cells. Adult stem cells have been found in tissues that develop from all three embryonic germ layers.

**Umbilical Cord Blood Stem Cells**

Non-embryonic stem cells can also be sourced from umbilical cord blood following birth (cord blood stem cells). These cells have properties similar to adult stem cells. Umbilical cord blood stem cells can also differentiate across tissue lineage boundaries into neural, cardiac, epithelial, hepatocytic, and dermal tissue.³⁵ Umbilical cord blood-derived stem cells offer multiple advantages over adult stem cells, including their widespread availability, immaturity, which may play a significant role in reduced rejection after transplantation into a mismatched host and their ability to produce larger quantities of homogenous tissue or cells.³⁵

**Embryonic Stem Cells**

These are collected from blastocyst, the inner cell mass of an early embryo (usually 5-6 days old) resulting in the destruction of the embryo (Figs 126.4 to 126.6).
In a blastocyst, the stem cells in developing tissues give rise to the multiple specialized cell types that make up the heart, lung, skin, and other tissues. Once these cells are removed from the embryo, they can no longer give rise to a whole organism. They have the ability to form virtually any type of cell found in the human body. They are pluripotent.

**Germline**

Embryonic germline stem cells are immature cells derived from the part of a human embryo or fetus that will ultimately produce sperm and egg cells (gametes). They are also pluripotent and their properties are similar to those of embryonic stem cells.

**Amniotic Fluid Stem Cells**

About 4 years ago, the discovery of amniotic fluid stem cells, expressing Oct-4, a specific marker of pluripotent stem cells, and harboring a high proliferative capacity...
Stem Cell Therapy

and multilineage differentiation potential, initiated a
new and promising stem cell research field. Since then,
amniotic fluid stem cells have been demonstrated to
harbor the potential to differentiate into cells of all
three embryonic germ layers. These stem cells do not
form tumors in vivo and do not raise the ethical
concerns associated with human embryonic stem cells.
Further investigations will reveal whether amniotic
fluid stem cells really represent an intermediate cell
type with advantages over both, adult stem cells and
embryonic stem cells. They can be used to generate
clonal amniotic fluid stem cell lines as new tools to
investigate molecular and cell biological consequences
of human natural occurring disease causing
mutations. The amnion possesses advantages that
the isolated cells can differentiate into all three germ
layers; they have low immunogenicity and anti-
inflammatory functions; and they do not require the
sacrifice of human embryos for their isolation, thus
avoiding the current controversies associated with the
use of human embryonic stem cells. Significant
research has been done based on mesenchymal stromal
cells isolated from various parts of the placenta or
epithelial cells isolated from amniotic membrane.

Placental Tissue

Placental tissue draws great interest as a source of cells
for regenerative medicine because of the phenotypic
plasticity of many cells types isolated from this tissue
and the immunomodulatory properties of the cells that
make it useful for future cell therapy-based clinical
applications.

Which Cells to Use?

Each of these is being used in active research, and all
have the potential to treat disease in future. Most
scientists feel research using embryonic cells being
pluripotent will be more fruitful. However, recently,
it has been shown that some adult stem cells may be
able to generate different tissues under the right
conditions and this may increase their therapeutic
potential.

Embryonic stem cells have a greater capacity for
renewal. Their uncontrolled growth may lead to
tumour formation that may restrict their use in cell-
based therapies. Embryonic germ and adult stem cells
do not form these tumors in culture, which may make
them better alternatives for transplant tissue sources.

Thus, most scientists agree that it is important to
continue to pursue research into embryonic stem and
germs cells and adult stem cells. Embryonic stem cells
have the potential to develop into organs and tissues
(such as kidneys) that could replace diseased organs.
This would help alleviate the shortage of organs and
tissues available for transplantation.

Embryonic stem cells and adult stem cells are being
compared in terms of their ability to proliferate,
differentiate, survive and function after transplant, and
means to avoid the immune rejection are being
explored.

Adult Stem Cell Plasticity

Adult stem cell plasticity or trans-differentiation has
been defined as the ability of some adult stem cells to
be "genetically reprogrammed", given the right
environment, into specialized cells that are
characteristic of different tissues.

MESENCHYMAL STEM CELLS

Multipotent mesenchymal stromal cells (MSC) are a
group of clonogenic cells present among the bone
marrow stroma and capable of multilineage
differentiation into mesoderm-type cells such as
osteoblasts, adipocytes and chondrocytes. These may
also be isolated from various adult tissue sources.
Mesenchymal stem cells from adult marrow can
differentiate in vitro and in vivo into various cell types,
such as bone, fat and cartilage.

Due to their ease of isolation and their
differentiation potential, MSC are being introduced
into clinical medicine in variety of applications and
through different ways of administration.
Mesenchymal stem cells preferentially home to
damaged tissue and thus may have therapeutic
potential.

Emerging evidence indicates that the class of single-
stranded non-coding RNAs known as "microRNAs"
also plays a critical role in the differentiation process.
Expression of unique microRNAs in specific cell types
serves as a useful diagnostic marker to define a
particular cell type. MicroRNAs are also found to be
regulated by extracellular signaling pathways that are
important for differentiation into specific tissues,
suggesting that they play a role in specifying tissue identity.\textsuperscript{41}

In vitro data suggest that MSCs have low inherent immunogenicity as they induce little, if any, proliferation of allogeneic lymphocytes. Instead, MSCs appear to be immunosuppressive in vitro.\textsuperscript{42} They inhibit T-cell proliferation to alloantigens and mitogens and prevent the development of cytotoxic T-cells.\textsuperscript{42}

Mesenchymal stem cells have also been separated from umbilical cord vein. These gave rise to a population of adherent cells with a typical fibroblast-like morphology. Similarly to bone marrow-derived MSCs, they highly expressed CD29, HLA-ABC, CD166, CD105, CD73 and CD44, and were negative for any hematopoietic and endothelial markers (CD45, CD34, CD14 and CD144).\textsuperscript{43} Functionally, these could differentiate into the osteoblast, adipocyte and chondrocyte.\textsuperscript{43}

**AUTOLOGOUS STEM CELL TRANSPLANTATION**

This has been widely used for autoimmune diseases and lymphoma.

**Autoimmune Diseases**

In a study, of the 1,000 patients that received an autologous hematopoietic stem cell transplant as treatment for a severe autoimmune disease, the majority were cases of multiple sclerosis, systemic sclerosis, systemic lupus erythematosus, rheumatoid arthritis, juvenile idiopathic arthritis, and immune cytopenias.\textsuperscript{44} Many patients have experienced long-term disease-free remissions and immune reconstitution studies have shown in some cases that a "resetting" of autoimmunity is possible.

There is a growing interest in the role and potential therapeutic application of mesenchymal stem cells in the immunomodulation of autoimmune diseases, as in the early experience with acute-graft-versus host disease.

Allogeneic stem cell transplantation is the treatment of choice for the majority of young patients with myelodysplasia who have a histocompatible donor (sibling or unrelated donor).\textsuperscript{35}

**Lymphoma**

High-dose therapy (HDT) followed by autologous transplantation of hematopoietic stem cells (ASCT) is frequently performed in patients with lymphoma.\textsuperscript{45} Patients with indolent or aggressive B-cell lymphoma may benefit from HDT/ASCT if considered as part of first-line therapy or at the time of relapse.\textsuperscript{45}

**ETHICAL ISSUES**

All scientists are aware that they must undertake their work ethically and within the bounds of the law, and these can vary from country to country.

Harvesting stem cells from embryos involves lots of ethical issues. These differ in different societies. The idea of destruction of a potential human conflicts with religious and moral views in some societies. For others, the potential for this research to provide treatments and possibly cures for debilitating illnesses that have no cure and significantly impact on our way of life overrides this concern.

Opinions vary on what actually constitutes the beginning of life for a human: from the moment of conception, to a 14 day embryo, to a living baby at birth.

As life is considered by some to begin at conception so it may be considered criminal to sacrifice an embryo for experimental and research purposes.\textsuperscript{47,48} Embryonic Stem Cells are derived from embryos that develop from eggs that have been fertilized in vitro and then donated for research purposes with informed consent of the donors. The main ethical conflict about Embryonic Stem Cells research is between the alleviation of human suffering that stem cell technologies may provide and the destruction of embryonic life that is involved in their extraction. With the autologous infusion, there are no ethical issues involved with the stem cell therapy. However, being a new therapy with no definite known long term results, it is being done only in selected institutes with full ethical clearance and with a special informed consent.

It is important to balance the harm that might be done against the potential good this research may provide for those suffering from debilitating diseases. In some countries like Australia, legislation states that no embryo may be created for the purpose of this research or to generate stem cell lines.

The embryonic stem and germ cells are obtained from either donated embryos not required for an IVF procedure that would otherwise be destroyed, or from
pregnancies that were terminated for medical or social reasons.

While research with embryonic stem cells continues to generate considerable controversy, human umbilical stem cells provide an alternative cell source that has been more ethically acceptable and appears to have widespread public support.35

Prerequisites
1. Ethical issues should be solved well in advance.
2. Harvested stem cells from umbilical cord blood or embryos require proper cross matching and may lead to complications like graft versus host reaction

LIMITATIONS
1. The rare occurrence of adult stem cells among other differentiated cells.
2. There are difficulties in isolating and identifying the cells with molecular "markers".49
3. There are difficulties in growing stem cells in tissue culture.50
4. There are obstacles to organ construction using human stem cells. Stem cell-derived organs will be grown outside the human body and will therefore require some type of scaffolding during development. Such scaffolds are presently being developed incorporating human or animal stem cells.
5. The injection of undifferentiated embryonic stem cells into an adult and an uncontrolled proliferation may carry the risk of teratoma formation at any stage after stem cell therapy. To avoid this, undifferentiated embryonic stem cells must be eliminated before injection. Current cell-sorting technology is not yet efficient enough to do this. Understanding how tumor suppressor genes impinge on quiescent stem cell populations could provide us with a means of designing more effective therapies to reduce the frequency of stem cell-derived tumor growth that occurs following treatment.
6. There is a problem of immune rejection if there is a poor match between the cells of the embryo from which the embryonic stem cells are derived and the recipient.
7. Scientists still have to elucidate what prompts the stem cell to take up a specific function.
8. The disregulation of imprinted genes can be associated with tumorigenesis and altered cell differentiation capacity and so could provide adverse outcomes for stem cell applications. Although the maintenance of mouse and primate embryonic stem cells in a pluripotent state has been reported to disrupt the monoallelic expression of several imprinted genes, available data have suggested relatively higher imprint stability in the human equivalents.51 Gene-specific differences have been demonstrated in the stability of imprinted loci in human embryonic stem cells and identify disrupted DNA methylation as one potential mechanism.51

STEM CELL CULTURE
Appropriate culture conditions are required for maintenance of signaling pathways and transcriptional networks to maintain murine and human embryos in a stable, pluripotent state.

Cultures of human pluripotent stem cells have active telomerase, which is an enzyme that maintains the length of telomeres and is important for cells to maintain their capacity to replicate.

In order to safely use stem cells or cells differentiated from them in tissues other than the tissue from which they were isolated, researchers will need purified clonal lines of adult stem cells. In addition, the potential for the recipient of a stem cell transplant to reject these tissues as foreign is very high. Modifications to the cells or the immune system, or both will be a major requirement for their use.

Evidence of structural, genetic, and functional cells characteristic of specialized cells developed from cultured human and mouse embryonic stem cells has been shown for pancreatic islet-cell like cells that secrete insulin, cardiac muscle cells with contractile activity, blood cells and nerve cells that produce certain brain chemicals.1

STEM CELL TRANSPLANTATION FOR NEURODEGENERATIVE DISEASES
Stem cell transplantation has the potential to improve function by replacing cells lost to the disease and reconstructing elements of neural circuitry or by providing support for host cells (e.g. by secretion of trophic factors).33
Other mechanisms, such as modulation of the immune system by bone marrow stem cell transplantation, pertinent to conditions such as multiple sclerosis, are emerging as therapies. Using stem cells to provide trophic support places less stringent requirements on the cells and this is the area in which many of the first clinical studies are taking place.

There are real prospects of stem cell technology having a place in clinical management of neurodegenerative conditions, but directing the differentiation of stem cells towards the appropriate neural phenotype remains a challenge.

**RECENT RESEARCH**

The spermatogonial stem cells can self-renew and generate a large number of differentiated germ cells. A balance between their renewal and differentiation in the adult testis is essential to maintain normal spermatogenesis and fertility. It has been demonstrated in adult mice that spermatogonial stem cells self-renewal could be controlled by glial cell-line-derived neurotrophic factor GDNF during the perinatal period of development while it is dependent on ERM, a transcription factor which is exclusively expressed in mature Sertoli cells, during the pubertal period.

Granulocyte-macrophage colony stimulating factor (GM-CSF) is a hematopoietic growth factor involved in the generation of granulocytes, macrophages, and dendritic cells from hematopoietic progenitor cells. Addition of Granulocyte-macrophage colony stimulating factor to adult neural stem cells in vitro increased neuronal differentiation in a dose-dependent manner as determined by quantitative PCR, reporter gene assays, and FACS analysis.

Bone marrow stem cells may offer the potential for treatment of acute kidney injury.

Neural stem cells may be used to investigate the molecular mechanisms involved in manganese developmental neurotoxicity.

Cancer stem cells with genetic instability can be considered as 'the best vehicle with the best engine', a formidable challenge for the future development of new anticancer therapies.

It has been reported that when transplanted into the denervated rat colon, neuroepithelial stem cells survived and could differentiate into neurons and glial cells in vivo thus could provide a promising cellular replacement candidate for enteric nervous system.

An important area of research that links developmental biology and stem cell biology is understanding the development of the embryo and the various factors like genes, molecules, growth factors and nutrients that function during development. A new source discovery of adult stem cells, carotid body stem cells, which proliferate in response to hypoxia and generate neurons that secrete dopamine, may be useful in therapies for treating Parkinson's disease.

The clinical scope of the use of stem cell therapy is expanding continuously. The pertinent areas include liver cirrhosis due to biliary atresia and severe forms of choledochal cysts and sclerosing cholangitis, spina bifida, Hirschsprung's disease, renal dysplasia, residual tumors, pancreatic insufficiency due to diabetes, following surgical resection (nesidioblastosis, tumors), neurogenic bladder and bowel. The authors have used stem cells in cases of biliary atresia, meningomyelocele and anorectal malformation with incontinence (Figs 126.7A to C).

**Figs 126.7A to C:**

A. Nodules and cirrhosis seen in aextrahepatic biliary atresia that presented at 6 months of age post Kasai’s procedure with a cirrhotic liver. B. The same patient 17 months after stem cell injection had a liver biopsy showing near normal hepatocytes. C. The same slide seen in high power field.
FUTURE APPLICATIONS

The application of stem cells to regenerative medicine could help the cure of a number of diseases that are affecting a large share of the population. Regenerative medicine is a new field based on the use of stem cells to generate biological substitutes and improve tissue functions, restoring damaged tissue with high proliferability and differentiability.38

Recent progress in the stem cell field includes clinically compliant culture conditions and directed differentiation of both embryonic stem cells and somatic stem cells.52 With a growing understanding, stem cell biology, and spinal cord injury pathophysiology, stem cell-based therapies are moving closer to clinical application.62

An important issue is to find out how a cell begins to proliferate or differentiate. Genome reprogramming, both following nuclear transfer and cytoplast action, will likely highlight some of the molecular mechanisms of cell differentiation and dedifferentiation. In turn, these clues should be useful to the production of populations of reprogrammed cells that could develop into tissues or, in the future, into proper organs.13 Cell lines that have been established will be useful for research into early human development. Embryonic stem cells might be 'programmed' to develop into neurones and then purified and injected into the brain to regenerate new tissues to replace those that are diseased.

The stem cell phenotype of human and murine ES cells has recently been shown to be maintained by a self-stabilizing network of transcription factors, NANOG, OCT4 and SOX2.63 Aberrant activation of the ES transcription factor network elicited by increased dosage of an embryonic gene cluster at 12p including NANOG, together with additional genetic and epigenetic alterations, appears to be a crucial event in the genesis of testicular germ cell cancers.63

Laser-assisted isolation of the inner cell mass may be applied for the derivation of new human embryonic stem cells lines in a xeno-free system for future clinical applications.64 These human embryonic stem cells lines can serve as an important model of the genetic disorders that they carry.64

Both adult neural stem cells and embryonic stem cells have shown the capacity to differentiation into multiple cell types of the adult nervous system.65 However, there are significant challenges remaining, including the identification of signaling factors that specify cell fate in the stem cell niche, the analysis of intracellular targets and mechanisms of these extracellular signals, and the development of ex vivo culture systems that can exert efficient control over cell function.65

Applications of imaging techniques to visualize stem cells for monitoring, control and treatment of biological systems, in particular the brain, is at the forefront of investigations.56

Potential new drugs could be tested for their toxicology on tissues developed from stem cell lines. Stem cells are likely be used to develop specialized liver cells to evaluate drug detoxifying capabilities.

In a mouse model, local RT delivered to the left leg causes preferential accumulation of bone marrow mononuclear cells to the irradiated site, with maximum signal intensity observed at 7 days post-RT.67 The combination of stem cell technology and tissue engineering has been investigated and offers promising avenues for myocardial tissue regeneration, and this shows great promise in future reconstructive surgery.68 The genome and transcriptome of Embryonic Stem Cells have been extensively examined in order to decipher their self-renewal and differentiation mechanisms.69 Epigenetic analysis reveals methylation patterns and microRNA profiles unique to Embryonic Stem Cells.69

Genetic engineering of adult stem cells from various sources with osteogenic genes has led to enhanced fracture repair, spinal fusion and rapid healing of bone defects in animal models.70 Many authors are now discussing the potential of gene-enhanced tissue engineering to enter widespread clinical use.70 Neural stem cells transplanted into the brain after neuronal ablation survive, migrate, differentiate and, most significantly, improve memory mouse model.71 Oligodendrocytes derived from stem cells are being used to remyelinate axons following spinal cord injury.72

Bone marrow derived mesenchymal stem cells are pluripotent cells which can differentiate into osteogenic, adipogenic and other lineages. The number of bone marrow mesenchymal stem cells but neither phenotype nor differentiation capacities changes with age of rats.73 Cellular therapies derived from embryonic stem cells have gained a renewed interest.
with the experimental demonstration that an embryonic stem cell line can be established from human blastocyst-stage embryos and prompted to differentiate into almost all types of cells present in the body including hematopoietic cells. Embryonic stem cells show great potential and it may be technologically feasible to transplant differentiated embryonic stem cells and to cure various kinds of blood disorders. The potential utility of embryonic stem cells for gene therapy, tissue engineering and the treatment of a wide variety of currently untreatable diseases has been recognized.

Stem cells are already being explored as a vehicle for delivering genes to specific tissues in the body. In future, antibodies could be developed to direct the differentiation of embryonic stem cells to control their proliferation once placed in patients. The need for surgery for therapy.

The major challenges faced by scientists today are to direct the differentiation of embryonic stem cells into specialized cell populations and to devise ways to control their proliferation once placed in patients. More refined experimental work is needed to study the mechanism of action of stem cells but the hurdles lie in creating the exact environment experimentally as found in the clinical setup.

Nanotechnology, "the technology of nanoscale materials or devices", is a unique phenomenon in the recent scientific development that has revolutionized the advancement of medicine and galvanized almost every specialty of science engineering and business community. The ability to characterize, manipulate and organize matter systematically at the nanometer scale has resulted a revolution in science, engineering, and technology. The progress in nanotechnology is happening at an astonishingly rapid pace. It has dramatically altered the area of electronics as well as computing towards development of smaller and smaller chips with extraordinary processing power. In the therapeutic arena, nanotechnology promises to expand the repertoire of innovative systems, thereby revolutionizing health care modalities. At the same time, it is changing the relevance of the existing business model of drug discovery, medical imaging, laboratory diagnosis and other health sectors. The unique properties of nanosized material or devices are being utilized to develop complex intelligent and interactive systems which can be used at molecular level in innumerable areas of pathobiology.

Before we proceed to understand the application of nanotechnology in medicine we should go through the following definitions:

Nanotechnology is the technology of design, characterization, production and applications of structures, devices and systems by controlling shape and size at the nanometer scale.

Nanoscience is the study of phenomena and manipulation of materials at atomic, molecular and macromolecular scales, where properties differ significantly from those at larger scale.

Nanomedicine can be defined as application of nanotechnology in health care.

HISTORY OF NANOTECHNOLOGY

The idea of nanotechnology was born on December 29, 1959, in the annual meeting of American Physical Society, at the California Institute of Technology (Caltech), when Richard P Feynman (Fig. 127.1) delivered an invited talk entitled, There is plenty of room at the bottom (http://www.zyvex.com/nanotech/feynman.html). The presentation and discussion was on the problem of manipulating and controlling things on a small scale. He asked the audience whether it would be possible to write the 24 volume of Encyclopedia Britannica on a pin head. Though it appeared to be science fiction at that time, it is reality in modern science.

Professor Feynman was awarded Nobel Prize in Physics in 1965. He was born in New York City on the 11th May, 1918. He studied at the Massachusetts Institute of Technology (MIT).
Institute of Technology where he obtained his BSc in 1939 and at Princeton University where he obtained his PhD in 1942. He was Research Assistant at Princeton (1940-1941), Professor of Theoretical Physics at Cornell University (1945-1950), Visiting Professor and thereafter appointed Professor of Theoretical Physics at the California Institute of Technology (1950-1959). He was Richard Chace Tolman Professor of Theoretical Physics at the California Institute of Technology when he received the Nobel Prize.

For more than a decade after the idea of miniaturization floated by Professor Feynman, there was hardly any scientific report in this area till 1974, when Norio Taniguchi first used the word "Nanotechnology" to refer to "production technology to get the extra high accuracy and ultra fine dimensions, i.e. the precision and fineness on the order of 1 nm (nanometer), 10^{-9} meter in length", in paper on ion-sputter machining. In 1977, Professor K. Eric Drexler conceptualized "molecular nanotechnology" at Massachusetts Institute of Technology. In 1981, he published the paper entitled, "Molecular engineering: An approach to the development of general capabilities for molecular manipulation" in Proc. Nat. Acad. Sci. USA. The progress in nano-research got a tremendous boost with invention of Scanning Tunneling Microscope (STM) or scanning probe microscope which was of great help for characterization of nanoparticles. Gerd Binnig and Heinrich Rohrer developed the first working STM while working at IBM Zurich Research Laboratories in Switzerland in 1981. This instrument helped Binnig and Rohrer to win the Nobel Prize in physics in 1986. This year was also memorable as the first book entitled, "Engines of Creation: The Coming Era of Nanotechnology" by Professor Eric Drexler was published in the area of nanoscience and the atomic force microscope (AFM) was invented. In 1988, for the first time a ten-week course on "Nanotechnology and Exploratory Engineering" was taught at Stanford during the spring quarter. The first scientific journal in this area entitled, "Nanotechnology" was published in 1990. The book "Nanomedicine, Vol. I: Basic Capabilities" by Robert A, Jr. Freitas was published in 1999 which opened the gate of application of nanotechnology in health care and medicine. In the year 2000, President Bill Clinton, announced US. National Nanotechnology Initiative. The current decade witnessed an explosion of nano research world over. There is maximum increase in number of publications over last 10 years in this area.

APPLICATION OF NANOTECHNOLOGY IN MEDICINE

Current applications of nanotechnology in medicine may be discussed under the following three headings:
A. Imaging
B. Clinical laboratory diagnosis
C. Drug and bio-molecular delivery system

Nanotechnology and Imaging

Imaging is one of the most important diagnostic tool in clinical medicine. The era of medical imaging started when Wilhelm Roentgen captured the first X-ray image of his wife’s hand in 1896. Following the X-ray technology, a large number of non-invasive imaging technologies have been successfully developed and applied in clinical medicine as well as medical research including cell-molecular biology and drug discovery. Currently available methods of imaging are summarized in Table 127.1.

Application of nanotechnology may revolutionize the area of medical imaging. It can improve the current modalities like CT and MRI in terms of sensitivity and specificity as well as study of cellular functional alterations. It may help to develop fluorescence-based in vivo imaging systems. Now fluorescent nanoparticles can be developed which are resistant to photobleach. The nanoparticles have tremendous ability to enhance the contrast as well as visibility by conventional radiological techniques.

Among the various nanoparticle-based optical contrast agents, few appears to have potential for clinical application which include; quantum

| Table 127.1: Commonly used non-invasive imaging techniques in clinical practice |
|---------------------------------|-------------------|
| Imaging technique           | Detection method     |
| Computed tomography (CT)   | X-ray               |
| Magnetic resonance imaging (MRI) | Magnetic field     |
| Positron emission tomography (PET) | Gamma rays         |
| Single photon emission computed tomography | Gamma rays       |
| Ultrasonography             | Ultrasonic waves    |
dots (QDs), gold nanoparticles, organically modified dye doped silica, up-converting phosphors and lanthanide-based contrast agents.

The development of quantum dots (QDs) for biological and biomedical applications is one of the fastest moving fields of nanotechnology today. The unique optical properties of these nanometer-sized semiconductor crystals make them an exciting fluorescent tool for \textit{in vivo} and \textit{in vitro} imaging as well as for sensoric applications. QDs are fluorescent semiconductor nanocrystals, a few nanometers in diameter whose size and shape are precisely controlled by the duration, temperature, and ligand molecules used during synthesis. These are generally composed of II-VI and III-V elements.\textsuperscript{4} Compared with conventional fluorophores, the nanocrystals have a narrow, tunable, symmetric emission spectrum and are photochemically stable.\textsuperscript{5} Single QDs can be observed and tracked over an extended period of time (up to a few hours) with confocal microscopy, total internal reflection microscopy, or basic widefield epifluorescence microscopy.\textsuperscript{5,7} Some of the most successful uses of QDs include immunofluorescence labeling of fixed cells and tissues; immunostaining of membrane proteins, microtubules, actin, and nuclear antigens; and fluorescence \textit{in situ} hybridization on chromosomes or combed DNA.\textsuperscript{7-12} Functionalized QDs like surface antibody tagged particles can be used to localize antigen \textit{in vivo}. Thus in future techniques can be evolved for detection of early metastasis or staging of the cancers easily with non-invasive methods utilizing QDs. Rapid development in this area will change the face of medical practice in near future.

Development of Cadmium sulphide nanoparticles, “Quantum Dots (QD)”, with unique stable luminescent capability has helped to develop labeling and advanced imaging techniques for detection of very small quantity of marker molecules and even few microorganisms which can not be detected by conventional methods available at present. QDs bioconjugates raise new possibilities for studying genes, proteins and drug targets in single cells, tissue specimens and even in living animals and enable visualization of cancer cells in living animals. Though the concepts are feasible the main hurdle in utilizing QDs in diagnostic imaging is their toxicity.\textsuperscript{13}

Due to the unique optical (colorimetric) properties, gold nanoparticles are now finding increased applications in the detection of biological systems.\textsuperscript{14} Gold nanoparticle with less than 2 nm in diameter may be used as safe and better radiocontrast agent. Gold has higher absorption than iodine with less bone and tissue interference achieving better contrast with lower X-ray dose. Nanoparticles clear the blood more slowly than iodine agents, permitting longer imaging times.\textsuperscript{15} However, safety issues related to systemic injection of gold nanoparticles as radiocontrast agent needs further study and confirmation.

**Nanotechnology in Clinical Laboratory Diagnosis**

The experimental applications of nanotechnology in laboratory and molecular diagnosis is expanding in such a rapid pace, it is beyond the scope of review in this chapter. However, some of the application with potential to be used in laboratory diagnosis may be enumerated as follows:

1. Nanotechnology for designing various biochips
2. Nano-barcode technology
3. Nanopore technology
4. Cantilever arrays
5. DNA micro-array for molecular diagnostics
6. Nanoparticle-based immunoassays
7. Resonance light scattering technology
8. Nanosensors

Within last few years, the biological and biomedical applications of micro- and nanotechnology (Biomedical or Biological Micro-Electro-Mechanical Systems [BioMEMS]) have become increasingly popular and have a potential for widespread use in a wide variety of diagnostics applications. The concept of "lab-on-a-chip" has become a reality today. Biochips, constructed with microelectromechanical systems on a micron scale, use micromanipulation, whereas nanotechnology-based chips are on a nanoscale acts on nanomanipulation.\textsuperscript{16} The size of devices to move (levitate) tiny fluid droplets has been reduced by using micron scale diamagnets to create a magnetic micromanipulation chip, which operates with femtodroplets levitated in air.\textsuperscript{17} The droplets used are 1 billion times smaller in volume than has been demonstrated by conventional methods. Thus, use of this technology of "lab-on-a-chip" would require micro- to nanoliter of sample for detecting different biomarkers, traces of toxic materials, signature
molecules of virus or other infections. The size of this integrated “lab-on-a-chip” will be small enough to carry like a pen or watch and enable the patients to carry out the tests at any place and time of their choice. The day will come when there will be no need of samples to be sent to laboratory ushering the era of personalized medicine or medical care.

Nano-barcodes are submicrometer metallic barcodes with striping patterns prepared by sequential electrochemical deposition of metal ions. The differential reflectivity of adjacent stripes enables identification of the striping patterns by conventional light microscopy. This readout mechanism does not interfere with the use of fluorescence for detection of analytes bound to particles by affinity capture, as demonstrated by DNA and protein bioassays. Nanobarcodes can be used for SNP mapping and multiplexed assays for protein diagnostics.18

Biobarcode assay is another ultrasensitive method for detecting protein molecules. It relies on magnetic microparticle probes with antibodies that specifically bind a target of interest and nanoparticle probes that are encoded with DNA that is unique to the protein target of interest and antibodies.19 Magnetic separation of the complexed probes and target followed by dehybridization of the oligonucleotides on the nanoparticle probe surface allows the determination of the presence of the target protein by identifying the oligonucleotide sequence released from the nanoparticle probe.

DNA-nanopore is formed by an individual DNA oligonucleotide covalently attached within the lumen of the alpha-hemolysin pore. The binding of single-stranded DNA (ssDNA) molecules to the tethered DNA strand causes changes in the ionic current flowing through a nanopore. The DNA-nanopores are able to discriminate between individual DNA strands up to 30 nucleotides in length differing by a single base on the basis of DNA duplex lifetimes substitution.20 One of the example of use of this technology is the detection of a drug resistance-conferring mutation in the reverse transcriptase gene of HIV.

Mechanical detection for biochemical entities and reactions is an interesting method used through the use of micro- and nano-scale cantilever sensors on a chip. These cantilever sensors (diving board type structures) can be used in two modes, namely stress sensing and mass sensing. In stress sensing mode, the biochemical reaction is performed selectively on one side of the cantilever. A change in surface free energy results in a change in surface stress, which results in measurable bending of the cantilever. The bending of the cantilever can then be measured using optical means (laser reflecting from the cantilever surface into a quad position detector, like in an AFM) or electrical means (piezo-resistor incorporated at the fixed edge of the cantilever). In the mass sensing mode, the cantilever is excited mechanically so that it vibrates at its resonant frequency (using external drive, the ambient noise or other methods). The resonant frequency is measured using electrical or optical means, and compared to the resonant frequency of the cantilever once a biological entity is captured. The change in mass can be detected by detection of shift in resonant frequency, assuming the spring constant does not change. One of the main advantages of the cantilever sensors is the ability to detect interacting compounds without the need of introducing an optically detectable label on the binding entities. Detection of bacteria or viral agents and cancer marker like prostate specific antigen are some of the examples of use of this technology.21,22

DNA micro-arrays have become the most successful example of the merger between microelectronics technologies, biology, and chemistry. The techniques used to define patterns on semiconductor surfaces were utilized to construct arrays of single-stranded DNA. Once single strands of known sequences (capture probes) are placed at specific known sites on a chip surface, hybridization with molecules of unknown sequence (target probes) can reveal the sequence. There are two basic approaches to ‘forming’ the DNA arrays, namely optical (fluorescence) and electrical. This technique is being commercialized for detecting single nucleotide polymorphisms (SNPs), short tandem repeats (STRs), insertions, deletions, and other genetic mutations.23

Simple convenient method of preparation of bright, negatively or positively charged, water-soluble CdSe/ZnS core/shell nanocrystals (NCs) and their stabilization in aqueous solution has been developed.24 Single NCs can be detected using a standard epifluorescent microscope, ensuring a detection limit of one molecule coupled with an NC, thus, increasing the sensitivity of the detection system. NC-antibody conjugates obtained by the method described can be
used for specific detection of antigens in paraffin-embedded formaldehyde-fixed cancer tissue specimens.

Surface plasmon resonance (SPR) is an optical-electrical phenomenon involving the interaction of light with the electrons of a metal. The optical-electronic basis of SPR is the transfer of the energy carried by photons of light to a group of electrons (a plasmon) at the surface of a metal. The next-generation microarray-based SPR systems are designed to help researchers profile and characterize biomolecular interactions in a parallel format.25

Several nanomaterials are highly sensitive to chemical or biological alterations. The nano-scale sensors with immobilized bioreceptor probes that are selective for target analyte molecules are called nanobiosensors.26 They can be incorporated into other technologies such as lab-on-a-chip to facilitate molecular diagnostics. They have potential for wide applications like detection of microorganisms in various samples, monitoring of metabolites in body fluids and detection cancer or genetic diseases. Various types of nanobiosensors may be fabricated. Boron-doped silicon nanowires (SiNWs) have been used to create highly sensitive, real-time electrically based sensors for biological and chemical species. The Ion Channel Switch (ICS™), a novel biosensor technology. It is based upon a synthetic self-assembling membrane, which acts like a biological switch that detecting the signaling the presence of specific molecules by triggering an electrical current. Virus particles are essentially biological nanoparticles. Herpes simplex virus (HSV) and adenovirus have been used to trigger the assembly of magnetic nanobeads as a nanosensor for clinically relevant viruses.27 Sensing of Phage-Triggered Ion Cascade (SEPTIC), uses a nanowell device with two antenna-like electrodes to detect the electric-field fluctuations that result when a bacteriophage infects a specific bacterium and then identifies the bacterium. This method had a 100% success rate in detecting and identifying strains of E. coli quickly and accurately. Probes Encapsulated by Biologically Localized Embedding (PEBBLE) nanosensors consist of sensor molecules entrapped in a chemically inert matrix by a microemulsion polymerization process that produces spherical sensors in the size range of 20 to 200 nm.28 These sensors are capable of real-time inter- and intra-cellular imaging of ions and molecules and are insensitive to interference from proteins. PEBBLE can also be used for early detection of cancer. Different optical biosensor devices are also developed based on surface plasma resonance and laser systems.25,29 Nanoshell biosensors can enhance chemical sensing by 10 billion times. Gold nanoshells can be used for detecting sub-nanogram per milliliter quantities of immunoglobulins in saline, serum, and whole blood.30 Optical nanosensor, based on singlewalled carbon nanotubes that modulate their emission in response to the adsorption of specific biomolecules, can be used as glucose sensor which may be an important tool for continuous blood glucose monitoring and development of real time biosensor-based therapy.31

**Drug and Biomolecular Delivery System**

In the journal Advanced Drug Delivery Reviews in 2004, the editorial by Vincent HL Lee chose the title as "Nanotechnology: challenging the limit of the creativity in targeted drug delivery". This is one of most popular and challenging field of nanomedicine and nanobiotechnology research.32 Development of nanoparticle based targeting system for delivering the toxic anticancer drugs in the cancer cells is a reality now which reduces the systemic toxicity as well as more effective for cancer therapy. Here the nanoparticles are used as vehicle to carry anticancer drugs to the cancer cells. Thus, the logistics and the modalities of this kind of drug delivery system are completely different from the conventional chemotherapy and dosage. The first step for nanoparticle based delivery system to reach the cancer cell is to avoid trapping by the reticuloendothelial (RE) system (e.g. liver and spleen). Hydrophilic nanoparticles less than 100 nm in diameter are less trapped by RE system (Fig. 127.2).

Difference in the structures and functions of different types of cancers, poor blood flow due to irregular distribution of blood vessels, increased intratumoral pressure due to lack of functional lymphatic drainage at the cancer site allow poor transport and inadequate delivery of conventionally administered drugs and thus poor treatment modalities.33,34 Also high doses of non-specific, highly cytotoxic anti-cancer drugs needed to achieve sufficient therapeutic concentrations at the site leads
to severe side effects like nephrotoxicity, neurotoxicity, weight loss, hair loss, etc. Although radiotherapy and surgical removal of solid tumors are of interest in the current treatment methods, the undesired side effects due to chemotherapy and radiotherapy, development of multi-drug resistance cancer cells from the residual cells after the surgery are showing equally disappointing results.34

But targeted drug delivery systems (TDDS) in the form of small sized architectures as injectable preparations, like nanoparticles, liposomes, micelles, dendrimers and antibody targeted systems, which have been in current research compromise those above said critical requirements and reach therapeutic phase.35 Especially targeted polymeric nanoparticulate carriers offer higher drug loading and programmable drug release properties depending upon the environmental conditions. Development of specific targeting of cancer cells avoiding normal cells is a major challenge. This requires targeting of cancer specific receptor or other molecules which has a high expression in cancer cells. For example, the overexpression of folate receptors only on the cancer cell surfaces, promises selective delivery of drug into the intracellular compartment.36,37 We are in the process of developing folate conjugated nanoparticles for selective cytotoxic delivery for breast cancer (Fig. 127.3).

The nanoparticle based drug delivery system for cancer can utilize several issues related to cancer biology. The different systems that can be used may be enumerated as in Table 127.2.38

Targeted delivery through enhanced permeability and retention based on the concept of poorly formed defective vasculature in the tumor which are more leaky in comparison to vasculature in normal tissue. This is often associated with poor lymphatic drainage from tumor tissue resulting in enhanced permeation and retention effect (EPR effect).39 The drug loaded nanoparticle may be sequestrated in the tumor due to EPR effect when injected in systemic circulation. This is a form of passive targeting.
Nanotechnology: Technology to Revolutionize the Future of Medicine

It is possible to target tumor specific antigen or other target molecule as mentioned earlier with nanoparticle. For example, Her-2 neu receptor of breast carcinoma can be targeted in case of Her-2 positive carcinomas. Similarly, CD20 may be targeted for B cell immunophenotype non-Hodgkin lymphoma. Angiogenesis is a process vital to the continued expansion of a tumor mass. Some of the most prominent angiogenesis stimulatory molecules include vascular endothelial growth factor (VEGF), basic fibroblast growth factor, platelet-derived growth factor and certain matrix metalloproteinases. Some endogenous angiogenesis inhibitors are the interferon family (a, h and g), thrombospondin-1 and -2, certain tissue inhibitors of matrix metalloproteinases and protein fragments such as angiostatin and endostatin. During active tumorogenesis the turnover rate of endothelial cells increases up to 50 fold with the formation of a new vascular sprout.

Because a vascularized tumor is capable of increased growth and is more readily able to metastasize, increasing amounts of research are focused on developing treatments to slow angiogenesis and limit tumor growth and dissemination. Nanoparticle based therapy to inhibit tumor angiogenesis is an active field of research and development which has a great therapeutic potential.

Targeting of tumor vasculature may be another mode of cancer treatment. Recent work has also shown that gene delivery may also be targeted to neovasculature by coupling lipid-based cationic nanoparticles to an integrin AVH-targeting ligand in tumor-bearing mice.

Research activity aimed towards achieving specific and targeted delivery of anti-cancer agents has expanded tremendously in the last 5 years or so with new avenues of directing drugs to tumors as well as new types of drugs. Currently nanoparticle loaded drug like paclitaxel is available in India marketed by Dabur India Limited.

Innovative modality like burning of tumor tissue with injection of gold nanorod in the tumor followed by low power laser irradiation may be an important safe alternative to radiotherapy with much less side effects. We have developed such a system (Fig. 127.4).

Caused production of intense heat due to alteration in surface plasma resonance of gold nanorods leading to burning of the impregnated tissue, C. This safer modality can be applied to solid tumor in place of radiotherapy.
Apart from conventional drug targeting innovative methods like magnetic sensor based drug release system, temperature sensitive drug release and other biosensor based system are being developed with multi-functional nanoparticle. In near future it will be possible to replace conventional cancer therapy with these smart multifunctional targeted system with least systemic toxic effect and it may safer than many antibiotic therapy.

SUMMARY

Advances in nanotechnology are providing nanofabricated devices that are small, sensitive and inexpensive enough to facilitate direct observation, manipulation and analysis of single biological molecule from single cell. This opens new opportunities and provides powerful tools in the fields such as genomics, proteomics, molecular diagnostics, drug delivery and high throughput screening. Nanotechnology has potential advantages in applications in POC (Point-of-care) diagnosis: on patient’s bedside, self-diagnostics for use in the home, integration of diagnostics with therapeutics and for the development of personalized medicines.

Laser Applications in Pediatric Surgery

Laser is an acronym which stands for “Light Amplification by the Stimulated Emission of Radiation.” The surgical applications of laser were introduced in 1965 even though the phenomenon was first proposed by Einstein as early as 1917.1,2 Today, lasers have added a new dimension to operative surgery because of greater precision, better hemostasis, lesser tissue damage and a diversity of uses.

**BASIC PRINCIPLES**

Laser energy is produced by the emission of photons from excited atoms. Photons are emission energy made up of electromagnetic waves released by atoms and these propagate with the speed of light (i.e. 300000 km/s). Under normal circumstances atoms are in the ‘ground state’ (i.e. the electrons orbit the nucleus in their respective designated orbitals). An atom gets ‘excited’ when a photon of energy strikes it (i.e. the electron moves from a lower to a higher orbital). The excited atom then releases a photon of energy in order to return to the ground state. This phenomenon is known as ‘spontaneous emission’. Emission of energy can be ‘stimulated’ by striking already excited atoms with photons — the excited atoms then release identical photons and return to the ground state. Lasers work on this principle of stimulated emission. The energy of photons is directly proportional to the frequency and is indirectly proportional to the wavelength. Atoms can be excited by ‘external energy’ which could be in the form of absorption of light, collision with electrons, a chemical process, electricity or nuclear fission. The amplification is done in a resonator or ‘laser medium’ which could be liquid (e.g. dye laser), solid (e.g. neodymium:yttrium-aluminium-garnet) or gaseous (e.g. argon, carbon dioxide). The wavelength of the emitted beam varies with the medium (0.2-10.0 μ).3,4 The laser beam is characteristically monochromatic (i.e. of a single frequency), coherent (i.e. the rays are spatially and temporally in phase) and collimated (i.e. the rays are parallel to each other).

**LASER INTERACTION WITH TISSUES**

The effects of laser on tissues can be photo-chemical, photothermal or photodecomposition. Surgical techniques mainly utilise the photothermal effects for vaporisation, cutting and coagulation (Table 128.1). The laser beam has to be absorbed for it to have the photothermal effect; if it is reflected, transmitted or scattered then it will not have the desired effect. The photothermal effect is governed by several factors including wavelength, mode of operation (pulsed or continuous), power density of the beam and the duration of exposure to the beam (Table 128.2). Generation of smoke, hemorrhage or charring result in scattering, reflection or absorption of the beam and hence the results may be undesirable. Photothermal effects are also modified by the presence of

chromophores (e.g. hemoglobin, melanin, etc.) in the tissues and this phenomenon has been utilized for selective photoablation of tissues, e.g. the treatment of hemangiomas and port wine stains.\(^5\,^6\)

The photothermal effect produces a characteristic lesion. A crater is formed at the centre of impact due to vaporization of the tissue. Immediately surrounding this crater is a zone of cellular coagulation produced by the diffusion of heat and surrounding this area is a zone of cellular edema. Focussed beams are used for cutting and defocussed beams are used for coagulation. The depth of injury will depend on the exposure time.\(^5\,^7\)

There are numerous kinds of lasers but the majority are essentially research tools. The types of lasers which have applications in medical science for clinical purposes or research have been categorized as gas lasers (e.g. Argon, Carbon dioxide, Excimer), chemical lasers, dye lasers, metal vapor lasers (e.g. Copper), solid state lasers (e.g. Nd:YAG, Er:YAG, Ho:YAG), semiconductor lasers, etc.

### LASERS WITH SURGICAL APPLICATION

**CO\(_2\)**

Carbon dioxide, nitrogen and helium are used as the medium in which excitation of nitrogen transfers the energy to carbon dioxide and helium returns it to the ground state. The emitted beam lies in the non-visible infrared range at 10600 nm (heat radiation). This laser is ideal for cutting because of the absorption coefficient and hence the tissue penetration is high and scattering within the tissues is low. 20-100 Watts power is usually sufficient for surgical uses.\(^7\,^8\) However, a very major disadvantage is that it cannot be transmitted through fibreoptic systems and hence needs either an operating microscope or a hand held probe. It has found great applicability in laryngeal and vocal cord lesions. This laser was developed by Patel in 1964.\(^9\)

**Nd:YAG and Ho:YAG:**

Neodymium atoms are used as the laser medium and are incorporated into a yttrium-aluminium-garnet crystal. The Nd:YAG laser emits a non-visible infrared beam of 1064 nm wavelength. Depending on the type of discharge lamp the laser can be continuous wave (cw) or pulsed (p) wave. The laser beam is delivered via a quartz fiber and this makes it ideally suited for endoscopic use. The surgical application of Nd:YAG laser is with 100 Watts power in the continuous mode. This is the most commonly used laser in surgical practice because of its versatility, it can coagulate blood vessels up to 2 mm, cut and vapourise tissues but the drawbacks are that it has a deeper tissue penetration and cause more tissue damage.\(^7\,^8\) The Nd:YAG laser was developed by Johnson in 1962.\(^6\)

**Holmium**

YAG laser is similar to the Nd:YAG laser but it has been found to be better for tissue ablation, renal stone removal and in dentistry. It has now taken over almost all the clinical applications of the Nd:YAG laser. The Ho:YAG laser can produce the same effects of the Nd:YAG laser with a lesser wattage and hence it is safer and less harmful to the surrounding tissues.

**Argon**

Argon ions are used as the laser medium. Two wavelengths are emitted - 488 nm in the blue light area and 514 nm in the green light area. The wavelength is close to the maximal absorption for melanin, myoglobin and hemoglobin and tissue penetration is only 1 mm. Hence, it is a very good laser for pigmenitary disorders and vascular malformations. It can be delivered through a fibreoptic cable and therefore it can be used for endoscopic surgery. The Argon laser generates a lot of heat which needs to be dissipated by an effective cooling system.\(^7\,^8\) It was introduced by Bennett in 1962.\(^10\)

**Dye**

Fluorescing dyes, e.g. rhodamine, stilbene and coumarine are used as the amplifying medium. Using different dyes and pump sources this laser can be tuned within a wide spectral region extending from ultraviolet to near infrared and depending on the pump source it can be either pulsed or used as continuous wave. They can be delivered through fibreoptic cables and hence are useful in endoscopic applications particularly for lithotripsy procedures.\(^7\,^8\)
KTP

When an Nd:YAG laser beam is passed through a potassium titanyl phosphate crystal, it results in a visible beam which has half the wavelength of the Nd:YAG laser beam and it can be delivered through a fibreoptic cable. Tissue penetration is approximately 1 mm deep and hence it is better for coagulation as compared to cutting.\textsuperscript{7,8}

ORGANIZING A LASER SET-UP

Lasers can be extremely dangerous if they are not used properly or if basic precautions are not taken.

Lasers can damage eyes and skin and can cause fires and explosions. The laser beam can be reflected from shiny or smooth unpolished metallic surfaces. Hence, in addition to the safety measures for heavy electric equipment, it is very important to follow the basic precautionary steps specifically for lasers:

1. It is preferable to have a theatre dedicated for lasers. If that is not possible then the staff should be dedicated to the laser set-up so that the basic drill for safety measures is ingrained in them.
2. There should be adequate warning signals when lasers are in use. `Casual’ visitors to the operating room should be discouraged.
3. Laser glasses should be worn by everybody in the room where lasers are being used.\textsuperscript{7,8}
4. Combustible material should not be used with lasers. Endotracheal/tracheostomy or other non-metallic tubes which are likely to be in the field of laser use should be adequately protected.

CLINICAL APPLICATIONS OF LASER IN PEDIATRIC SURGERY

Due to reduced blood loss the operative field is clean and thus lasers help in providing a high degree of surgical precision. The laser technology and the fact that it can have a fiberoptic transmission has given significant advantages and improved the results of surgery in a number of difficult areas and has also opened up possibilities for the treatment of conditions which were considered impossible or very hazardous:

1. Vascular malformations; cutaneous or those which can be reached by endoscopes.
2. Airway lesions; vocal cord nodules, laryngotracheal papillomas, tracheal diverticulum, tracheoesophageal fistula, choanal atresia.
3. Gastroenterological procedures; coagulation of upper or lower gastrointestinal bleeders.
4. Minimally invasive surgical procedures.
5. Resections of solid organs; hepatectomy, partial nephrectomy.
6. Urologic procedures; posterior urethral valves, urethral strictures, ureterocele, bladder tumors and vascular malformations, lithotripsy.\textsuperscript{11}

The photothermal properties of lasers have made it particularly useful in pediatric surgical practice because it provides a high degree of precision and reduces blood loss significantly.\textsuperscript{8}

THE AIIMS EXPERIENCE

The Nd:YAG laser was commissioned at AIIMS in March 1997, and was in use till the very early 2000s. During this time it was extensively utilized by the general surgeons, plastic surgeons, urologists, gynecologists, ENT surgeons, gastroenterologists and of course pediatric surgeons. The author’s experience is summarized in Table 128.3.

The main advantages of laser surgery are that it is bloodless, very precise, does not cause damage to surrounding tissue, there is no morbidity, there has

| Table 128.2 : Factors governing use of Nd:YAG lasers\textsuperscript{7} |
|------------------|------------------|------------------|------------------|------------------|
| Power (Watts)    | Distance (mm)    | Exposure time (seconds) | Interval (seconds) | Mode |
| Coagulation      | Minor bleed      | 30-35    | 2-5             | 0.5-2.0        | 0.2 | P       |
|                   | Major bleed      | 50       | 2-5             | 0.5            | 0.2 | P       |
|                   | General          | 35       | 2-5             | -              | -   | cw      |
| Cutting          | 50-100           | 0.5      | -               | -              | cw/p |
| Resection        | 100-120          | 0.5      | -               | -              | cw   |
been no mortality and the majority of children have been treated as day care cases. It is particularly advantageous in the respiratory tract where congenital and recurrent tracheoesophageal fistulae can be treated endoscopically and without a major operative procedure, thus avoiding considerable morbidity and mortality (Figs 128.1A to C).

In posterior urethral valves and other urethral/bladder conditions the property that the laser can be transmitted through a fibre has been used very effectively. Since the laser does not have a deep tissue penetration and the tissue ablation is bloodless, the majority of urethral endoscopic surgery can be done

**Figs 128.1A to C:** A. Endoscopic view of ‘H’ type tracheo-oesophageal fistula. B. Laser fiber in position inside the fistula. C. Following vapourization of the mucosa

**Figs 128.2A and B:** A. Endoscopic view of tracheal papillomas being vapourized using the laser fiber. B. Following the vapourization the trachea is clean
without postoperative catheterization and the patients can be discharged within a few hours of the surgery. Also, the risk of postoperative stricture formation is negligible.

Similarly, in tracheal lesions, e.g. papillomatosis, the lesions can be vapourized without damaging the surrounding tissues (Figs 128.2A and B). The only draw back is that tissue may not be available for histopathological examination. In tracheoesophageal fistulas, the mucosal lining of the fistula is vapourized thus allowing the fistula to close.

The initial expenditure on the laser machine and the set-up in an existing operation theatre complex is estimated to be approximately Rs. 50 lacs. Hence, considerable thought must be given to the type of laser which is required for the needs of the hospital and a central facility should be created. The recurring expenditure can be minimised by re-using the laser fibers.

**LASER IN FETAL SURGERY**

Lasers have been recently used in fetal surgery for indications that merit antenatal intervention to improve the prognosis. Anterior and posterior urethral valves have been fulgurated with laser beams.\(^\text{16,17}\) Rarely, laryngeal webs have been fulgurated with a laser beam when diagnosed during the antenatal period. Though these conditions can be treated after birth, the condition in vogue today as a preferred indication for fetal laser treatment is twin-to-twin transfusion syndrome.

Twin-to-twin transfusion syndrome (TTTS) is a severe fetal condition that has regained attention since surgical endoscopic treatment proved beneficial.\(^\text{18-20}\)

Selective laser photoagulation of communicating vessels technique has been described for the treatment of twin-to-twin transfusion syndrome that is thought to result from a net transfer of blood from the donor twin to the recipient twin.\(^\text{18}\) It has been reported that laser coagulation of the arteriovenous anastomoses from the donor to the recipient first would result in an improved hemodynamic status and decreased likelihood of intrauterine fetal demise of the donor twin.\(^\text{18}\)

Perinatal survival was significantly higher when treatment was performed in the early stages.\(^\text{20}\) Twin weight discordance and donor fetus intrauterine growth restriction appear to improve after laser therapy for TTTS.\(^\text{21}\) In a 5 year multicenter, prospective, randomized controlled trial with primary outcome variable as 30 day postnatal survival of donors and recipients, there was no statistically significant difference in 30-day postnatal survival between fetoscopic laser photoagulation vs serial amnioreduction treatment for donors or recipients.\(^\text{22}\)

Most series report comparable results with laser photoagulation and serial amnioreduction. However, some authors have reported that laser therapy is associated with better outcomes and less major neonatal morbidity.\(^\text{23,24}\) The perinatal survival rate varies from 65-70%.\(^\text{20,25}\)

The percutaneous technique has gained wide acceptance, with an acceptable risk of maternal morbidity but a significant risk of miscarriage (6.8-23%) or preterm rupture of the membranes (5-30%).\(^\text{25}\)

In a review of perinatal outcome of 1300 TTTS cases treated by laser from 17 publications, with a median perinatal survival rate of 57% (50-100%); brain lesions were present in 2-7% of the survivors at the age of 1-6 months.\(^\text{25}\) Other complications reported include Pseudoamniotic band syndrome (1.8%) and TTTS cardiomyopathy in recipient survival.\(^\text{22,26}\)

**ACKNOWLEDGEMENT**

This chapter was first published in Textbook of Neonatal Surgery, Ed., DK Gupta, Modern Publishers, New Delhi, 2000. It is being reproduced with kind permission of MBD publishers.

**REFERENCES**

The story goes that, some one hundred years ago, a Californian farmer approached for the first time a curious instrument called "telephone". Being the operator temporarily away he managed on his own: he scribbled few words on a sheet of paper, rolled it up and poked it into the receiver with all the gentleness typical of the rugged Westener. Needless to say, his message encountered some problems getting through this new technological gadget: the same problems that many "computer greenhorns" likewise experience when sitting for the first time in front of the fiendish instrument. Hence the funny stories of people using as a "cup-holder" the sliding driver for CD/DVD, or searching desperately for the key "ANY" - among the various CTRL, INS, DEL, ALT keys - to comply with the message "press 'any' key to continue".

As a sort of retaliation to the binary system being at the basis of the computer science, understanding only "0" or "1", "on" or "off", "true" or "false", it seems that the feeling of the common people towards "the computer" splits in only two definite and mutually uncommunicative groups: the one of "computer-addicts" - sharing with their instrument a feeling dangerously near to the romantic love - and the one of "computer-convicts" - curtailing their approaches to the intimately hated machine at the very minimum exacted by the circumstances.

Physicians in general and pediatric surgeons in particular can be as well roughly divided in these two groups. "Computer-addicts" will forejudge this chapter absolutely elementary if not definitely useless, while "computer-convicts" will expect something esoteric, dealing with topics fully unrelated to their daily job, and hence again definitely useless. In spite of that, what follows presumes to present an overview - basic but hopefully not too sketchy - of the extremely various ways in which a physician in general and a pediatric surgeon in particular can interact with a computer, offering to the "addicts" some remarks and tricks of interest, to the "convicts" some hints and incitement to brave the unappreciated but, all things considered, indispensable tool.

In order to explain as clearly as possible the subject this chapter will be divided in three main parts, dealing respectively with the computer used as "standalone" (i.e. as a single, isolated apparatus not connected with others), with the computer used as an element of the hospital information system (the so-called "Intranet") and eventually with the computer acting as a way to navigate the fascinating world of Internet. It must be emphasized again that this subdivision is aimed merely to schematize the matter and hasn't any substantiation in the general practice (the same computer can obviously be used as standalone and to access Internet). Every part will be subdivided in paragraphs with a question as a heading, just to emphasize the practical layout of this chapter trying to give some answers to the many questions that computer technology can raise. At the end of the chapter two appendices will help: (1) to wriggle out of the jungle of computer science technicalities and acronyms (terms described in this glossary are followed in the text by an asterisk); (2) to avoid some computer-related troubles.

**STAND ALONE**

**What is a computer?**

A computer is an electronic apparatus structurally similar to a TV set, a HiFi player, a mobile phone that simply has been designed to perform different tasks.
As all machines, it has no discretional capacity whatsoever: paradoxically, a computer is rather "stupid" machine understanding only two statuses, "on" or "off", "passage" or "non passage" of electricity in a circuit. These statuses can be expressed also with the digits "1" (on) or "0" (off), that constitute the so-called "binary system", by which an infinite set of numbers can be written using only "bits" (Binary digITS, 0 and 1). Arranged in blocks of 8 bits, called "bytes", these numbers are used to draw sets of instructions enabling the computer to perform an enormous amount of activities. These instructions are listed in sequences (named "algorithms" from the name of the Arab mathematician Muhammad ibn Musa al Khuwarizmi, who lived in Baghdad in the first half of IX century), structured according to arithmetical and logical rules into different sets of instructions named programs, each one intended for a particular task. Thus, although apparently quite different from each other, activities of a computer can basically be traced back to computing and rearranging at a terrific speed. For example, simple numerical data used to express figures, letters, pictures, sounds, etc.

Tangible components of a computer system are defined the hardware, while intangible programs that let the hardware work are called the software.

**From where computers evolved?**

Modern computers are the evolution of a long series of computing machines, dating back from the Babylonian abacus of the X century BC through the "Pascaline" designed by B Pascal in 1642, the punched cards ideated in 1887 by H Hollerith and used in the 1897, USA, census operations, until the first electronic computer realized in 1946 by JW Mauchly and JP Eckert at the Moore School of Electrical Engineering of the University of Pennsylvania for the negligible sum of well over 5 millions US$ (!). The ENIAC (Electronic Numerical Integrator and Computor - sic!) was able to perform 100 operations per second through 20 registers of 10 digits, 18,000 thermionic valves, 70,000 resistors, 10,000 capacitors and 6,000 switches for a total RAM of 18 Kbytes. It was not exactly an handy tool: hosted in a 200 m² university gym needing an heavy air-conditioning for the huge amount of heat produced by the valves, 30 mt long and 2.5 mt wide, it weighed 35 tons and consumed 140 kW. Wiring of the ENIAC was so complex that it wasn’t at all unusual to find a dead bug short-circuiting two valves thus causing whimsical effects: hence the word "debugging" used till now to mean search and correction of hidden mistakes and faults ("bugs") in computer programs.

Trying to foresee the future of computers, the journal "Popular Mechanics" in 1969 optimistically observed "While ENIAC has 18,000 valves and weighs 30 tons, future computers will have only 1,000 valve and will possibly weigh only one ton and half". Invention of transistor - instead of the huge thermionic valve - and of silicon technology for microcircuitry - instead of the many km of electrical wiring needed by the ENIAC - altered just a bit this prediction: the Pentium Pro processor hosts 5.5 millions of transistors in an area of 306 mm² (2 × 1.5 cm) with an external cache of 31 millions of bytes. To visualize the hectic pace kept by computers’ evolution-schematically represented in Tables 129.1 and 129.2 — it has been observed that first computers were computing in milliseconds, modern ones in nanoseconds: ratio between the two time units is the same than the one between two years and a minute! If aeronautics had the same evolution, today a Boeing 737 would cost less than 500$ and could complete the round-the-world flight in 20 minutes consuming 20 litres of kerosene. All this well justifies the observation that, after agricultural and industrial revolution, computer science revolution is the third fundamental revolution of mankind civilization.

**How many types of computers do exist?**

There are many categories of computers, subdivided according to the computing power and the utilization. This distinction can sometimes be rather vague, but some reference categories can be indicated:

**Supercomputer**

It’s an elaboration system planned to obtain extremely high calculation powers. Until the early 90’s those computers were just built with more sophisticated hardware than common computers. Today, instead, most of them are based on hundreds of thousands of calculation units not much more powerful than a good personal computer working together. Due to the current speed of the technological development in computer science and microprocessors field, they
usually lose the "Super" prefix after few years from their birth.

**Mainframe**

Those are big computers used in government administrations, large companies, banks, wherever a centralized running of a huge data processing network system is needed. Mainframes are direct successors of the first large computers, and still maintain their basic structure with a central machine linked with several secondary terminals.

**Workstation**

Direct consequence of the minicomputer (an appliance midway from a PC and a Mainframe), it’s considered like a more powerful version of a PC, engineered for a specific task and provided with purpose-built software. They are often present in research laboratories and in universities, used for heavy duty calculations or for advanced graphical purposes (virtual sets, multimedia editing, movie special effects, etc.).

**Personal Computer (PC)**

This term, once a trademark of IBM, denotes the computer we are used to have at home or in office, used for one of the many tasks mentioned afterwards. Put on the market in 1981, the PC was designed for the use in small companies or as a home gadget whose tasks were rather obscure ("recipes archive" was one of the suggested uses!). So minimal was IBM
confidence in this new product that they didn’t even bother to develop a dedicated operating system. It was in fact adopted a system already present on the market, the MS-DOS written by a small software house called MicroSoft, owned by a young man on his early twenties bound to become the richest man in the world, Bill Gates.

In the slowly developing market of the PC the MS-DOS established itself as the standard; computers working with this system were called “IBM compatibles”, while all machines working with other operating systems were soon turned out the market. Only exception to this rule was represented by the Macintosh (or “Mac”) produced by the Apple Computers since 1984 and still present on the market with the iMac and PowerMac. The Mac, although similar to the PC, is not usually defined as such, considering this term as synonymous with ”IBM compatible”. Most of the PC are “assembled” computers, i.e. computers realized assembling parts produced by different manufacturers, while the Macs, as well as the laptops, are only branded goods: for this reason the former are cheaper than the latter.

Among PC there is another classification related to the shape and dimensions of the computer:

- "Desktop" is defined a computer with horizontal box; originally all computers were as such, while now there are more diffused models with vertical box, the “Tower Computers”, occupying less space on the desk or positioned on the floor. There are the sizes, minitower, miditower and fulltower (or Bigtower) according to the number of the appliances hosted inside.
- Portable computers (Laptop) are suitable for users needing to move around with their computer at hand; an internal battery with some hours of autonomy allows using the computer also during transfers. To maintain this autonomy it is advisable to let the battery go completely flat at least once a week. Laptops can be used also on the airplanes once the permission is obtained from the crew. In recent models, more and more lights and thins, are also known as ”Notebooks”.
- PDA (Personal Digital Assistant) once known as “Palmtops” or ”Pocket PCs”, are the evolution of the pocket electronic notebooks able to perform some basic computer functions such as Internet navigation, e-mailing, word processing in addition to the normal notebook functions (schedule, phonebook, reminder, calculator). Usually endowed with both keypad and touch screen, and small enough to stay in one hand, they implement most of the functions of a PC and all the functions of a cellular phone. It’s easy to imagine why they are one of the most promising branch of modern informatics.

**How does a computer work?**

Basically, a computer is an instrument that receives data, process and stores them and as a result gives back the processed data. To do so it needs devices to introduce the data and to give them out, the so-called input/output devices (I/O); systems to memorize these data (disk drives, streamers, etc.) and finally a central core where these data are processed, usually contained in a desktop or tower case. All devices not pertaining to this central core are defined ”peripherals”.

Let’s remove the cover of our desktop and have a look inside it (if you want really do that, remember beforehand to pull out the plug!). In a basic setting you will find on the back slots for add-on cards and a power supply with a transformer and its cooling fan, on the front the sliding holder for the CD/DVD and some USB ports, in the middle a large printed circuit board that houses all the circuitry, called the motherboard. The motherboard contains the CPU, the real ”brain” of the computer that executes instructions of the various programs and supervises the functioning of all the system, as well as other chipsets, cache memory and BIOS. Directly attached to the motherboard or, more often, through separated expansion cards we will also find connections to the various I/O devices that allow the computer to interact with the outer world (pediatric surgeons among it!): display adapter card for the monitor, video acquisition cards for retrieving images from a recorder or a TV set, audio card for the recording or reproduction of sounds and music, SCSI cards to control devices needing particular speed in data transfer, etc.¹

**The Central Processing Unit (CPU)**

The CPU is a microprocessor (Intel compatible for the Microsoft Windows system, Motorola compatible running MacOs operating system) whose internal activity is synchronized by an electric signal, called
clock, made by extremely rapid impulses each one corresponding to one elementary operation. Speed of the clock is measured in MegaHertz (MHz) or, more recently, in GigaHertz (GHz): the higher the value of the clock the faster the computer. CPU speed doubles approximately every 12 to 18 months (Moore’s law): the fastest CPU now available, with a clock of 3 GHz, is able to perform some 3 billions operations per second. A CPU is composed by: (a) a control unit; (b) an arithmetic/logic unit (ALU); (c) a work memory, divided in two parts, one smaller not transient and one bigger whose contents disappear when the computer is switched off. The first is called ROM (Read Only Memory) and contains the basic routines for the functioning of the computer. It runs the boot program at the switching on and controls at the lowest level all the components and peripherals of the computer. This part of the memory maintains its contents unchanged, when the computer is switched off and cannot be modified by the user to avoid unfortunate troubles. The remainder of the memory, called RAM (Random Access Memory) can on the contrary be read and written, and is the memory where are the data temporarily store under processing and the instructions of the program used for that particular process.

For example, to write a letter the CPU loads a program used for typing (word processor), receives the input from the keyboard, converts letters in numerical code (usually ASCII), arranges the report according to the instructions of the word processor and stores temporarily what results in the RAM. When the user launches the order to “save” his work, the letter is copied from the volatile memory of the RAM to the permanent memory of the hard disk or removable device such as a pen drive. Hence, the fact that, in the event of a blackout while working with a computer, the data contained in the RAM and not yet saved on a disk are lost. Why then not to give up the RAM and to work directly on a disk? Because writing/reading from the RAM is enormously quicker than writing/reading from a disk (some hundreds of thousands times quicker). RAM capacity is measured in MB; the last generation of operating systems (like Windows XP, old Linux, or Mac OS X 10.4 "Tiger" for Apple Macintosh) worked with RAMs of 128 to 512 MB. At now, most of the common PCs have 1 GB RAMs (512 MB at least are needed to run the base versions of the last OS, like Leopard, successor of Tiger, and Windows Vista), that, thanks to the dual channel technology, can easily be extended to 3-4 GB in about 20 minutes of do-it-yourself on the insides of your computer. If this capacity is not enough to contain all the needed data, the CPU runs an operation called “swap”, by which part of the content of the RAM is temporarily copied on a disk and then retrieved when needed, thus freeing some space in the RAM. Obviously this time-consuming operation is more often required when the RAM is scanty, and then the bigger the RAM (within certain limits) the quicker the computer.

RAM dimension and CPU speed are precisely the two main parameters in defining a computer performance.

Mass Storage Devices

Mass storage devices can be divided in four main categories:

I. Magnetic Disks

Those are disks in which data are memorized magnetizing their surface by a writing/reading head. Data can be written and cancelled as many times as desired without wearing the support. Magnetic disks are nevertheless volatile: a huge magnetic field can destroy in few seconds the entire content, therefore they must be kept well away from possible sources of magnetic field (magnets, power supply transformers, electrocardiographs, etc.).

The hard disk (HD) is the permanent memory of the computer, where programs, data and documents are stored. HD are manufactured in two technologies, EIDE and SCSI: the latter are faster but a bit more expensive. The HD is the only major component with moving parts subject to failure: being the storage of an often invaluable amount of data and documents, is strongly advisable to back up all critical data in some other removable media to be kept in a safe place, away from excessive heat, humidity or magnetic fields. The best solution is to have a second hard disk, external to the PC, with independent electric input and to be connected via an USB port; available are also compact external hard disks, smaller than the standard external HD, not needing an independent power supply but powered directly through the USB port. Hard disks capacity is measured in GB: models now available have
usually up to 250 GB (billions of bytes) of capacity for the internal disks, and up to the incredible capacity of one TeraByte (a thousand GB, or one thousand billions of bytes!) for the external ones.

II. Removable Memory Devices

Removable memory devices such as floppy disks, zip disks and LS-120 and Jaz disks, in wide use till few years ago, have been totally superseded by the USB flash drives.

They are flash memory data storage devices integrated with a USB connector, typically small, lightweight, removable and rewritable. (USB Memory card readers are also available, whereby rather than being built-in, the memory is a removable flash memory card housed in what is otherwise a regular USB flash drive). USB flash drives offer potential advantages over other portable storage devices, particularly the floppy disk. They are more compact, faster, hold more data, are more reliable due to their lack of moving parts, and have a more durable design. Additionally, it has become increasingly common for computers to ship without floppy disk drives. USB ports, on the other hand, appear on almost every current mainstream PC and laptop. With nothing being mechanically driven in a flash drive, the name is something of a misnomer. It is called a "drive" because it appears to the computer operating system (and the user) in a manner identical to a mechanical disk drive, and is accessed in the same way. An account on all technical details can be found at the site http://en.wikipedia.org/wiki/USB_flash_drive.

III. Optical Disks

These are disks in which memorization is done through a laser beam that "carves" the shiny surface, thus becoming dull. Usually they are of the WORM type (write once read many), although now are available disks (CD-RW) that can be re-written for a limited number of times (due to the low cost of the standard disk, their use is not advisable; moreover, they have been largely ousted by pen drives).

CD-ROM: They are exactly the same disks used for music recording, typically contain 650 MB (corresponding to 74’ recording) and are very cheap. They can be read in dedicated drives, marked 20x, 32x, 52x: these numbers indicate the reading speed of the disk, being 1x the reading speed of the standard audio CD. Masterizers drives are used to write on an empty CD: writing on a CD is a delicate operation that cannot be interrupted for any reason, otherwise all the CD will be spoiled.

Mini CD are CD with reduced diameter (8 cm) and contain up to 180 MB or 21’. Are compatible with standard CD drives, except for the drives loading through a slot and not with a sliding holder.

DVD externally identical to a CD, can hold from 9 to 17 GB. In addition to be used to store digital movies, they can be used as well for storing large amounts of data; the only problem is that a definite standard does not exist yet. To be read a DVD requires an appropriate drive (normal CD drives cannot read a DVD, while a DVD drive can read a normal CD).

IV. Magneto-optical Disks (MOD)

Magneto-optical disks are magnetic disks that can be written only at high temperature with a laser beam, and cannot be erased by magnetic fields. They are scarcely diffused, being ousted by the CD-ROMs, and are used mostly for the storage of large amounts of data in safety conditions.

Input/Output (I/O) Devices

To interact with a computer the pediatric surgeon, as well as all other users, needs devices to input data and to retrieve results. I/O devices, listed in Table 129.3, are connected with the motherboard by special "sockets" called ports. Ports are divided in parallel (LPT) with 25 holes and "serial" (COM) ports with 9 holes; before connecting a new I/O device to a port the system must be switched off. Keyboard and mouse can be connected through special PS/2 ports or more often through an USB port, used also to accommodate digital cameras, printers, scanners, etc.; to plug / unplug a device into an USB port there is no need to switch the computer off.

- Keyboard is usually connected to a PS/2 special port. It can have 101 or 104 (Windows adapted) keys, divided in four groups:
  1. Function keys (F1, F2, etc.), placed in the upper row, their exact function depends from the
program used in that moment. The F1 key in almost all programs is used as the "help" key, opening a file giving instructions on how to use the program itself. Its use is strongly advised when approaching a program little known.

2. **Alphanumeric keys** in addition to the standard keys (such as in a typewriter) there are the modifying keys CTRL ("Control") and ALT ("Alternate") that, together with the SHIFT key, are used to modify the function of other keys, according to the program used in that moment.

3. **Number keypad** located on the right side of the keyboard, is a simple duplication of the numeric keys (on the second upper row), for user’s convenience. To this purpose the "BLOC NUM" key, located on the left upper hand corner of the number keypad, must be pressed (warning light on).

4. **Cursor keys** between alphanumeric and number keypads are located the keys used to shift cursor and pages. In some keyboards cursor keys are included in the number keypad; to be used as such the "BLOC NUM" toggle key must be off (warning light off).

- **Monitor** is the main interface between user and computer. The most diffuse type is probably still the cathode-ray tube, the same as old television screen, but it’s been slowly replaced, as it becomes more and more obsolete, by (Liquid Crystal Display (LCD). In a computer’s monitor, images are composed by a grid of dots, each one called "pixel". The highest the number of pixels, the highest the sharpness of the screen images; today’s LCD screens support resolutions from 800 × 600 to 1920 × 1080 pixels, and even further for special applications.

- **Printers** can be divided in three main categories:
  1. **Dot impact printers**: old type printers, totally outdated because slow, noisy and of poor quality results.
  2. **Laser printers**: They share technology with photocopiers: fit for high volume of prints because it is quick and noiseless, and with results of the highest quality. More expensive than dot impact printers, particularly if color printers.
  3. **Inkjet printers**: Slower but cheaper and smaller than laser printers, they work spraying an extremely thin jet of ink on the paper, giving a print of good quality although slightly less than laser printers. The best solution when colour print is requested.

- **Plotters** are a particular type of printers using ink nibs to draw on wide size sheets.

- For what purposes a computer can be used?
  It is quite difficult to enumerate the ways in which a computer, also if used just as a standalone, can be useful for a pediatric surgeon. Very schematically we can identify some basic activities:

---

a. Text processing (word processor)
b. Images processing and CAD
c. Calculations (spread sheet)
d. Data recording and retrieving (database)

Each one of these tasks needs a dedicated program: it is well outside the scope of this chapter to elaborate how to use each one of them, and therefore we will give only some elementary advice. The first one is condensed in a famous acronym, reading RTM (Read the Manual), or in a more gross version, RTFM (we leave to the reader’s fertile imagination realizing what the F stands for!). In other terms, before loosing time and hopes trying to get out from a program seemingly mocking you, have a look at the manual. Almost all programs are provided with an on-line help, which typically can be opened by pressing the F1 key; some sophisticated on-line help programs allow to directly formulate a question, while others are more schematic. For people starting from scratch it is advisable to read beforehand some written instructions: far better are the simple booklets explaining just the basics, available in all specialized bookshops, rather than the ponderous tomes sometimes enclosed in the program package.

Basic programs are now often sold in comprehensive packages including a word processor, a spreadsheet, a database, etc. Characteristic of these packages is that fundamental instructions, as well as the graphic presentation of the commands, are the same in various applications so as to simplify their learning and use. For example, in all MS-Office environment applications, pressing simultaneously the keys "Ctrl" and "C" (Ctrl+C) after selection of a text or an image copies it in the computer memory, Ctrl+X cuts the selected items (deletes and copies in the memory; this item remains in the memory until a new item is overwritten or the computer is switched off), Ctrl+V retrieves what has been copied and paste it somewhere else (also in a different file), Ctrl+Z undoes the last action made, etc.

Images Processing and CAD

The market offers plenty of programs for images processing, to be used for various tasks. Most useful for pediatric surgeons are programs: (1) to frame and store clinical images, taken directly in the theater or in the ward by a digital camera or a standard camera, to be then digitized with a scanner (e.g. Photoshop); (2) to prepare presentations for a congress or a lecture, either in slides or directly through a LCD beamer (e.g. Power Point). For pediatric surgeons involved in teaching and lecturing, it is highly advisable to build up a virtual library of such images, framed and stored in appropriate indexed files, to be retrieved for inclusion in presentations easily changed and adapted according to the needs. While preparing presentations, it is recommendable to avoid busy slides with crowded tables, long texts, showy colors (eventually illegible); ideal is considered a text no longer than six lines of seven words each per slide.

A particular field of image processing is represented by the computer-aided design (CAD), a software realized for professional design and planning, as well as for virtual reality applications. Through this technology, computers are able to reproduce objects and situation with astonishing three-dimensional realism. In pediatric surgery, CAD has been used to develop a virtual model of an infant’s body wall, stomach, and hypertrophied pylorus as well as laparoscopic cannulas and two experimental sets of retractable hook for laparoscopic treatment of hypertrophic pyloric stenosis. Tridimensional visualization and computer-assisted operational...
planning based on CT data are being increasingly used for difficult operations in adults, and an initial experience with 3D-visualized MRI with volume rendering in planning pediatric abdominal surgery has been described, as well as a computer-assisted navigation system in pediatric intranasal surgery, realized utilizing a wireless passive marker system that allows the calibration and tracking of virtually any instrument, adapted to children and used during pediatric endoscopic sinusonasal surgery.

Calculations

"Computers" draw their name from making calculations, or computing; that actually was their first task, and the conquest of the moon would have been impossible without computers. It is rather unlikely that pediatric surgeons will need to undertake this kind of calculations, but a "spreadsheet" will turn out to be rather useful to them in many ways. With this term is defined a program (e.g. MS Excel) presenting an array of squares, called "cells", arranged in rows and columns identified respectively by a number and a letter, exactly as in the warships game. Cells can be linked each other by a mathematical, logical or statistical formula, and a number input in a cell will automatically change the content of all linked cells. For example, a spreadsheet can be programmed so as the input of weight and height of a patient will give as output body surface, caloric needs, quantity of intravenous drips and drugs' dosages. This latter task is particularly helpful in the running of complex multidrugs protocols, such as in pediatric oncology. Moreover, spreadsheets are indispensable in the everyday administrative management of a clinical ward, particularly if the DRG system is adopted (DRG encoding is elaborated by a specific software called grouper). As an added benefit, most spreadsheet programs include also utilities for standard statistical data elaboration; for more complex calculations it is possible to export the relevant fields of a database into a spreadsheet, having higher calculus power and flexibility.

Data Recording and Retrieving

French term for "computer" is "ordinateur", i.e. "orderer", "sorter", thus emphasizing one of the earlier tasks given to computers, to store huge amount of data and to sort them according to a particular order (alphabetical, chronological, etc.) with special programs named "databases" (e.g. MS Access). These data are grouped in logical sets, named "files", each one divided in single entities named "records", each one in turn subdivided in different parts named "fields". For example, patients' archive of a hospital can be divided in one "file" per department, each single patient's data collected in a "record" containing various "fields" (name, date of birth, diagnosis, etc.). Former paper archives were formed by file-cards ("records") arranged according only to a single field, and to have the same amount of data arranged in two different ways implied to double literally each file-card. A typical example was that of libraries, needing an author catalogue and a subject catalogue, arranged in two different cardholders, the more awkward to use the many file-cards were contained. On the contrary, a computer database can record an almost unlimited number of data, which can be quickly retrieved according to each one of the fields by which records are composed. On this subject, it is advisable not to exceed in the number of fields per record (say, 50 to 100 maximum), not to slow the data processing. If a higher amount of fields per record is required, it is better to create two different files with two parallel sets of records linked by a shared field. For example, if I need to record 300 different parameters for each patient included in a trial (rather complex a trial, I must admit!), it is better to split these parameters in two or three subgroups and to store the data in two or three different files, with the name of the patient acting as a shared field in all three sets of records. A database allows unsophisticated numerical elaboration of the contained data; for more complex calculations it is possible to export the relevant fields of a database into a spreadsheet, having higher calculus power and flexibility.

Databases are meant to store and retrieve data put in manually (patients' records, scientific experiment results, addresses of colleagues, etc.). Moreover, the computer allows retrieving data already gathered and digitized in form of electronic encyclopedias, medical treatises, MedLine collection of medical abstracts, anatomical atlases, interactive dictionaries, etc. Typically these data are multimedial, i.e. composed not only by text but also by pictures, videos, sounds, and are contained in a CD-ROM whose sophisticated
Pediatric Surgeon and the Computer

The internal architecture allows condensing in a single disk the equivalent of up to one or two dozens of volumes. The most attractive feature presented by this system of data retrieving is the possibility to carry along in a compact DVD case the equivalent of a small library, at hand - with a laptop available - almost everywhere.

On top of these basic, general activities computers can intervene in so many other medical fields to foster the creation of a scientific society devoted to this very issue, the International Society for Computer Aided Surgery (http://www.iscas.net/), with the mission to encourage scientific and clinical advancement of computer-aided surgery and related medical interventions throughout the world. According to the statutes, the scope of Computer Aided Surgery encompasses all fields within surgery, as well as biomedical imaging and instrumentation, and digital technology employed as an adjunct to imaging in diagnosis, therapeutics, and surgery. A quick survey of some of the papers published on the last available issue [13 (2), 2008] of the society’s journal, Computer aided surgery, published six times a year in simultaneous print and online edition, can offer a rough idea of the front-line researches on this field: "Providing metrics and performance feedback in a surgical simulator", "Virtual reality-enhanced ultrasound guidance: A novel technique for intracardiac interventions", "Surgery with cooperative robots", "Multimodal virtual bronchoscopy using PET/CT images", "Electromagnetic navigation improves minimally invasive robot-assisted lung brachytherapy", and so on. Quite a long way from the "recipes archive" before mentioned.

INTRANET

The term of "Intranet", clearly derived from the one of "Internet", describes the informatics technology system of a definite and restricted area, such as for example a factory or an office block. In medical field it defines the connecting system of all the components of the so-called Hospital Information System (HIS) (Fig. 129.1).

Conventional organization of medical services currently relies on paper documents as a storage medium of clinical data and on physical transport of the information (sheets of paper) as a communication system. In this traditional framework, the patient acts as "deliveryman of himself", first moving himself as a source of medical information (for example, going to the radiologist for a chest X-ray) and then moving the medical information he generated (bringing back the radiograph to the ward). Obviously this system
implies delays, nuisances for the patient, difficulties in data storage and retrieval: all troubles that pediatric surgeons working in a hospital know well.

HIS aims to realize a computerized system in which information are as digitally formalized as possible and therefore amenable to be treated with computer technology. In detail: (a) a computerized clinical management system (biomedical data input, case sheets); (b) a patient accommodation management system and a hospital administrative system; (c) an integration of all hospital services (biomedical, administrative, accommodation) through dedicated hardware and software linking all hospital departments.

What can a Medical Intranet be used for?

A fully operational HIS is expected to perform a good array of different tasks, such as:

2. Optimal utilization of all hospital structures.
3. Transmission of biomedical data in real time.
4. Better assistance and monitoring of the patient.
5. Home assistance via telemedicine apparatuses.
6. Computerized database of general archives of the hospital data.
7. Computerized lecture halls for training of medical and paramedical personnel.
8. External gateways for connection to Internet - Medline.
10. Management of emergency network (ambulances, helicopters, first aid teams, etc.).

Computer-based Patient Records

Medical computing allows realizing an electronic case sheet (including history, surgical report, daily report, lab results, digitalized X-rays, etc.). The system can also aid clinicians in the areas of billing, documentation, reporting, and data retrieval. Value-added features like decision support and event monitoring facilitate patient outcome, decrease health care costs and allow improved administration. Problems in security and confidentiality of clinical data introduced in the system must be always carefully considered. Time-saving for redaction of a computerized discharge letter and a surgical report was quantified respectively from 66 and 37 to 24 and 14 minutes (p < 0.0001). Computer technology includes bar code-based electronic positive patient and specimen identification systems, utilized to reduce identification errors in the daily management of laboratory specimens. A 3-year study conducted in a pediatric oncology hospital showed a significant reduction in the median percentage of mislabeled specimens, with a decline from 0.03% to 0.005% (P < 0.001).

Computer-assisted Diagnosis/Expert Systems

Ability of computers to deal easily with huge amounts of data has fostered the development of plenty of programs intended to enhance the diagnostic capabilities of many electromedical tools, urodynamics, rectal or anal manometry among many others. These programs are usually part of a HIS, but can run also on a standalone computer. Also the sophisticated image-processing possibilities offered by computers has been extensively utilized in various pediatric surgical fields, such as computer-assisted analysis of lung area in infants with CDH, advanced-stage neuroblastomas, tumor volume determination, hepatic hilar bile ducts in biliary atresia, ischemic injury to the gut, etc.

Expert systems, intended as a computer program able to suggest directly a diagnosis once acquired a sizeable amount of patient’s clinical data, have been extensively studied and implemented in the last years but recently have fallen a bit into disuse. This because expectations were possibly too optimistic: variables to be taken into account while diagnosing a disease are far too many, and only few can be fully expressed in digits, the only input a computer can understand. Nevertheless, research in this field is still in progress, although no experiences are recorded in pediatric surgery.

What is needed to implement an intranet?

Hardware components needed to realize practically a HIS are:

1. Communication infrastructure or Local Area Network (LAN): A LAN can be technically realized with wired transmission (twisted pair or coaxial cable), fiberoptic cable or radio link (mobile phones). The more reliable medium for a LAN is considered to
be fiberoptic linkage, allowing a transmission speed up to 20 MB per second.

2. *Data I/O terminals acting as sources/destinations of information.* Radiology dept. with scanners or digital radiological equipment, laboratory instruments with digital output of results, admissions office, theater, nuclear medicine dept. etc.

3. *Patient monitoring devices:* ECG, oxymeter, thermocouple for temperature check, etc.

4. *Data Management Center:* running and maintenance of the HIS, data storing and management.

5. *External gateway:* Connection with the external network → Intranet - Internet linkage.

**INTERNET**

In the 1960’s, the coldest years of the cold war, a nightmare facing military intelligence was a complete breakdown of a centralized communication network in the aftermath of a nuclear holocaust. The notion of creating several nodes of super computers that convey each other through standard telephone lines was thus developed and realized in the USA: ARPANet, the Advanced Research Project Agency Network (1969). It was a distributed network, without a centralized and vulnerable branch point but with all nodes equally able to put through all information sending the data in small packages that would meet at the other end of the line, in order to stand a nuclear attack and to be able to run on also after the destruction of part of the system. This technical solution was so brilliant, particularly for its modular structure allowing a simple and quick development of the system, that soon after many other networks were established, essentially for military and research purposes.

In the 1980’s the networking was already so extended that ARPANet architects realized the need of using a uniform protocol of communication and regrouping data packages, to allow the different networks to "understand" each other and to guarantee the interchangeability of communication: it was thus created the Transmission Control Protocol / Internet Protocol (TCP/IP). This protocol immediately became the international standard for all networks in the meanwhile developing in many countries, thus allowing the development of a worldwide network using the same modular architecture and the same "language", named precisely Internet. Its potentiality in terms of real-time transmission, extent of audience, unrestrainable contents was dramatically tested in 1991 during the attempted coup d’etat in the former USSR. With Gorbachev under arrest and the KGB having censored the press and cut off all radio and phone communication lines with the rest of the world, the RelCom, a small factory in Moscow connected via e-mail to the Internet - and therefore to hundreds of thousands people, at that time, turned out to be the only link with the outer world. A handful of people, sending in Internet hourly messages disclosing what was going on, was able to defeat the powerful KGB which paradoxically had its headquarters few hundred meters away from a networked computer, a unknown weapon destined soon to change the world.

In the same years (1989-1991) at the CERN laboratories in Geneva, Switzerland, Tim Berners-Lee and coworkers were developing the World Wide Web (www), the ultimate and most versatile resource of the Internet, used to publish information that can reach and be accessed in almost every corner of the planet, organized in sets of one to hundreds of pages each, called sites. In 1993, there were 130 sites available, in 1994 some 3,000, in 1998 10,910,997; in 2002 the total number of webpages available in Internet sites, well over 6 billions, exceeded the number of people on the whole Earth! Total number of Internet users grew in parallel, now reaching more than a billion people scattered from Afghanistan to Zimbabwe (first and last world country in alphabetical order), as detailed in Table 129.4.17

Today, Internet is so deeply intermingled with everyday life’s events that we can assume it as a reliable gauge of their overall impact. A dramatic example of that is shown in Fig. 129.2, plotting internet performance the 11th of September 2001. Few minutes after 9:00 a.m., New York time, a sudden drop in Internet reachability was recorded, due to the enormous amount of people crowding the Net trying to find there in real time a clue on what was going on. The first stroke sensibly decreased Internet performance, but within one hour the shock was deaden and the Net was running again smoothly: a further brilliant proof, if yet needed, of Internet’s intrinsic strength.
But Internet presents also a dark side: web involvement in our lives is so deep to induce even behavioral changes, particularly among children and adolescents that, according to a recent Italian study, spend on the Net an average of 22 hours/month for children, with a jump to 87 hours/month for adolescents. A new psychopathology has been described, the Internet Addiction Disorder, particularly affecting nightly users of the Net, diminishing patients’ individual quality of life and disabling their time control. Mental impact can be so devastating to induce the so-called "Net suicide": suicide pacts that are prearranged between strangers who meet over the Internet. Japan has one of the highest "Net suicide" rates in the world, particularly among adolescents: as many as 60 people a year have died of this method and the numbers continue to rise.

**What do I need to get connected with internet?**

To gain access to Internet you will need a telephone line or a wireless connection, hardware, software, and a service provider. Telephone line should be an ISDN or DSL dedicated line allowing a faster communication with the service provider and the use of the telephone while connected to the Internet (ISDN) or a 24 over 24 hours link with the provider without interfering with the telephone (DSL). Usual telephone lines on twisted pair are painstakingly slow in connection.

**Wireless connection:** A wireless LAN or WLAN is a wireless local area network, which is the linking of two or more computers - one of which is the server of the service provider - without using wires. WLAN

**Fig. 129.2: Internet reachability the 11th September, 2001**
utilizes spread-spectrum or OFDM modulation technology based on radio waves to enable communication between devices in a limited area, also known as the basic service set. This gives users the mobility to move around within a broad coverage area and still be connected to the network. For the home user, wireless has become popular due to ease of installation, and location freedom with the gaining popularity of laptops. Public businesses such as coffee shops or malls have begun to offer wireless access to their customers; some are even provided as a free service. Large wireless network projects are being put up in many major cities.

Hardware is exactly the computer described before under "standalone", simply supplemented with a modem providing the telephone line communication or with an expansion card connecting the computer to a LAN, or else with an internal antenna to link to the WLAN. Modems can be external (hosted in a box to be connected to the computer through a port) or internal, located on a slot into the computer box; the former is easier to check and to maintain, the latter less cumbersome. There are four modem types in commerce nowadays: (1) Analogic modems have a working speed from 14 to 56 KB per second - Kbps -; obviously, the cheaper the modem the slower the transmission. It should be however noted that, before buying an expensive, fast modem, the maximum workload of the telephone line must be checked (it's useless to have a 56 Kbps modem and a line allowing only 14 Kbps). Connection to the telephone line through the modem is controlled by dedicated software included in the standard package of an OS. (2) ISDN modems can reach 128 Kbps, reduced to 64 Kbps when the telephone line is used simultaneously. (3) DSL modems can run from 640 KBPS to 100 MBPS, and are the most common way of access to the net, together with wireless. (4) GPRS/EDGE/UMTS/HSDPA modems are usually integrated on last generation cellular phones.

Software needed to navigate the web is known as web browser. Web browsers are in essence a navigational aid for moving around and between the various nodes and links of the WWW; actual Internet trend is to concentrate all current utilities in a single program. Some web browsers are non-graphic like Lynx, and graphical like: Mosaic, Mozilla and MS Internet Explorer, with these latter being the leading companies.

Internet service providers (ISP) are either private or universities based. The service provider will give access to the Net using a local or toll-free telephone number. Some may include web space with the monthly rate offer, while a university-based ISP usually provides service for a nominal or none rate. To select a provider it's a must to consider various factors: (1) Does it directly own a server? (2) Which bandwidth has it? The higher the bandwidth, the faster the access to the web; (3) Does it offer a technical service "on line" 24 over 24 hours 365 days a year? (4) How many users per modem does the provider have?

Once chosen the ISP, it will provide detailed instructions for the connection, usually on a CD-ROM containing also the web browser to be installed on the computer. The computer is thus ready to connect with Internet.

What can an Internet be used for?

Basically, tools offered by Internet to the pediatric surgeon are:\n
1. E-mail
2. Discussion lists
3. File transfer/USENET/TELNET
4. WWW
5. Long-distance education
6. Telemedicine.

E-mail

This abbreviation stands for electronic mailing: this possibly is the most useful resource offered by Internet, allowing sending mail (composed by text, images, videoclips, etc) through the net in an extremely convenient and fast way. It takes on average 2 to 8 minutes for messages to reach another computer node at the antipodes for the cost of a local phone call. With e-mail is possible to consult colleagues on a clinical problem, send a draft of paper for peer revision, take part to long-distance CME programs, participate to discussion lists, etc.24

An e-mail address is composed by the username (one single or more words separated by dots), the ampersand @ (the typical symbol marking e-mail addresses, introduced first in 1972 by Ray Tomlinson),
the ISP and the domain name separated by one or more dots. For example, e-mail addresses of the author are gbparigi@unipv.it or gbparigi@smatteo.pv.it for office use and gbparigi@hotmail.com for private use. In these, ”gbparigi” is the username, followed by the @ characterizing the e-mail, the ISP name, indicating respectively the University of Pavia (unipv), the ”S Matteo Hospital” of Pavia (smatteo.pv), a commercial ISP (hotmail), and finally the domain name separated by a dot (.it for Italy or .com for commercial). While choosing a username it is advisable to pick up something easy to spell and to remember (think about a friend asking your address through a mobile phone in a noisy road !).

E-mailing will soon become an essential tool in medical research, teaching medical students, clinical practice, postgraduate studies, although the lack of a traditional peer-review process and author identification might prevent e-mail text from being taken as authoritative.25 Another problem raised by e-mail communication in the medical environment is related to important questions of legal, ethical, and professional propriety. This new technology is not free from potential associated hazards, and policies and practices that mitigate its weaknesses must be sought for.26

Discussion Lists

A discussion list is a list of e-mail addresses of people sharing the same interest and wishing to keep in touch via Internet (members of a society, alumni of a college, chocolate lovers, Star Trek Theologians -not joking! etc). Curiously, the first discussion list developed among scientists was called the Science-Fiction list.27 Messages posted by authors to the list or discussion group are automatically mailed to all subscribers.

Free software is available to adhere or to build up a new list: Listserv, Majordomo, Yahoogroups, with this latter being the most diffuse with some 2,652,614 groups already created as per March 2008 (www.groups.yahoo.com). Environmental motivations have created an informal code of conduct known as "netiquette" (net-etiquette), dealing with politeness in replying along with accessibility, identification of the author and social responsibility (a full list of netiquette rules can be found at http://www.dtcc.edu/cs/rfc1855.html). Problems to avoid once joined a discussion list are: not signing, replying to the whole group when answering privately to one person, including the entire text of the received message when replying.

List servers for different surgery and pediatric subspecialties exist: NICU-Net, PICU-Net, cardiology, gastroenterology, neurology, emergency medicine, critical care, pediatric pain, etc.28 A popular list among Pediatric Surgeons worldwide is the Paediatric Surgery List, developed in July 1995 by Tom Whalen, Chief of Pediatric Surgery at Robert Wood Johnson Medical School in New Jersey. Scopes of the list are discussion of difficult clinical cases, technical tricks and options, exchange of ideas, consensus on management, career opportunities, referral of patients to other parts of the world, meetings and all possible topics dealing with the development of our specialty. The list is intended for pediatric surgeons and interested general surgeons and residents; technical problems imposed to close the original list of 1057 members, exchanging in 7 years 15285 "clinical" messages, in a new one - Pedsurg 2006 - for the moment joining 324 pediatric surgeons throughout the world.23 The list can be freely joined by sending a message to Pedsurg 2006-subscribe@yahoogroups.com. While posting messages to the list it is paramount to remember: (1) not to betray privacy; (2) to be extremely wary in identifying patients; (3) to back comments with published citations; (4) not to waste the carrying capacity of the Net (bandwidth) with heavy attachments such as pictures; (5) not to post unsolicited advertising (spamming); (6) to identify clearly the author. The inclusion of e-mail and address at the end of a message represent a legal signature for all aspects of the law.29 Disclaimers notice stating the medico-legal responsibility behind frequent response to complex medical problems are being asked for to list server administrators.30

File Transfer/USENET/TELNET

File transfer provides the unique opportunity of retrieving archives from public file libraries, with free software also available (FTP). Downloading of data into the hard disk of the computer is very straightforward.

USENET is a news discussions system distributed among hosts worldwide. News articles are grouped into newsgroups, which cover almost any topic one can imagine.
TELNET is a term referring to both the protocol and the terminal emulator that allows the user to connect across the Internet and to log onto another computer as if he was connected directly.

WWW

The www — known also as "The Web" - can be seen as an enormous and continuously expanding library, composed not by books but by "sites". As a book, a site is composed by pages (webpages), written in a particular language (HTML - its successor has already been proposed, the XML), consisting of all one medium, such as text, or including multiple media such as graphics, sounds, animation, and video. As a book, every site is identified by a "title", known as uniform resource locator (URL), that actually is a unique numerical address, composed by four blocks of up to 3 digits each, divided by a dot. Contrary to a book, the Web is fully interactive, allowing the user to buy a good while visiting a commercial site or to try one's fortune while entering a virtual casino. Just to give a very rough idea of the fields of interest of Web users, Fig. 129.3 shows the Internet sites categories most visited in Italy in 2007 expressed in percentage on the total of Internet navigators.

The most attractive feature of the Web is the possibility to jump from one page to another one (to "navigate" or "surf the Web"), in the same site or in another one, through links to other URL. Links are identified by a text underlined or in a different color, where the cursor of the pointer device changes (usually assuming the shape of a pointing hand) as though sensing an executable movement. By either clicking the device or hitting the return key, Internet "navigator" will be moving to that link, addressing in few seconds to a site that can physically be hosted in a computer located in the most remote spot in the world but nevertheless connected to the Net.

URL essential ingredients are protocol, site name, domain and directory, divided by slash or dots. For example, the address of the Medline service named "Entrez" at the National Library of Medicine of the National Institutes of Health is: http://www.ncbi.nlm.nih.gov/PubMed/. http:// is the protocol name; ncbi.nlm.nih the name of the site, in this case composed...
by the different acronyms of the involved organisms; gov is the domain name; /PubMed/ the directory inside the site. Domain names indicate the origin of the site, either top level geographical or institutional, and are summarized in Table 129.5.

Internet sites cannot only be read, but also individually written and published, exactly as in the case of a book, but at an enormously cheaper price. What is needed is just only a Web editor that can be downloaded from different suppliers in the Net. Once written, the site must be hosted on a server; many ISP allot a space on their servers for free or for a nominal fee to customers willing to publish on the Web.

**Long Distance Education**

Due to the overwhelmingly increasing offer of on-line courses today available, a computer connected to the Internet can be seen as a dedicated teacher, available for free all over the world 365 days a year, holidays included, on a incredibly wide array of different topics taught by some among the most authoritative academics available. This is the so-called Computer Assisted Instruction (CAI), otherwise described as Computer Assisted (Based) Learning (CAL/CBL) or Computer Based Education / Training (CBE/CBT).

<table>
<thead>
<tr>
<th>Table 129.5: Domain names</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>gov</strong> government only agencies of the USA Federal government</td>
</tr>
<tr>
<td><strong>com</strong> commercial used for commercial entities, particularly if present in more than one country</td>
</tr>

<td><strong>.zw</strong> Zimbabwe National domains, always composed by two letters and derived from the international Country code (.in for India)</td>
</tr>
</tbody>
</table>

These terms define a teaching system in which the user has the possibility to learn in an interactive way through a computer program. In a CAI teaching session, the student send messages through an input device to the computer; these messages can be answers to questions posed by the program, or requests to the computer about a particular topic covered by the program. Didactical strategies envisaged for the CAI can be summarized as: (1) tutorial: teaching goes on as a simulated dialogue, with questions of progressively increasing difficulty; (2) Drill and practice: the teacher presents a traditional lecture, then a computer program trains the student on the concepts presented; (3) Evaluation: student/computer interaction aimed to define areas of competence of the student within a particular field of knowledge; (4) Simulation: the program simulates a particular system, chemical, physical or biological, thus allowing the student to perform procedures through various input devices and to study the results of his action (particularly useful in teaching videolaparoscopic techniques); (5) Problem solving: aimed to teach the procedure to analyze and solve a particular problem (e.g. a clinical case), deepening student's knowledge by applying rules progressively more sophisticated for the solution of the simulated problem.

Among the tools offered by long distance education deserves a mention the largest encyclopedia now available on Internet, Wikipedia, that in its English version describes today some 2,279,919 articles (http://en.wikipedia.org/wiki/Main_Page); noticeable also the offer of 1800 on-line free courses given by the Massachusetts Institute of Technology (http://ocw.mit.edu), from "Aeronautics and Astronautics" to "Writing and Humanistic studies", or the one by Yale University (http://open.yale.edu) offering free and open access to seven introductory courses taught by distinguished teachers and scholars.

In a more specific medical field, it is possible to follow CME accredited long-distance teaching programs, sometimes offered for free such as Medscape (http://www.medscape.com), challenges subscribers with complex clinical cases to be solved.

This possibility of building a purpose-specific Internet site, with all its interactive features, offers to pediatricians and to pediatric surgeons a still largely unexplored field of creativity, such as the Internet-based interactive asthma educational and monitoring
Telemedicine

The possibility of sending through Internet all clinical data that can be digitized (X-rays, CT, MRI, PET, scintiscans, echocardiograms, intraoperative photographs, histologic images, etc.), as well as real time video and audio technology (clinical rounds, lectures, videolaparoscopic procedures, etc.) has ushered the development of the so called Telemedicine. This technologic tool allows to consult in real time specific experts in the subspecialties of childcare, even if in the other corner of the world; to train and guide surgical trainees by experts without their physical presence; to link hospitals and research centers in virtual multicampuses; to link rural health clinics and central hospital, or physician to hospital for transfer of patient information; to distribute programs for public education on health care issues; to resort on video and satellite relay to train health care professionals in widely distributed or remote clinical settings, etc. Added benefits are improved access to areas in need of health service, reduced cost of travelling, reduced professional isolation, improved quality of the care given. Development of the infrastructure needed along with cost containment issues are two of the problems faced by this technological advance; nevertheless, telemedicine is bound to become soon an integral part of the health care of children and the training of pediatric surgeons.

How to find an e-mail address on the Internet?

The easiest way to get an email address is simply to get someone to mail you first and to record his address on your list: but this is not always possible, and then some of these tricks can help.

1. **Consult a paper directory:** Bookshops were used to sell Internet directories, and some of these include interesting and useful email addresses. This technique can work well if you want a commercial email address.

2. **Consult an on-line directory:** The InterNIC directory and database at http://www.internic.net is a 'directory of directories' that lists all the widely used public access on-line directories. Useful for anyone looking for commercial or educational email contacts.

3. **Consult an on-line archive:** Doing a web search on someone's surname can turn up some surprisingly useful leads, as can searching through the Usenet archives. If someone has posted to Usenet, his e-mail address will be included in Usenet mailing lists.

4. **Mail: postmaster@...** If you know the name of the organization where the person has an e-mail account, you can mail the postmaster there and you'll often get their full address by return.

How to find a particular site in the Web?

We have just compared Internet to an immense public library accessible from anywhere: unfortunately such a wealth of information has not any index or table of contents. Therefore finding something on the Web when one doesn't know exactly where to look can be a time-consuming task, if not frustrating at all due to the huge amount of rubbish present in the Web. A survey on the evolution of Internet use in health care based on the experience of 1129 healthcare professionals applying the medical Net showed that the main obstacle encountered was the lack of time (56.14%), and that the most burdening shortcoming of e-health experienced is the time-wasting information searches (58.89%). Not without a reason the new Internet produced job for retrieving information is called "data mining"!

User's ingenuity can sometime be helpful in figuring out the possible address of the requested site: for example, searching for the site of the American Academy of Pediatrics, one could try writing "www" (the Web mark), then a dot ".", the acronym of the Society "aap", again a dot and eventually the domain name "org" (organization): "www.aap.org" will actually take this fortunate "netter" (= the one who navigates in the Net!) to the requested site. Unfortunately this procedure does not always works: searching for the Journal of American Medical Association under "www.jama.org" you will be taken to the site of Japan Automobile Manufacturers Association! (Try better under www.jama.ama-assn.org).
Solution of this problem was sought for since the very beginning of the Web: some extensive indices and catalogues were created, such as Gopher, Veronica, WAIS and Archie, but the tumultuous evolution of the Web made soon outdated these indexes. New search tools were thus devised, aiming at retrieving in few seconds a more or less complete list of URL responding to definite key words introduced by the user: the so-called "search engines".

Unfortunately most of these search engines are completely non-discriminatory about the information they index. This inability to discriminate the quality of information is exacerbated in technical domains, where the source and prestige of information take on added importance. In the health care field, for example, information from peer-reviewed journals, followed by that from health sciences universities and government agencies, is valued much higher than other information. Postings not signed by an author or not subject to peer review are unlikely to be used for educational purposes or to make serious clinical decisions. For this very reason some search engines specialized in medical field have been created: unfortunately again, also the number of search engines - both general and specialized in medical field - grew exponentially (up to the incredible number of 9,608,000 and 499,500 respectively, according to a ... search made through a search engine!). To address the reader in this pandemonium of information, we will suggest some sites among the most reliable.

**General Search Engines**

Search engines are giant computer systems that search the web automatically and collate the results into a useable index of web addresses (URL). This index can be browsed in a variety of ways. Some search engines use a keyword system - you specify the words you want to find on the web, and the search engine returns a list of relevant web addresses. Note that it's not just the addresses that are searched - the text of the pages is searched as well, so if the word you are looking for is embedded deep inside a web site, you'll get the URL of the page that contains it, not the main 'welcome mat' URL for the rest of the site.

Search engine indexing can be performed either automatically through a robot or manually through redaction of thematic indexes: the former system is more inclusive, the latter more selective. Thematic indexes, known also as category searchers, catalogues or directories, are links to information sources organized in hierarchical trees.

**Indexing Robots**

*Altavista (www.altavista.com)*

Offers a great quantity of hits in any search, excellent options for advanced search and allows the use of wildcards. Utilities Advance, Compact and Detailed turned out to be really useful.

*Hotbot (www.hotbot.com)*

Search engine created by the magazine Wired (USA); is a great indexer. The best rival of Altavista, its advanced search is as easy but with less quantity of addresses. If properly utilized can offer an extensive guide of shareware. Its homepage is not impressive: better to use it with Super Search for more refined searches.

*Lycos (www.lycos.com)*

Search is quick and allows searches advanced and rather exhaustive, although not always satisfying. Some utilities are somewhat puzzling.

*Metacrawler (www.metacrawler.com)*

A meta-search engine, originally developed in 1994 at the University of Washington, that searches simultaneously some other search engines such as Google, Yahoo! Search, MSN Search, Ask Jeeves, About, MIVA, LookSmart and more. The site, owned and operated by InfoSpace Network, is particularly indicated for searches of unusual terms.

**Thematic Indexes**

*Excite (www.excite.com)*

Sorts out a good deal of addresses but does not number them. Offers a lot of interesting features, but using them is a bit disappointing. Allows reducing the search field with key words or sentences and obtaining good results with titles and abstracts. Needs to be used jointly with Power Search.

*Google (www.google.com)*

The largest human-edited directory on the web, searching the Web, Usenet, and images. The core of the system is represented by software developed at Stanford University, PageRank™, able to classify web sites in order of importance. One of Google's main
features is the high search speed, due partly to the search algorithm and partly to the high number of PC networked. The system is fancy enough to give, together with the results of the search, also the time needed to complete it (just as a curiosity, to retrieve 87,900 sites dealing with “gastroschisis” it took 0.16 seconds).

Yahoo (www.yahoo.com)
Born at Stanford University (USA) in 1994, is the biggest and most utilized thematic catalogue. Its descriptions are nonetheless very concise. It’s linked through a cooperation agreement with Allavista thus allowing transferring to this search engine quests not offering any result with Yahoo. To obtain best results is advisable to choose with the mouse the relevant category or to pick out the national database of interest.

Scientific Search Engines

ArticleSciences (http://articlesciences.inist.fr)
Website devoted to search and order scientific articles, realised by INstitut de l’Information Scientifique et Technique of Centre National de la Recherche Scientifique. Although based in France, can be browsed in many languages.

CiteSeer (http://citeseer.ist.psu.edu/)
CiteSeer is a scientific literature digital library and search engine that focuses primarily on the literature in computer and information science. CiteSeer was developed in 1997 at the NEC Research Institute, Princeton, New Jersey, and is now hosted at the Pennsylvania State University’s College of Information Sciences and Technology. CiteSeer was the first digital library and search engine to provide automated citation indexing and citation linking using the method of autonomous citation indexing.

ISI HighlyCited (http://isihighlycited.com/)
Search engine aiming to identify individuals, departments and laboratories that have made fundamental contributions to the advancement of science and technology in the period 1981-1999. Subdivided in 21 broad subject categories in life sciences, medicine, physical sciences, engineering and social sciences, the site identifies the 250 most highly cited scientists within each category, and comprise less than one-half of one percent of all publishing researchers.

Online Journals Search Engine (www.ojose.com)
Online Journals Search Engine is a free scientific search engine enabling to make search-queries in up to 60 different databases by using only 1 search field. Within the site it is possible to find, download or buy scientific publications (journals, articles, research reports, books, etc). A bit complex in its use.

Scirus (http://www.scirus.com/srsapp/)
Scirus is among the most comprehensive scientific research tools on the web. With over 450 million scientific items indexed at last count, it allows researchers to search for not only journal content but also scientists’ homepages, courseware, pre-print server material, patents and institutional repository and website information.

SciSeek (http://www.sciseek.com)
Portal aiming to provide a central place through which universities, medical centers, journals, government agencies, corporations and other organizations engaged in research can bring their news to the media. Organized in sections under the title of Science news, Science forums and Free Magazines. Offers links to many free magazines on health care.

Medical Search Engines

Cancernet (http://www.meb.uni-bonn.de/cancer.gov/index.html)
Redistributed by the University of Bonn Medical Center, it allows searching via a WAIS-full-text-index the Cancernet - Database in English and German. Good amount of pediatric surgical oncology items.

CiteLine (www.citeline.com)
Aggregator of medical Web information, offers - with some commercial flavor - a search of global clinical trials intelligence to the pharmaceutical industry and a complete picture of ongoing worldwide drug development activity.
Clinical Trial Finder (http://www.clinicaltrialfinder.com/)

Scope of this site is to match "...investigators with studies. Investigators can find studies that suit them and sponsors have immediate access to suitable investigators. Investigators can apply immediately for a study reducing the time taken for sponsors and doctors to get in touch. Investigators are alerted to new studies in their therapeutic areas allowing sponsors to target investigators specifically for their study". Needs registration.

Doc Guide (http://www.docguide.com)

Very rich site, with some aspects relevant for pediatric surgeons, presents news, clinical cases, Congress Resource Center, presentation of new drugs, online medical dictionary.

Harriett Lane Links (formerly Pediatric Points of Interest) (http://derm.med.jhmi.edu/poi/index OLD Nov2005.cfm)

Specialized search engine managed by the Johns Hopkins University, Baltimore, USA. The Harriett Lane Links provide an edited collection of pediatric resources (6,285 links) on the WWW. Maintained and edited at the Johns Hopkins University, this site attempts with rather a good result to catalogue, review and score existing links to pediatric information on the Internet.

Health on the Net Foundation (http://www.hon.ch/)

Swiss based non-profit private Foundation aimed to "...promote the effective and reliable use of the new technologies for telemedicine in healthcare around the world." HON is now presented as "...one of most respected not-for-profit portals to medical information on the Internet" featuring, among other items, two widely used medical search tools, MedHunt® and HONselect® and the HON Code of Conduct for the provision of authoritative, trustworthy Web-based medical information. The search for "Pediatric Surgery" made through these tools retrieves 98 pediatric surgical sites subscribing to the HONcode, 150 sites visited and described by HON and 5484 sites and pages automatically retrieved by a robot. The sites retrieved by the system are really many, but unfortunately not always completely focused on the request, having sometime only a very slight pertinence with pediatric surgery.

MedExplorer (http://www.medexplorer.com/)

General search engine with some sections of interest for pediatric surgeons. Noteworthy are the nutritional section, presenting a detailed database on infants' different foods. Updated world Congresses and Conferences program. Worth of a visit the "Humour" section, displaying jokes with medical flavor or "unusual statistics" such as the percentage of British fluid intake that is tea (42%).

MEDLINEplus (http://medlineplus.gov/)

Official US Government site run by the world’s largest medical library, the National Library of Medicine, offering authoritative and up to date medical information based on extensive information from the National Institutes of Health and other trusted sources on over 750 diseases and conditions, as well a Medical Encyclopedia including pictures and diagrams, Dictionaries with spellings and definitions of medical words, Information on drugs, health information from the media, and links to thousands of clinical trials.

MedMark (http://www.medmark.org/peds/pds2.html)

A search engine developed in Korea by the MedRIC (Medical Research Information Centre), covers a good amount of pediatric surgical items (although mostly neurosurgical) and offers a list of medical search engines.

PubMed, a service of the National Library of Medicine, provides access to over 17 million MEDLINE citations back to the 1950's and additional life science journals. PubMed includes links to many sites providing full text articles and other related resources. PubMed is a search and retrieval system that integrates information from databases at NCBI. These databases include nucleotide sequences, protein sequences, macromolecular structures, whole genomes, and MEDLINE, through PubMed. Together with MEDLINEplus, this is one of the most authoritative and reliable specialist search engines available on the Net.
Navigate in Internet without a search engine is like crossing the ocean without a boat: but also the choice among the different engines undergoes a "geopolitical" stratification, with Google being the leader worldwide but with some exceptions. According to an analysis performed by Alexa (www.alexa.com), a company specialised in collecting and publishing web information and statistics, Yahoo is the preferred search engine in India and Japan, LiveSearch in Colombia, Salvador and Paraguay, Rambler in Kazakhstan, Naver in South Korea, Yandex in Russia and Baidu in China. Also in the Internet era Chinese do not forget their poetic heritage: "Baidu" is the title of a poem written more than 800 years ago during the Song Dynasty. The poem compares the search for a retrofitting beauty amid chaotic glamour with the search for one's dream while confronted by life's many obstacles: "...hundreds and thousands of times, for her I searched in chaos, suddenly, I turned by chance, to where the lights were waning, and there she stood." Baidu, whose literal meaning is hundreds of times, represents persistent search for the ideal. By the way, the site is written fully in Chinese.

**How to perform a search on a search engine?**

First of all, it is mandatory to choose the proper key words and the most suitable search engine. As a general rule, for a very uncommon keyword is better to resort to robotic indexes, while for wider topic a thematic index or better a specialized search engine will give a less cumbersome number of web matches. To give a rough idea of the results that can be obtained with search engines, Table 129.6 presents the results of a search trough general and specialized search engines, conducted on a wide pediatric surgical argument such as the Wilms' tumor, a less common one as the gastroschisis and a definitely unusual one as the pentalogy of Cantrell, together with a request about "Pediatric Surgery " in general.

The search for a site with one of those search engines can be simple or advanced, using more than a simple keyword: the more detailed the choice of key words, the best the results. Important notice: not all search engines work in the same way, then not all the following rules can apply to all engines (what changes is in particular the use of wildcards).

1. **Simple search** requires entering the more significant keyword / words, and usually provides a long list of addresses in decreasing order of relevancy. For example, if we introduce "surgical treatment of appendicitis" we'll have a substantial amount of documents containing whatever of these words. This search can be extended or refined with the use of wildcards. In such way are defined the symbols * and ?, used to stand for one (?) or more (*) not specified characters in a word. For example, entering "child*" will give as a result "child", "children", "childhood", "childcare", "childish", etc; entering "surg*" → "surgery", "surgical", "surgeons", etc; entering "surgeon?" → "surgeon" and "surgeons", and likewise "p?ediatric" → "paediatric" and "paediatric"; "tumo?r" → "tumor" and "tumour" (please note that a wildcard can stand also for no characters at all).

2. **Advanced search** is performed with exactness, boolean logical and complement operators (from George Boole, author in 1847 of the treaty on "Logical Theory of the Binary Systems"). Among these:

- **AND**: all terms joined by this operator must be present, also if separated. If we type for example pediatric AND surgery the search will give back all documents containing both these terms, also if one dealing with the pediatric neurology department and the other with the dental surgery department of a hospital. If we want to search exactly for "pediatric surgery" we must enter our request in this very way, i.e. including the words within inverted commas ("...").

**Table 129.6: Results given by a search through general and specialized search engines on pediatric surgical topics**

<table>
<thead>
<tr>
<th>Topic</th>
<th>General search engines (results x 1000)</th>
<th>Specialized search engines</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Google</td>
<td>Yahoo</td>
</tr>
<tr>
<td>Wilms' tumor</td>
<td>685</td>
<td>1.190</td>
</tr>
<tr>
<td>Gastroschisis</td>
<td>86</td>
<td>278</td>
</tr>
<tr>
<td>Cantrell's pentalogy</td>
<td>6.7</td>
<td>19.4</td>
</tr>
<tr>
<td>Pediatric surgery</td>
<td>1.320</td>
<td>23.300</td>
</tr>
</tbody>
</table>
Typing two or more keywords without any operator in between gives (usually) the same results than using AND. In some searchers AND is replaced by the sign +, or can be left unexpressed.

- OR: with this operator the search will give back all the documents containing at least one of the terms. It is a very useful operator when dealing for example with a pathology known under different names: "Wilms' tumor" OR nephroblastoma (please note the use of the wildcard "?" to extend the search to both terms "tumor" and "tumour", and the use of inverted commas to link this word to "Wilms". Otherwise the search would give back all the documents containing the word "Wilms" and "tumor", also if in totally different contexts).

- NOT: this operator excludes all documents containing the marked keyword. To avoid misunderstanding by the system the better form is AND NOT. Searching for example for documents dealing only with omphalocele (known also as exomphalos) and not with gastroschisis, the advanced query will be: omphalocele OR exomphalos AND NOT gastroschisis. In some searchers NOT is replaced by the sign: –

- NEAR: This operator acts as the "and", searching for all specified keywords, but gives back as result only documents in which keywords are separated only by few in-between words (default being usually 10, with the option in some searchers to change this value). If we seek for documents dealing with the treatment of omphalocele, our request will be: omphalocele NEAR treatment.

- (): round brackets are used to join two or more keywords under the same operator. The query: Toddlers NOT neonates OR newborns will give back all documents containing the words "Toddlers" or "newborns", excluding only the word "neonates". This is obviously a rather senseless result: if we want to include in our search only toddlers excluding all babies under one month of age, proper query will be: Toddlers NOT (neonates OR newborns). All right, it sounds a bit crazy, but who said that computers are simple and brainy?

**Which Pediatric Surgical sites are worth a visit?**

Just to offer Pediatric Surgeons surfing the Web an edited guide a sort of an index of virtual pediatric surgical information, we will present some selected sites (written in English), divided in four categories according to their prevailing features: (1) Educational mostly text; (2) Educational mostly images; (3) Online journals; (4) Structured indexes of links.

### Educational-mostly Text

**E-medicine (www.emedicine.com):** E-Medicine (a US company privately held launched in 1996) is one of the largest clinical knowledge base available on the Net, covering some 7,000 diseases and disorders and containing an Image Bank of nearly 30,000 multimedia files. The evidence-based content provides current practice guidelines in 62 medical specialties; for Pediatric Surgery look under "Pediatrics". Subchapter on "General Surgery" is unfortunately still empty, but plenty of pediatric surgical pathologies -schematically but comprehensively treated- can be found in the subchapters "Urology", "Gastroenterology" and "Neonatology".

**Multilingual glossary of medical terms (http://allserv.rug.ac.be/~rvdstich/eugloss/welcome.html):** Project financed by The European Commission (DG III) and executed by the University of Gent (Belgium), it offers glossaries in which are discussed 1830 technical and popular medical terms (with cross-references between them) in nine languages: English, Dutch, French, German, Greek, Italian, Spanish, Portuguese and Danish.

**Neonatology on the web (www.neonatology.org):** Private-owned site run by a Cedars-Sinai Medical Center physician, features some utilities useful also for pediatric surgeons, such as: (1) General reference materials (Tables and charts commonly used in routine neonatal intensive care; (2) Medications for Neonates (Formulary for neonates, with dosing guidelines by gestational age and weight and references); (3) Teaching Files and Guidelines (an extensive list of links to teaching files and guidelines for neonatal-perinatal medicine); (4) Neonatal Drips calculator.
OMIM - Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/sites/entrez?db=omim): This database is a catalogue of human genes and genetic disorders developed for the Net by the U.S. National Center for Biotechnology Information (NCBI). The database contains textual information, pictures, and reference information, as well as the OMIM Morbid Map, a catalogue of genetic diseases and their cytogenetic map locations arranged alphabetically by disease. A visit to the site is a must for all pediatric surgeons dealing with gene-related pathologies (from Adenomatous polyposis to Wilms’ tumor).

Pediatric Surgery Update (http://home.coqui.net/titolugo): Humberto Lugo-Vicente's website is by far the most known and complete among those devoted to Pediatric Surgery in the Net. The volumes of the Journal, appeared in July 1993, cover a wide array of topics; the Pediatric Surgery Handbook for residents is possibly the most complete in the web; well worth of interest are the section on "New techniques in pediatric surgery" and the challenge to the skills of readers in "What is your diagnosis" section.

The Pull-thru Network (http://www.pullthrough.org/): The Pull-thru Network, a chapter of The United Ostomy Association, Inc., is a non-profit support and resource organization dedicated to the families of children who have had or will have a "pull-through" type surgery. The site hosts a full-text quarterly newsletter intended to report items of interest with regard to imperforate anus, cloaca, VATER association, urinary incontinence, Hirschsprung's disease, spinal and renal anomalies, as well as a glossary of medical terms, online terms, surgeries, and abbreviations.

The Hasbro Children's Hospital Pediatric Surgery Handbook (http://bms.brown.edu/pedisurg/Handbook.html): Site designed by the Warren Alpert Medical School of Brown University, it presents a practical handbook dealing with pediatric surgical technicalities such as the choice of catheters and g-tubes, nutritional and fluids intake calculations, trauma management, preoperative care.

Vesalius (http://www.vesalius.com/welcome.asp): Defined as "The Internet resource for surgical education" this site is organised in "Clinical Folios", a collection of graphical educational narratives on surgical anatomy and procedures designed for online reference and study, whose contents are arranged by topic. Narratives are an ordered series of related images, animations, or short videos linked by descriptive text that together explain the key steps in a surgical procedure or the anatomy relevant to one or more surgical procedures; Thumbnails are pages that provide an index of the principal images and text paragraphs in a Narrative; Transparencies are short interactive programs or movies that present a layered or rotational view of surgical anatomy; Discussions are text-based summaries of the epidemiology, etiology, diagnosis, and treatment associated with an underlying condition.

Educational-mostly Images

Leading symptoms in pediatric surgery (http://www.kco.unibe.ch/daten_e/startmenue/login.html): An instructional program for undergraduate and postgraduate study in medicine of the Institute for Medical Doctrine (IML) and the university clinic for pediatric surgery of the Inselspital, Bern, created by Prof. Georges L Kaiser, offers some 1700 pictures and schematics and 20 videos relating to clinic, radiology and situations during surgery illustrate 27 key symptoms in pediatric surgery. Requires free registration.

Pediatric Radiology and Pediatric Imaging (http://paediatricradiology.com/) The site, partly sponsored by the Radiological Society of North America’s Research and Education Foundation, is an extremely rich pediatric radiology and pediatric imaging digital library. It features imaging appearances of 402 (!) common pediatric diseases covered by 1,886 cases; needless to say that a huge amount of these cases are of surgical interest.

The Hasbro Children’s Hospital Pediatric Surgery Image Bank (http://bms.brown.edu/pedisurg/Brown/IBCategories.html) Visual counterpart of the Handbook before presented, it offers a wide choice of images on various pediatric surgical topics from CDH to NEC, from benign liver tumors to congenital lung lesions.

Virtual Children’s Hospital Correlapaedia (http://www.virtualpaediatrichospital.org/providers/CAP/CAPHome.shtml) "Correlapaedia", a site developed at University of Iowa College of Medicine, is a correlative encyclopedia of
pediatric imaging, surgery and pathology. Its goal "...is to create for the medical apprentice a collection of patient stories in which imaging and pathology plays a key role in diagnosing and managing surgical diseases in children. By reviewing these stories, it is hoped the medical apprentice will be able to add them to their memory and be able to recall them when needed in the future to aid in their diagnosis and treatment of patients." Fifty six clinical stories beautifully illustrated in their imaging, surgical and pathological aspects are organized by age, organ and clinical presentation.

Online Journals

Annals of Improbable Research (http://www.improbable.com/): As an exception to the rule of selecting only sites of pediatric surgical interest, we recommend a visit to this journal although (unfortunately?) no pediatric surgeons are, at least for the moment, among the contributors. The visit is particularly worthwhile in case of depression after a heavy workday or in case of lack of inspiration for further studies. It will be then possible to have details on "The gentle art of political taxidermy", or on "Alteration of the platelet serotonin transporter in romantic love," or else how "carefully collecting, classifying, and contemplating which kinds of containers his patients chose when submitting urine samples". The list of the IgNobel prizes awarded by the Journal boasts gems as "The collapse of toilets in Glasgow Public Health" or "The Relationship Among Height, Penile Length, and Foot Size" as well as "The Effects of Unilateral Forced Nostril Breathing on Cognition" (by the way, all these papers before being awarded the IgNobel prize have actually been published!).

European Journal of Pediatric Surgery (http://www.thieme.de/ejps)
Full text is available from issue 3/2000. Subscribers of the printed journal can easily register to get free access to the full text online version. Abstracts are available for free.

Free Medical Journals (http://www.freemedical-journals.com/htm/special.htm): Site promoting free access to medical journals, now totaling over 900 titles subdivided in 96 specialties (Pediatric Surgery unfortunately not among them; Pediatrics 28 journals, Surgery 17 journals). The home page offers good functionality, with the options of viewing journal sites by specialty and by language. It also has a separate listing of journals that are new to the online world.

Journal of Pediatric Surgery (http://www.jpedsurg.org/index.html): Full text is available starting with the September 2000 issue. Tables of contents and abstracts before January 2000 will be added to the site incrementally during the first quarter of 2001. Access to full text is complimentary for a limited period.

Structured Links

General Pediatrics (http://www.generalpaediatrics.com/): The site is an award-winning digital library that identifies and organizes high quality, authoritative General Pediatrics WWW sites. Information is available on almost 400 common pediatric problems, some of them of surgical interest, plus policy statements, clinical practice guidelines, consumer health information and more.

Martindale’s Health Science Guide - 2003 (http://www.martindalecenter.com/HSGuide.html): Guide edited by the University of California at Irvine, in a midst of a wealth of medical links (135,500 MedicalCases and Grand Rounds; 62,300 Teaching Files; 1,295 Courses / Textbooks; 1,735 Tutorials; 420 Journals; 4,410 Databases) it is possible to find something interesting under the heading "Pediatrics/Anesthesiology and Surgery Center".

Pediatric Surgery on the Internet: Problems and Perspectives

"Is the truth out there?" is the provocative question raised by the observation that Internet information on pediatric surgery, as well as in all other medical domains, varies significantly in quality. Access to medical information via the Internet has the potential
to speed the transformation of the patient physician relationship from that of physician authority ministering advice and treatment to that of shared decision making between patient and physician: however, barriers impeding this transformation include wide variations in quality of content on the Web, potential for commercial interests to influence online content, and uncertain preservation of personal privacy. According to Chen et al 75.7% of 141 websites searched for information on various pediatric surgical pathologies contained accurate information, although 93.1% of these were incomplete. A multi-institutional review appeared in JAMA says that most of times health information we consult in Internet is, even in the best pages, difficult to find or understand, inaccurate and incomplete. It concludes that only 1 out of 5 web pages that appear to be useful has important information. Although only the most renowned sites were evaluated, investigators assume that only 45%, in average, affords accurate information and that 53% of times they offer contradictory information about the same subject. Same conclusions are drawn by Minzer et al. looking for information about infantile hemangiomas on the Net: they found only few sites accurately depicting the full disease spectrum from innocuous to severe. Still more pessimistic is the conclusion of the study of Corpron et al, simulating parents’ search of information for a child affected by ambiguous genitalia: out of 300 sites retrieved by search engines, only 5 (1.6%) of accessible pages offered appropriate medical information to parents. The situation becomes even worse when the patient bypasses his physician seeking a treatment directly on the Net: a custom that leads to easily predictable complications, going from eye lesions caused by contact lenses purchased over the Internet, to lithium intoxication caused by an Internet self-prescribed “dietary supplement”. On the other hand the average patient, although agreeing on the importance of using technology for health-information delivery, still prefers to receive information from health-care staff by face-to-face contacts, and also access to physicians who do internet or e-mail consults is generally low and did not increase between 2001 and 2003, despite growth in internet access and in other internet-related activities; it seems therefore that Internet will not overthrow the traditional relationship between a patient and his doctor.

What will possibly be overthrown, on the contrary, is the traditional printed medical journal. It is actually easily foreseeable that the journal of the future will be only electronic, will have a less volatile cost structure, will be supported more by services than by content and will be less able to rely on subscription revenues. Since anyone can publish in the Net online, electronic journals will develop with new peer-review concepts: editors, reviewers, and authors will need to adjust to the use of this information technology. Online publication in Pediatric Surgery will increase as printed form of actual journal joins the cyberspace domain. Cyber citations as proposed by the American Psychological Association or Modern Language Association have yet to be standardized by the American Medical Association to be used as bibliographical style. Authors that use online references will need to keep printed or digital file copy of such articles, since there is no way to avoid drastic changes or movement done to this domain address.

Internet evolution can worsen the gap (digital divide) between developed and developing countries also in the medical field, as it was observed in the 4th World Congress of Medicine in Internet, held in Heidelberg (Germany) in 1999. Among the important conclusions arrived in that congress, it is self-evident, today more than ever, that the difference and the gap between rich and poor countries may become too wide to be crossed on account of the new technologies in information and telecommunications. The group of experts on this subject was able to define the following concepts: (1) Internet is seen by Occident as a means to improve sanitary attention as well as the training and updating of their professionals and public in general. (2) Developing countries are lagged in attaining and using this new technology. (3) This situation will be almost impossible to reverse, unless the economical condition of those countries changes. Colleagues living in these countries have begun to connect to Internet only recently, although Internet diffusion also in these countries is increasing at enthusiastic pace, and also African adolescents utilize the Internet for health information seeking purposes.

At the other end of the spectrum, in the USA, next generation of Internet is in the near future. Meaningfully named "Internet2", this collaboration project among more than 150 universities throughout

## APPENDIX 1
### Glossary of computer and Internet terms

<table>
<thead>
<tr>
<th>Term</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ALU</td>
<td>Arithmetic Logic Unit A special chip performing all calculations in the motherboard</td>
</tr>
<tr>
<td>ARPANET</td>
<td>Advanced Research Project Agency Network Military network, forefather of Internet</td>
</tr>
<tr>
<td>ASCII</td>
<td>American Standard Code for Information Interchange Numerical code to express letters, digits, symbols, etc.</td>
</tr>
<tr>
<td>Backbone</td>
<td>High-speed network linking main computers</td>
</tr>
<tr>
<td>Baud</td>
<td>Speed of data transmission by a modem. It is roughly equal to one bit per second (bps)</td>
</tr>
<tr>
<td>beamer</td>
<td>Peripheral to be connected to a computer to project the monitor on a wall or a screen (e.g., for slides presentations, interactive sessions, etc.)</td>
</tr>
<tr>
<td>BIOS</td>
<td>Basic input/output system Special chip on the motherboard issuing booting instructions to the computer in 3 phases:</td>
</tr>
<tr>
<td>bit</td>
<td>Binary digit Cipher expressed in a binary system</td>
</tr>
<tr>
<td>Boot program</td>
<td>Program starting automatically at the switching on of the computer, arranging CPU and peripherals</td>
</tr>
<tr>
<td>Bounce</td>
<td>What happens to e-mailing not properly addressed and/or lost in the net, consequently &quot;bouncing&quot; back to the sender</td>
</tr>
<tr>
<td>Bps</td>
<td>Bit per second See Baud</td>
</tr>
<tr>
<td>byte</td>
<td>Set of 8 bits - basic unit of measurement of data in computer technology</td>
</tr>
<tr>
<td>Cache memory</td>
<td>&quot;Hidden&quot; service memory used to temporarily store frequently accessed data to be transferred from the RAM memory to the processor, in order to increase computing speed.</td>
</tr>
<tr>
<td>CAD</td>
<td>Computer Aided Design Software dedicated to the industrial and scientific planning and design</td>
</tr>
<tr>
<td>CAI</td>
<td>Computer Assisted Instruction Teaching system based on interactive learning through a computer program</td>
</tr>
<tr>
<td>CD-R</td>
<td>Compact Disk - Readable A drive allowing to write your own audio and data CD-ROM's. These data cannot be erased or rewritten</td>
</tr>
<tr>
<td>CD-ROM</td>
<td>Compact Disk - Read Only Memory A large capacity read-only media similar to audio compact disk</td>
</tr>
<tr>
<td>CD-RW</td>
<td>Compact Disk - Readable Writable The same as CD-R, but the disk can be erased and rewritten</td>
</tr>
<tr>
<td>CERN</td>
<td>Conseil Européen Recherche Nucléaire Birthplace of the WWW</td>
</tr>
<tr>
<td>Clock</td>
<td>Internal timer of the computer, synchronizing all the CPU operations, with a frequency measured in MHz or GHz</td>
</tr>
<tr>
<td>COM (1,2,3...)</td>
<td>Abbreviation indicating a serial port and its progressive number</td>
</tr>
<tr>
<td>CPU</td>
<td>Central Processing Unit The &quot;heart&quot; of a computer that performs instructions as directed by the OS and programs</td>
</tr>
<tr>
<td>DAT</td>
<td>Digital Audio Tapes Magnetic support for backup of large amount of data</td>
</tr>
<tr>
<td>Default</td>
<td>Parameter or value assigned automatically by the system failing specifications by the user</td>
</tr>
<tr>
<td>Display resolution</td>
<td>Number of pixels, or dots, used to display the image on the monitor, usually expressed as width by height.</td>
</tr>
<tr>
<td>DNS</td>
<td>Domain Name System A DNS server is a computer used to translate machine names into IP address</td>
</tr>
<tr>
<td>Domain</td>
<td>The last part of an Internet address: .com, .edu, etc.</td>
</tr>
</tbody>

<td><strong>ISDN</strong></td>
<td>Integrated Services Digital Network</td>
</tr>
<tr>
<td><strong>ISOC</strong></td>
<td>Internet Society</td>
</tr>
<tr>
<td><strong>ISP</strong></td>
<td>Internet Service Provider</td>
</tr>
<tr>
<td><strong>Java</strong></td>
<td>Programming language allowing Web sites to load computer programs into the user’s Web browser</td>
</tr>
<tr>
<td><strong>KB</strong></td>
<td>Kilo Byte</td>
</tr>
<tr>
<td><strong>Kbps</strong></td>
<td>Kilo Byte per second</td>
</tr>
<tr>
<td><strong>LAN</strong></td>
<td>Local Area Network</td>
</tr>
<tr>
<td><strong>LCD</strong></td>
<td>Liquid Crystal Display</td>
</tr>
<tr>
<td><strong>Listserver</strong></td>
<td>Server dedicated to the management of an e-mailing list</td>
</tr>
<tr>
<td><strong>Logon/Logoff</strong></td>
<td>To connect/disconnect to an host system</td>
</tr>
<tr>
<td><strong>LPT (1,2,3…)</strong></td>
<td>Abbreviation indicating a parallel port and its progressive number</td>
</tr>
<tr>
<td><strong>MB</strong></td>
<td>Mega Byte</td>
</tr>
<tr>
<td><strong>MFLOPS</strong></td>
<td>Mega FLOating Point Second</td>
</tr>
<tr>
<td><strong>MHz</strong></td>
<td>MegaHertz</td>
</tr>
<tr>
<td><strong>MIME</strong></td>
<td>Multipurpose Internet Mail Extension</td>
</tr>
<tr>
<td><strong>MoDem</strong></td>
<td>Modulator Demodulator</td>
</tr>
<tr>
<td><strong>motherboard</strong></td>
<td>Large printed circuit board housing the circuitry to make the whole machine run</td>
</tr>
<tr>
<td><strong>MS-DOS</strong></td>
<td>Micro Soft - Disk Operating System</td>
</tr>
<tr>
<td><strong>Netiquette</strong></td>
<td>Net-etiquette</td>
</tr>
<tr>
<td><strong>Network</strong></td>
<td>Communication system linking two or more computers, up to the several millions of computers interlinked through Internet</td>
</tr>
<tr>
<td><strong>Newsgroup</strong></td>
<td>Usenet conference</td>
</tr>
<tr>
<td><strong>OCR</strong></td>
<td>Optical Character Reader</td>
</tr>
<tr>
<td><strong>OMIM</strong></td>
<td>Online Mendelian Inheritance in Man</td>
</tr>
<tr>
<td><strong>OS</strong></td>
<td>Operating System</td>
</tr>
<tr>
<td><strong>Parallel Port</strong></td>
<td>A 25-hole port used to connect printers and scanners</td>
</tr>
<tr>
<td><strong>Peripheral</strong></td>
<td>A device not pertaining to the central core of a computer</td>
</tr>
<tr>
<td><strong>Ping</strong></td>
<td>Program able to trace the route of an e-mail between two computers</td>
</tr>
<tr>
<td><strong>Pixel</strong></td>
<td>Pictures element</td>
</tr>
<tr>
<td><strong>POP</strong></td>
<td>Post Office Protocol</td>
</tr>
<tr>
<td><strong>Port</strong></td>
<td>Inlet/outlet socket, usually located on the back of the PC box, used to connect peripherals to the CPU. See also LPT, COM and USB.</td>
</tr>
<tr>
<td><strong>Program</strong></td>
<td>A series of instructions that the computer can read to perform a particular task (writing a text, playing a CD-ROM, surfing Internet, etc.)</td>
</tr>
<tr>
<td><strong>Prompt</strong></td>
<td>Request from the host system to input something (a password, a query, etc.)</td>
</tr>
<tr>
<td><strong>Protocol</strong></td>
<td>Set of rules according to which the networked computers send and receive data</td>
</tr>
<tr>
<td><strong>RAM</strong></td>
<td>Random Access Memory</td>
</tr>
<tr>
<td><strong>README file</strong></td>
<td>File usually hosted in an FTP site explaining the contents of the site and how to use it</td>
</tr>
<tr>
<td><strong>Removable media</strong></td>
<td>Any type of permanent storage that can be removed such as FD, Zip or Jaz drive</td>
</tr>
<tr>
<td>Term</td>
<td>Definition</td>
</tr>
<tr>
<td>--------------</td>
<td>-----------------------------------------------------------------------------</td>
</tr>
<tr>
<td>ROM</td>
<td>Read Only Memory Permanent memory that performs basic tasks on a computer.</td>
</tr>
<tr>
<td>Scanner</td>
<td>Device used to input in the computer digitized images taken from a slide, a picture, a book, etc. The market offers flat scanners, used mostly for pages and pictures, and slide scanners. Useful complement to a scanner is an OCR program, to recognize a scannerized text.</td>
</tr>
<tr>
<td>SCSI</td>
<td>Small Computer System Interface Technology used to interface at a high velocity peripherals with the motherboard</td>
</tr>
<tr>
<td>Serial port</td>
<td>A 9 or 25 pin port used to connect peripherals, such an external modem.</td>
</tr>
<tr>
<td>Server</td>
<td>Computer able to host and automatically allocate websites (or information or files) on the net</td>
</tr>
<tr>
<td>Shareware</td>
<td>Software downloadable from the Internet for a nominal fee to be paid to the author of the program</td>
</tr>
<tr>
<td>Site</td>
<td>See Website</td>
</tr>
<tr>
<td>SMTP</td>
<td>Simple Mail Transfer Protocol Protocol used to transfer e-mail messages between the user and the mail server</td>
</tr>
<tr>
<td>Spam, spamming</td>
<td></td>
</tr>
<tr>
<td>SPF</td>
<td>Standard Picture Frame</td>
</tr>
<tr>
<td>Streamer</td>
<td>I/O peripheral used to write and read data on magnetic tapes or DAT.</td>
</tr>
<tr>
<td>Sysadmin</td>
<td>System Administrator Person in charge of the management of a system (HIS, LAN, host system, etc)</td>
</tr>
<tr>
<td>TB</td>
<td>Tera Byte One thousand of billions (1,099,511,627,776 or 2^{40}) bytes</td>
</tr>
<tr>
<td>TCP/IP</td>
<td>Transmission Control Protocol / Internet Protocol The communication protocol used in Internet to transfer files from a network to another. The heart of the Internet.</td>
</tr>
<tr>
<td>Toggle key</td>
<td>Key using a toggle system to switch ON or OFF a particular circuit (e.g., the BLOC NUM key, used alternatively to activate and deactivate the number keypad)</td>
</tr>
<tr>
<td>Upload</td>
<td>To copy a file into an host system from a computer</td>
</tr>
<tr>
<td>URL</td>
<td>Uniform Resource Locator Univocal name of an site available on the Internet</td>
</tr>
<tr>
<td>USB</td>
<td>Universal Serial Bus A new type of serial port through which it is possible to connect multiple devices. Its main feature is that this can be done while the computer is on.</td>
</tr>
<tr>
<td>WAIS</td>
<td>Wide Area Information Services Extensive index and catalogue created at the outset of Internet</td>
</tr>
<tr>
<td>Webmaster</td>
<td>Person in charge of the management of a site</td>
</tr>
<tr>
<td>Website</td>
<td>Set of information to be published in Internet, composed by text, picture, audio, video, organized in various parts called “pages” linking of two or more computers without using wires, also for Internet connection</td>
</tr>
<tr>
<td>WLAN</td>
<td>Wireless local area network</td>
</tr>
<tr>
<td>WORM</td>
<td>Write Once Read Many Name of a CD that can be written only once by a CD-R drive and read as many times as desired</td>
</tr>
<tr>
<td>WWW</td>
<td>World Wide Web Commonly called the Web. Access to hypertext on the Internet through the HTTP protocol</td>
</tr>
<tr>
<td>WYSWYG</td>
<td>What You See is What You Get Expression used to define interactive programs using pointer mouse</td>
</tr>
<tr>
<td>XML</td>
<td>Extended Markup Language The proposed successor to HTML</td>
</tr>

</table>
APPENDIX 2

How to avoid computer troubles: tricks and suggestions

Problems Caused by Improper Use

• A potentially severe problem is to change inadvertently the computer configuration. To avoid it, not to "play" with the many applications in the Control Panel if you do not know exactly what you are doing. In particular, do not mess up files in the operating system or in the applicative software in program files.
• Do not leave files in disorder in the HD, but rather create a rational subdivision with appropriate subfolders in the "My Documents" folder.
• Do not let old e-mail to clog your e-mail box, but rather delete it once read.

Problems Caused by Breakdowns

• The file on which you are working is contained in the volatile RAM until you do not save it on a disk. A blackout or a problem in the computer will delete everything you have written on the computer after the last save: hence the opportunity to save often your file (say, every 5 to 10 minutes). There is also the option of an automatic save after a selected interval.
• If your electricity supply is unreliable it is advisable to connect the computer to an UPS system (Uninterrupable Power Supply); otherwise, save still more often.

Problems Caused by Software

• Is not unusual (particularly with Windows) a crash in a program, with the ensuing message "This program has executed an invalid operation and will be aborted" and loss of all your work since last save. It is almost always a non-worrying and self-solving problem, once switched off and on the computer, provided that the work has been saved recently (see above). Strongly advisable to save before any multitasking application.
• HD faults are much more dangerous, since all data are contained there; to avoid the risk of losing all one's own work, it is mandatory to backup all data either in a second HD on the same computer, or better in an external HD, or a CD-DVD.
• Magnetic disks are by their nature faint, and a heavy magnetic field can delete them completely; more permanent are laser-written data on a CD-DVD.

Problems Caused by Virus

• One of the least appreciable features of Internet is the possibility to get a virus in one's own computer while surfing the web. A virus is a malicious program whose sole intent is to cause problems on a computer, created by "virtual terrorists" for merely destructive purposes. A virus is self-spreading through infected mailing or flash drives, and is able to interfere with the computer in an unpredictable way, from simple files alteration till complete destruction of the HD content.
• Virus can be of various types. (1) Programs - Do not open ".exe" e-mail attachments; beware of attachments sent by unknown persons, or having a double extension, such as: "message_for_you.txt.vbs" (where .txt = text, or .gif .jpg = images are inoffensive extension, the second, hidden extension vbs = visual basic script; .pif = program information file; .exe = executable; .com = command, are programs). For no reason a file has two extensions, if not to use the first to conceal the second: a two-extension file is therefore positively a virus. (2) Trojan Horses: as the name suggests, these virus steal in the infected computer and allow their creator, a hacker, to surreptitiously seize control of the computer, unknown to the owner himself. (3) Macro Viruses: virus concealed in a Word or Excel file containing a macro (executable program embedded in a file). The only defence is to deactivate all macros before opening a file.
• The list of known virus is available at: http://www.viruslist.com/
• To check this threat the market offers many anti-virus programs that are absolutely indispensable once connected to the Net. Highly recommendable are anti-viral programs able to monitor each access file that can become part of computer system whenever downloaded from Internet. Protection against viruses offered by these programs is satisfactory on condition that they are kept updated at least weekly (much better automatically every day), downloading appropriate files from the sites of the software houses producing antiviral software. Free antivirus is available at www.tucows.com or free.grisoft.com/doc/help/us/.

If you run a windows OS, use often the "Windows Update" tool to download patches used to avoid "script" type virus to enter the system.
Problems Caused by Improper Use of e-mail

• The ISP stores e-mail messages until the electronic box owner retrieves the message. Files can be attached to messages, but avoid over-dimensioned attachments: attachments under 500 Kbyte do not pose any problem, up to 1-2 MByte are tolerable, over 2 Mbyte are meant to clog many e-mail boxes if not large-sized (such as g-mail).

• If a heavy attachment has to be sent, it is advisable to split it in smaller files to be sent with different mailings. Remember also that usually commercial ISP allot a limited amount of memory in the mailing box (2 to 8 MB average): it is therefore mandatory to read regularly one’s own e-mail and to empty the mailing box at regular intervals, to avoid the risk of missing messages finding the box full.

• Avoid agreeing with chain mailing, petitions, and appeals: usually they are groundless or positively deceitful, mostly related to urban legends. For an update on this topic see Urban Legends Reference Pages at www.snopes.com.

• Mailing chains, as well as mailing lists, can divulge considerable amounts of e-mail addresses that are the pabulum for the e-mail degeneration known as "spamming", i.e. unsolicited and unauthorized advertising through e-mail. Refrain from answering to these annoying intrusions in your computer, because this just helps the spammer to verify that your address is correct. If you are able to trace the origin of the spamming you can send a message to the ISP from where this originated (technically difficult). To prevent e-mail misuse, avoid to spread liberally addresses of your mailing list: if a message must be sent to many people, write their addresses in the "Bcc" (blind carbon copy) field of the e-mail browser, in order to keep these addresses unknown to third parties.

Problems Caused by Internet Frauds

• Being Internet a mirror of human nature, it is not unlikely to meet with swindlers while surfing the Web and using imprudently e-commerce, particularly if through sites of doubtful reputation. Avoid entering in Internet credit card codes or other sensible data if you are not in protected mode. This is a system, offered to the customers by all reliable providers, that codes messages in order to avoid unauthorized access to the data transmitted. A protected site can be recognized by its URL, starting with "https://" (see glossary) instead of "http://". Most browsers highlight protected mode with the icon of a closed padlock in the navigation bar.
HISTORICAL AND INSTITUTIONAL BACKGROUND

The Union of European Medical Specialists (UEMS) was founded on 20th July 1958, one year after the Treaties of Rome, signed the 25th March 1957, established the European Economic Community (EEC) – with the quality as the main issue tackled, trying to obtain from the European Commission and member States a high level of training for the future medical specialists of the Common Market countries (Belgium, France, Germany, Luxembourg, Italy, Netherlands).¹

In the following years the EEC, that with the Treaty of Maastricht in 1993, changed its name in European Union (EU), progressively enlarged to include Denmark, Ireland and the United Kingdom (1/1/1973), Greece (1/1/1981), Spain and Portugal (1/1/1986), Austria, Finland and Sweden (1/1/1995), Cyprus, Czech republic, Estonia, Hungary, Latvia, Lithuania, Malta, Poland, Slovakia, Slovenia (1/5/2004) and eventually Bulgaria and Romania (1/1/2007), raising the total number of EU Countries to 27, hosting a population just a bit short of half a billion inhabitants.

In the meanwhile UEMS, preceding the European unification process, opened to the EFTA–non EU Countries (Iceland, Norway and Switzerland), as well as to the Countries in the "waiting list" to enter EU, thus becoming Associate Members in the General Council of the Union before achieving the status of Full Member. Most of associate Members become, in recent years, Full Members; today, on top of Countries in the waiting list to enter EU, Associate Membership has been offered also to Countries outside the geographical boundaries of Europe, raising the total number to 5 (Azerbaijan, Croatia, Georgia, Israel, Turkey).

Since 1962, when the process of building Europe was still at its beginning, the UEMS created Specialist Sections for each of the main disciplines recognized and practised in at least three of the member Countries. Objectives of the sections were to defend at international level the title of Specialist and his professional status in society; to study, promote and defend the quality of the comparatively high level of specialist care given to the patients; to contribute to the creation and maintenance of solidarity amongst the European Specialists, particularly the specialists in the same field; to study, promote and defend before the international authorities, the free movement and the moral and material interests of European Specialists.²

Specialist Sections increased in time to a total number of 38, Pediatric Surgery (PS) among them, together with 7 Multidisciplinary Joint Committees (Table 130.1)—enlarged their field of interest creating in the early 1990s the European Boards, working groups of the Sections aiming to guarantee optimal care in the field of the speciality concerned by bringing the training of medical specialists to the highest possible level, as well as dealing with CME / CPD issues, the assurance of quality in specialist medicine and the defence of the autonomy of practice of medical specialities and specialists; among them the European Board of Pediatric Surgery (EBPS) is the one dealing with pediatric surgical issues. Every Section is ruled by a General Council, meeting at least once a year and composed by two National Delegates for each of the member Countries, elected four-yearly by the relevant
National Scientific Society; the Council elects among its members the President, the Secretary/Treasurer and six Executives, meeting usually at least twice a year to discuss executive matters.

In order to define aims and limits of PS, after a long gestation period and confrontation with the central UEMS offices, in 1995, the Pediatric Surgical Section of the UEMS issued a statement under the title of "The Scope of Pediatric Surgery" (SPS - Table 130.2). This review article will compare the ideal contents of this document with the factual situation in Europe, taking into account the points covered in the document – namely Children, Pediatric Surgery and Pediatric Surgeons – emphasising problems and perspectives that our Speciality is facing.

CHILDREN

The first point of the SPS states that "...the field of pediatric surgery encompasses the surgical care of the growing individual … from before birth up till the final stages of development." Letting aside the problem about which upper age limit to consider of "pediatric" interest, variously indicated in Europe from 14 to 18 years according to the different national regulations and diplomatically overcome in the SPS with the formula of "growing individual"—thus saving both our specificity and national peculiarities and... jealousies, one of the most powerful obstacles to the real unification of Europe—let us face first the main question: how many are those "growing individuals", in Europe? And, moreover, which is the trend in the natality in our Continent?

Europe is sometimes indicated as "the Old Continent": looking at some of the demographic indicators presented in Table 130.3, with the notable exception of Turkey, this definition sadly sounds more than appropriate, particularly if European data are compared with those of India detailed at the bottom of the table. Eleven countries present a population growth rate with the "minus" sign (should we speak of a "population extinction rate"?), mirroring a birth rate × 1000 inhabitants of less than 10 new Europeans a year in 14 countries. Ireland and Turkey are the only two countries in which 0-14 years-old inhabitants ratio is over 20%, in other words in which at least one inhabitant out of five is less than 14 years old; Latvia
Table 130.2: The Scope of Pediatric Surgery

1. **Pediatric surgery**
   The field of pediatric surgery encompasses the surgical care of the growing individual. It includes management and perioperative care from before birth up till the final stages of development.

2. **Pediatric surgical centers**
   Pediatric surgery should be provided in pediatric surgical units based in centers where a full range of medical and surgical facilities for the care of the sick child are available. Most of these centers should provide postgraduate training in pediatric surgery and research facilities. The pediatric surgical unit should be headed by a trained pediatric surgeon.

3. **Pediatric surgeon**
   A pediatric surgeon is a surgeon specifically trained in the care of children.

4. **Specialist pediatric surgery**
   Specialist pediatric surgery should be performed in a pediatric surgical center or in a specialized center with possibilities to provide adequate care to children.

5. **Training of surgeons, other than pediatric surgeons**
   Surgeons taking care of children should have had adequate training in a pediatric surgical unit. They should also continue to have regular exposure to this type of patients. Moreover, they should stay informed about new developments in the field of pediatric surgery.

6. **Hospital**
   All children should be treated in a hospital environment appropriate for their age group. Children should not be admitted to hospital if this can be avoided.

7. **Referral advice**
   Children should be treated by practitioners experienced in this field. If the expertise is not available, the child should be referred to a centre as defined at article 2.

is at stand at the other end of the scale, with only one inhabitant out of seven (13.6%) younger than 14 years. If we eventually have a look at the "young/old population ratio", i.e. the number of young people (< 14 years old) for every one old people (> 65 years old), we can observe that in 16 out of 27 (!) European countries the "pyramid age" describing the age distribution of a population has turned upside down with less than one "under 14" for every "over 65" (0.69 to 1 for Italy), while on the other end of the scale Turkey present a 3.6 to 1 ratio and India a 6.2 to 1 ratio. Possibly no other indicator is more striking in emphasising such a radical difference in the demographic composition.3

Another striking difference within Europe emphasised in Table 130.3 is the huge difference in infant mortality ratio among the western and eastern part of the continent. Although this differentiation is now considered "politically incorrect" and seen somewhat with impatience in the hallways of the European commission, it is nevertheless a crude fact that average infant mortality in the former 15 EU countries is 4.38 x 1000, while in the new 12 countries average ratio more than doubles to 9.28 x 1000, with a worrying two-digits figure in Bulgaria and Romania (19.1 and 24.6 x 1000 respectively). The chances for a Swedish newborn to survive his first year of life are 9-fold greater than those of his Romanian mate: we simply cannot limit ourselves to emphasize the difference, we must work to reduce and ultimately to cancel that difference.

What about future? From a demographic point of view, European perspectives for next years are somewhat dark, at least according to the projections presented in Tables 130.4 and 130.5 and in Figs 130.1 and 130.2. Table 130.4 shows the demographic trend in Italy in the years 1992/96 and 2002/064: natural balance of the population is in the negative since 1993, with a slight tendency to an increase in the very last years. Total population is slowly increasing only thanks to the immigration input, that in 2003 accounted on the population balance (+ 609, 580 immigrants) more than the natural increase (+ 544, 063 live births). These data emphasize two huge demographic problems, typical not only to Italy but to Europe as a whole:

</table>
1. Immigration is becoming the main demographic input to Europe. Considering also that immigrant families have a birth rate much higher than indigenous families, this phenomenon will soon modify the population composition, with all the enormous amount of adaptation problems that this implies.

2. Actual Italian generation, a bit more than half a million newborns a year, is the "product" of the previous generation, that of the 1970s, composed by roughly a million newborns a year: what will happen when this generation, "halved" in relationship to the one of 30 years ago (mean age of an Italian primipara being now 28.3 years), will enter the parental age? Figure 130.1 gives a graphical answer to this question, emphasising the dramatic drop in pediatric population that Italy will experience in the next two decades.

European situation as a whole will not be much better, as detailed in the Table 130.5 and Fig. 130.2. Here is tabled and graphically expressed the total fertility rate in European countries as well as some other countries world-wide: according to the fact the level of "growth 0" is reached when the fertility rate (= number of children per woman) is > 2.1, is immediate the observation that all European Countries will be well below that danger level.4,5

1. The aphorism stating that "... a child is not simply a little adult..." is well known and possibly also overindulged in pediatric area, but it seems still completely unknown (or forgotten ?) by general

PEDIATRIC SURGERY
practitioners and by general surgeons in particular.

In the SPS is underlined the need that: "All children
should be treated in a hospital environment
appropriate for their age group ... by practitioners
experienced in this field ". Situation in Europe on this
issue is far to be uniform. In some countries, namely

Denmark, Netherlands and Belgium, PS is not even
recognized as an independent speciality, although this
shared status does not mirror in common situations.

Our Danish and Norwegian colleagues are struggling
for "independence" against state regulations aiming
to reduce medical specialities to a minimum – and
consequently not recognizing the uniqueness of
expertise of a pediatric surgeon, comparing him to a
surgeon "tout court", while Belgium has temporarily
solved the problem introducing a "certification of
competence in PS" to be awarded only to those
surgeons particularly trained to deal with children.

On the other hand, also in countries in which PS is
officially recognized there are "fights" about definition
of the field of competence of a pediatric surgeon.

Matter of debate are usually borderline pathologies
involving particular organs or apparatuses in children,
such as pediatric neurosurgery or pediatric
orthopedics. Table 130.6 summarizes the situation in
some European countries, inferred from the number
of subspecialities whose clinical experience is
mandatory during training in PS. At the bottom of
every column is indicated the number of countries in
which that particular subspecialty is dealt with in PS

Centers; optional subspecialties are counted as 0.5. Abdominal, Oncological, Thoracic, Urology, and Head and Neck Surgery constitute the core of PS and are dealt with by pediatric surgeons in most if not all countries, while Vascular Surgery, Plastic Surgery - Burns, Traumatology and Neurosurgery are performed by our colleagues in a minority of countries, with Austrian and Swiss as the more "broad spectrum" of all, dealing with all subspecialties (but not without problems with other involved specialties, at least in Austria). To solve "conflicts of jurisdiction" between PS and Urology about the issue of Pediatric Urology the UEMS has created since 2002 a Multidisciplinary Joint Committee in which representatives of Urology and PS Sections, together with the European Society of Pediatric Urology (ESPU), meet regularly to settle incoming problems.

Just as an example, according to the data of the Italian Ministry of Health, in 1998, the percentage of children admitted in pediatric departments on the total of children hospitalized was as high as 89.7% for neonates, reducing to 71.1% for toddlers 1 to 4 years old and quickly dropping to 44.5% for children 5-14 years old. Table 130.7 details were these children are admitted: on the total, in Italy less than two-thirds of them are admitted "...in a hospital environment appropriate for their age group..." as requested in the SPS and in the first article of the "Declaration of

mebooksfree.com
Pediatric Surgery” that the World Federation of Associations of Pediatric Surgery (WOFAPS), approved in the Kyoto meeting the 7th April, 2001. Actually, inappropriate admission of infants and children in adult departments seems to be a problem very common in many countries around the world, according to the words of the President of the WOFAPS, Jay Grosfeld, that in his presidential address at Washington meeting of October 8th, 1999: stated: “...one of the greatest threats to pediatric surgery in the next few years is the potential loss of leadership role in the surgical care of infants and children. In some places, pediatric surgery has remained provincially repressed by other groups with a conflict of interest such as general surgical departments and pediatric subspecialists who grow in numbers often well beyond the needed workforce requirements”.

**PEDIATRIC SURGEONS**

Definition of the optimal number of Pediatric Surgeons per number of people served is still an unsettled problem. Moreover, further confusion comes from the different ways in different countries to define a "Pediatric Surgeon": fully trained independent surgeon at consultant’s level or just member of the staff of a PS department, possibly not yet fully independent? Legislation also in different European Countries varies substantially, particularly according to the level of clinical "independence" of the staff members from the Chief of Department, rather total in the British system and formally rather nil in other countries. This observation partially explains the huge differences than can be observed in Table 130.8, summarizing the last available data (1999 - updating process ongoing) on the pediatric surgical centers and manpower in some European Countries.

For example, is striking the difference between Ireland, credited with only 4 Pediatric Surgeons (consultants), and Italy that boasts 440 staff surgeons, only 57 of who are Chief of Department. Empirical evaluation adopted by the BAPS indicates as optimal the numbers of 1 consultant Pediatric Surgeon every 500,000 inhabitants, of 1 Pediatric Surgical Center

</table>
every 2,500,000 inhabitants and the optimal ratio of 1:1 trainee to consultant. Substantial differences among countries are immediately evident, with huge overcrowding of medical doctors in some countries and a lack of trainees in others: thus, Greece has roughly a 40% of unemployed trained pediatric surgeons, Italy some 20%, Germany some 14%, Spain some 10%, Italy an UK and Netherlands. On the other hand, in UK a training program perhaps too long (6 years) and the demographic shift determines a shortage of pediatric surgeons, while in Portugal mean age of pediatric surgeons is over 40 years thus prompting the need of young colleagues. Moreover, this country as well as others (France, UK) are used to host trainees from former colonies and "export" there pediatric surgeons once trained.9

"WORK IN PROGRESS" AND PERSPECTIVES

This striking variability among European Countries, once more highlighted by differences in training policies and number of training centers summarized in Table 130.9, prompted the Section of Pediatric Surgery of the UEMS to set up a "peer review system" aiming to harmonize performances and training in PS throughout Europe at the highest standard reasonably attainable. This system is based on four activities: (1) Site visit of training centers; (2) European Register of Pediatric Surgeons and European examination; (3) CME/CPD fostering policies; (4) European Syllabus on Pediatric Surgery.

**SITE VISIT OF TRAINING CENTERS**

In 1997, the EBPS appointed visiting commissions to check the level of training in relevant PS Centers throughout Europe. Since then, twenty training centers have been awarded the European Certificate (Table 130.10). These site visits are performed in two days, the first spent visiting the Institution with all the facilities, laboratories, library, etc. and the second day spent interviewing the trainees, inspecting their

logbooks as well as obtaining details regarding their views on gaining employment after the completion of their training.

An accreditation from the Board, although still devoid of any legal value, it is now recognized as a mark of excellence within the pediatric surgical community: a clue about the esteem in which the certificate is hold comes from the request of centres outside the geographical boundaries of Europe to be visited by the EBPS Committee. First of these "intercontinental" Site Visits will be held in 2008.

EUROPEAN REGISTER OF PEDIATRIC SURGEONS AND EUROPEAN EXAMINATION

The EBPS set up an European Register of Pediatric Surgeons, involving the Certification of Pediatric Surgeons from European Countries. This task was accomplished through a process that in the past was addressed to established Pediatric Surgeons (grandfather clause), trained before 1993, requested to present their application form to be scrutinized by a body organized by the National Scientific Societies to ensure that the applicants were bona fide pediatric surgeons who had undergone training in their own country. These forms were further scrutinized by the Executive Council of the EBPS in January 1997, and a bit more than 1000 colleagues entered the Register, now published on the Section's website.

To allow younger colleagues to be registered also after the "grandfather clause" was no more active, it was designed a full process of European Examination, again with the expressed goal of setting a standard of excellence, setting a bench mark which most pediatric surgeons should strive to achieve. The EBPS Register has not yet legal status but ensures a high standard of candidates who have completed their pediatric surgical training. Since 2005, the European Examination is organized in two parts, hold at least twice a year. Part one is a Multiple Choice Questionnaire with 100 questions in ten sections to be answered. All trainees are eligible to sit this Part, that is valid for up to five years. Candidates successful in Part one can sit for the Part two, subdivided in four events each lasting 45 minutes: (1) Clinical Examination - to include one problem based major case and 2-3 short cases; (2) Neonatal Surgery Oral Examination; (3) General Pediatric Surgery Oral Examination; (4) Genitourinary Surgery Oral Examination. Knowledge of basic sciences will be tested in this examination, including clinically applied physiology, anatomy, biochemistry and embryology. In addition, the candidate will be expected to be familiar with antenatal management of pediatric surgical conditions and to understand the relevance of the genetic basis of its causation. Part two exam, lasting two days, is hold in a training center usually chosen between those already approved (Table 130.10). Since the beginning, in 1999, to the last examination in Budapest in 2007, 77 candidates successfully passed the examination and become Fellows of the European Board of Pediatric Surgery.
(FEBPS). Although devoid of any legal value, this Fellowship is a mark of excellence that should ideally distinguish all and only those Pediatric Surgeons whose level of professional value meets the demanding standards set by the European Board.

Wishing to offer also to colleagues non EU-citizens the possibility to challenge themselves with the European Examination since 2006, the Board decided to open the application to candidates from all over the world: successful ones will be awarded the European Board Certification (EBC), being the Fellowship for legal reasons reserved to EU citizens.

**CME FOSTERING POLICIES**

There is a strong tradition of continuing medical education (CME) in the medical profession and the most powerful motivating factors are positive ones: doctors' awareness of their responsibility for safe medical performance, recognition of peers, collective emphasis on the quality of medical practice. CME has its definite place in the so-called "Quality Agenda", based on the three items of:

1. Quality Improvement – a continuous striving to provide better practice;
2. Quality Assurance – a process applied to the confirmation or continuing fitness to practice (audit, performance review);
3. Quality Control – a wholly distinct area, related to medical regulation, in which doctors who have been identified as having difficulties with their practice are assessed and appropriate action is instituted.

Continuous Medical Education is the most effective form of quality improvement now available and the new password in the field of medical updating, fostered by UEMS since 1993 with the publication of the European Charter on CME, followed in 1998 by the EBPS guidelines for CME (published in the Section website at the URL http://www.uemspaedsurg.org/CME.htm) and in 1999 by the establishment of EACCME, the European Accreditation Council for CME, operational since 2000. Main aim of this body is "...to harmonize and improve the quality of specialist medical care in Europe... by improving quality of CME and accessibility to CME for the medical specialists in Europe" by means of transfer of CME credits (the units of evaluation of CME) in case of migration of a specialist within Europe, between European countries, between different specialties and between the European credit system and comparable systems outside Europe (such as the ABMS – American Board of Medical Specialties). CME activities are classified in three categories:

1. External formally planned CME (Scientific Congress, EACCME registered or not, Courses, Workshops, Seminars and distance learning programs).
2. Internal CME, Hospital based (Postgraduate meetings, Research meetings, Department meetings, Hospital grand rounds, Journal club, Audit meetings) or independent based (Reading medical literature, medical writing, editorial or refereeing work, Internet learning, self assessment examination, medical audiotapes and videos).
3. Other CME activities can be visits to specialized units, preparation and delivery of formal lecture or seminar, preparation and delivery of audit report, publication or presentation of scientific papers or books, teaching, postgraduate examination work.

Adequate completion of CME requirements is mandatory for all Pediatric Surgeons registered into the European Register of Pediatric Surgeons in order to maintain their status of FEBPS.

**EUROPEAN SYLLABUS OF PEDIATRIC SURGERY**

Being fully within the mission of EBPS to give an expert and authoritative advice, although not legally binding, on what and how has to be taught in a training course in Pediatric Surgery, in January 2006 the Executive Committee decided to prepare a Syllabus on Pediatric Surgery, to stand as reference document for all training centers throughout Europe on which are the contents of Pediatric Surgery, what is essential and what not essential, which fields are mandatory and which just optional, and how should be organized the training. An "ad hoc" Committee, created in full synergy with the European Pediatric Surgeons' Association (EUPSA), prepared the draft that, after four major revisions and two years of work involving all the National Scientific Societies of Europe, it is now ready for publication and will be presented at the IX European Congress of Pediatric Surgery to be held in Istanbul in June 2008.
EUROPEAN WORKING TIME DIRECTIVE (EWTD)

Organization of Training Centers in Europe had recently to be significantly modified according to the rules imposed by the EWTD. This directive states that every European worker (trainees included) cannot work more than 8 hrs per day = 48 hrs per week over 6 working days; in hospitals up to 10 hrs per working day are possible = 60 hrs maximum per week; within 1 working day a minimum time of rest of 45 min has to be assured; after 1 working day minimum time of continuous rest is 11 hrs, thus meaning that no night duty is possible after a working day; after night duty the trainee has to leave the hospital and rest for a minimum of 11 hrs. Born originally as "protection of the clinical personnel against overwork for the benefit of patient" — a really critical issue in some cases in which training of young doctors was including up to 80-100 hrs per week. The solution imposed by the EWTD has actually entailed severe consequences on the training of competent surgical specialists. Among these, it has been emphasized a reduced presence of trainees (only 150-160 days per year instead of > 200 days); a reduced participation of trainees in clinical care as well as in attendance to the OR (30-40% fewer operations than before); impossibility to follow a patient's full clinical history from admission to discharge; available time taken up predominantly by routine work; structured training reduced, with impaired participation in educational seminars, teaching rounds, etc.

WHAT ABOUT FUTURE?

Future development of our specialty in the EU needs to seek a harmonization between what imposed by the EWTD and the concept of Continuous Professional Development (CPD), slowly but steadily overcoming the one of CME, and defined as “…the educative means of updating, developing and enhancing how doctors apply the knowledge, skills and attitudes required in their working lives… the UEMS therefore believes that CPD is essential for ensuring high standards of medical practice". The task now facing UEMS is to define the desired outcomes of CPD - both the maintenance of safe standards of practice, and encouraging the achievement of the highest quality standards; to determine the processes required to achieve these outcomes, making CPD more readily available and making involvement in CPD more effective and verifiable; to agree on structures and funding sources, specific to each country's health care structure, that will support the implementation of CPD for all specialist doctors, pediatric surgeons among them. In this process, the new organization of work determined by the EWTD with a closer supervision of the senior staff on the trainees will might help to avoid pitfalls and secure the continuous medical care of our little patients, and the possibilities offered by long distance web-based learning might replace traditional structured theoretical education.

New approaches and techniques for old concepts: to keep as high as possible the level of care that we are daily called upon to offer to our children.

Townes-Brocks syndrome 825

Tracheoesophageal fistula (TEF) 136

Transanal endorectal pull-through (TEP) 733
complications 737
early 737
late 737
contraindications 734
follow-up 737
indications 733
outcome 737
preoperative assessment 734
preoperative preparation 734
redo tept 738
surgical technique 735

Transfusion in disease states requiring multiple transfusions 88
hemolytic disease of the newborn 88
hemophilia 88
oncology patients 89
sickle cell disease 88
thalassemia 88

Transhiatal ophagectomy 400

Transplant immunogenetics 969

Transplant tolerance and molecular therapeutics 984

Traumatic brain injury 150

Traumatic hemobilia in children 321
clinical presentation 321
investigations 321
angiography 322
contrast enhanced CT scan 322
dendoscopic retrograde cholangiopancreatography 322
MRI and MR angiography 322
radionuclide scans 322
ultrasonography and color Doppler 322
upper GI endoscopy 322
management 322
angiographic embolization 323
non-surgical treatment 323
surgical management 323
pathophysiology 321

Treatment of humoral refection 982
Tumors of the adrenals 1410
Turcot's syndrome 773, 775
Types of liver graft 963
living donor liver graft 963
monosegmental grafts 964
split-liver graft 963

U
Ulcerative colitis 758
clinical manifestations 760
extraintestinal manifestation 760
gastrointestinal manifestation 760
diagnosis 761
clinical examination 761
endoscopy 761
laboratory assessment 761
radiology 761
epidemiology 759
etiology 759
medical and nutritional management 762
pathology 759
surgical management 763
indications for operation 763
surgical approaches 763
surgical outcome 766
Ultrasound 135
cranial sonography: equipment and technique 135
special applications 136
umbilical hernia 525
umbilical ring 525
upper extremity musculoskeletal trauma 1332
elbow injuries in children 1333

V
Vaginal anomalies and reconstruction 1387
approach to a high vagina 1391
passerini-Glazel procedure 1392
posterior sagittal approach 1394
pull through vaginoplasty 1391
approach to a low vagina 1390
cutback vaginoplasty 1390
flap vaginoplasty 1390
classification 1387
vaginal agenesis 1388
skin flaps 1395
expanded skin 1398
full thickness skin grafts 1396
myocutaneous flaps 1396
surgical principles for vaginoplasty 1388
vaginoplasty 1389
vaginal substitution 1395
Variant Hirschsprung's disease 701
hypoganglionosis 704
immature ganglia 704
internal sphincter achalasia 705
intestinal neuronal dysplasia 702
smooth muscle cell disorders 705
Vascular anomalies 1099
arteriovenous malformations 1099
classification and pathology 1099
presentation and clinical course 1101
treatment 1102
Vascular injuries in children 298
assessment 299
characteristics of pediatric injuries 298
iatrogenic injuries 300
peripheral vascular access 302
umbilical artery catheters 300
imaging modalities 299
digital subtraction arteriography 300
Doppler studies 299
mechanisms of trauma 298
prevention 306
traumatic injuries 303
blunt injuries 304
compartment syndrome 304
penetrating injuries 303
truncal injuries 304
abdominal injuries 305
cervicothoracic injuries 304
Vascular injury 290
diagnosis 291
mechanism 291
physical examination 291
ultrasonic flow detection 291
vessel repair 292
Vascular rings 374
Vascular tumors 1095
Ventilatory support in children 90
  applied respiratory physiology 90
  airway resistance 91
  pulmonary compliance 91
  time constants 91
  work of breathing 91
  care of the patient of ventilator 100
    care of the unconscious patient 100
    care of the ventilator aspects of the patient 100
  care of the ventilator 100
  breathing system 100
  complications of ventilation 99
    barotrauma (rupture of lung parenchyma) 99
    repeated extubation 99
    volutrauma 99
  endotracheal tube or tracheostomy 99
  indications 98
    ICU indication 98
    postoperative 98
    preoperative 98
  mode of ventilation 94
    basic modes 94
    modes that allows patient machine interaction 95
    modes to increase FRC 94
    modes useful for children 97
    modes useful in weaning 96
    permissive hypercapnia 99
    role of muscle relaxant analgesia and sedation 99
  understanding the ventilator 91
    anatomy 91
    physiology 92
ventilatory strategy 98
  choosing the right ventilator and the mode of ventilation 98
  weaning 101
  Ventriculoatrial shunt 1139

Waardenburg’s syndrome 683
Webster’s article 776
Weil-Marchesani syndrome 1255
Wilms’ tumor 30
